Friction, Lubrication, and Wear Technology

ASM INTERNATIONAL®

The Materials Information Company

Publication Information and Contributors

Friction, Lubrication, and Wear Technology was published in 1992 as Volume 18 of the *ASM Handbook*. The Volume was prepared under the direction of the ASM International Handbook Committee.

Volume Chair

The Volume Chairman was Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory.

Authors

- **Arnold E. Anderson** Consultant
- **Walter K. Arnold** Fraunhofer Institute
- **Betzalel Avitzur** Metalforming Inc.
- **Stephen C. Bayne** University of North Carolina
- **Charles C. Blatchley** Spire Corporation
- **Peter J. Blau** Oak Ridge National Laboratory
- **Raymond H. Boehringer** DuBois Chemical Inc.
- **Royce N. Brown** Dow Chemical U.S.A.
- **Kenneth G. Budinski** Eastman Kodak Company
- **R.F. Bunshah** University of California, Los Angeles

Foreword

The publication of this Volume marks the first time that the *ASM Handbook* has dealt with friction, lubrication, and wear technology as a separate subject. However, the tribological behavior of materials and components has been of fundamental importance to ASM members throughout the history of the Society. ASM International traces its origins back to 1913 with the formation of the Steel Treaters Club in Detroit. This group joined with the American Steel Treaters Society to form the American Society for Steel Treating in 1920. In the early history of the Society as an organization devoted primarily to heat treating, one of the key interests of its membership was improving the wear properties of steel.

In 1933 the organization changed its name to the American Society for Metals, completing its transformation to an organization that served the interests of the entire metals industry. This change led the Society into many other areas--such as metalworking, surface finishing, and failure analysis--where friction, lubrication, and wear are key concerns. In 1987 the technical scope of the Society was further broadened to include the processing, properties, and applications of all engineering/structural materials, and thus ASM International was born. This Handbook reflects the wide focus of the Society by addressing the tribological behavior of a broad range of materials.

The comprehensive coverage provided by this Volume could not have been achieved without the planning and coordination of Volume Chairman Peter J. Blau. He has been tireless in his efforts to make this Handbook the most useful tool possible. Thanks are also due to the Section Chairmen, to the members of the ASM Handbook Committee, and to the ASM editorial staff. We are especially grateful to the over 250 authors and reviewers who so generously donated their time and expertise to make this Handbook an outstanding source of information.

Preface

Friction, lubrication, and wear (FL&W) technology impacts many aspects of daily life, from the wear of one's teeth to the design of intricate, high-speed bearings for the space shuttle. Nearly everyone encounters a FL&W problem from time to time. Sometimes the solution to the problem is simple and obvious--disassembling, cleaning, and relubricating a door

hinge, for example. Sometimes, however, the problem itself is difficult to define, the contact conditions in the system difficult to characterize, and the solution elusive. Approaches to problem-solving in the multidisciplinary field of tribology (that is, the science and technology of FL&W) often present a wide range of options and can include such diverse fields as mechanical design, lubrication, contact mechanics, fluid dynamics, surface chemistry, solid-state physics, and materials science and engineering. Practical experience is a very important resource for solving many types of FL&W problems, often replacing the application of rigorous tribology theory or engineering equations. Selecting "the right tool for the right job" was an inherent principle in planning the contents of this Volume.

It is unrealistic to expect that specific answers to all conceivable FL&W problems will be found herein. Rather, this Handbook has been designed as a resource for basic concepts, methods of laboratory testing and analysis, materials selection, and field diagnosis of tribology problems. As Volume Chairman, I asked the Handbook contributors to keep in mind the question: "What information would I like to have on my desk to help me with friction, lubrication, or wear problems?" More than 100 specialized experts have risen to this challenge, and a wealth of useful information resides in this book.

The sections on solid friction, lubricants and lubrication, and wear and surface damage contain basic, tutorial information that helps introduce the materials-oriented professional to established concepts in tribology. The Handbook is also intended for use by individuals with a background in mechanics or lubricant chemistry and little knowledge of materials. For example, some readers may not be familiar with the measurement and units of viscosity or the regimes of lubrication, and others may not know the difference between brass and bronze. The "Glossary of Terms" helps to clarify the use of terminology and jargon in this multidisciplinary area. The discerning reader will find the language of FL&W technology to be somewhat imprecise; consequently, careful attention to context is advised when reading the different articles in the Volume.

The articles devoted to various laboratory techniques for conducting FL&W analyses offers a choice of tools to the reader for measuring wear accurately, using these measurements to compute wear rates, understanding and interpreting the results of surface imaging techniques, and designing experiments such that the important test variables have been isolated and controlled. Because many tribosystems contain a host of thermal, mechanical, materials, and chemical influences, structured approaches to analyzing complex tribosystems have also been provided.

The articles devoted to specific friction- or wear-critical components are intended to exemplify design and materials selection strategies. A number of typical tribological components or classes of components are described, but it was obviously impossible to include all the types of moving mechanical assemblies that may experience FL&W problems. Enough diversity is provided, however, to give the reader a solid basis for attacking other types of problems. The earlier sections dealing with the basic principles of FL&W science and technology should also be useful in this regard.

Later sections of the Handbook address specific types of materials and how they react in friction and wear situations. Irons, alloy steels, babbitts, and copper alloys (brasses and bronzes) probably account for the major tonnage of tribological materials in use today, but there are technologically important situations where these workhorse materials may not be appropriate. Readers with tribomaterials problems may find the sections on other materials choices, such as carbon-graphites, ceramics, polymers, and intermetallic compounds, helpful in providing alternate materials-based solutions. In addition, the section on surface treatments and modifications should be valuable for attacking specialized friction and wear problems. Again, the point is to find the right material for the right job.

This Volume marks the first time that ASM International has compiled a handbook of FL&W technology. The tribology research and development community is quite small compared with other disciplines, and the experts who agreed to author articles for this Volume are extremely busy people. I am delighted that such an outstanding group of authors rallied to the cause, one that ASM and the entire tribology community can take pride in. I wish to thank all the contributors heartily for their much-appreciated dedication to this complex and important project in applied materials technology.

General Information

Officers and Trustees of ASM International (1991-1992)

- **William P. Koster** President and Trustee Metcut Research Associates Inc.
- **Edward H. Kottcamp, Jr.** Vice President and Trustee SPS Technologies
- **Stephen M. Copley** Immediate Past President and Trustee Illinois Institute of Technology
- **Edward L. Langer** Secretary and Managing Director ASM International
- **Leo G. Thompson** Treasurer Lindberg Corporation
- **Trustees**
- **William H. Erickson** Canada Centre for Minerals & Energy Technology
- **Norman A. Gjostein** Ford Motor Company
- **Nicholas C. Jessen, Jr.** Martin Marietta Energy Systems, Inc
- **E. George Kendall** Northrop Aircraft
- **George Krauss** Colorado School of Mines
- **Kenneth F. Packer** Packer Engineering, Inc.
- **Hans Portisch** VDM Technologies Corporation
- **Lyle H. Schwartz** National Institute of Standards and Technology
- **John G. Simon** General Motors Corporation

Members of the ASM Handbook Committee (1991-1992)

- **David LeRoy Olson**(Chairman 1990-; Member 1982-1988; 1989-) Colorado School of Mines
- **Ted Anderson** (1991-) Texas A&M University
- **Roger J. Austin** (1984-) Hydro-Lift
- **Robert J. Barnhurst** (1988-) Noranda Technology Centre
- **John F. Breedis** (1989-) Olin Corporation
- **Stephen J. Burden** (1989-) GTE Valenite
- **Craig V. Darragh** (1989-) The Timken Company
- **Russell J. Diefendorf** (1990-) Clemson University
- **Aicha Elshabini-Riad** (1990-) Virginia Polytechnic & State University
- **Michelle M. Gauthier** (1990-) Raytheon Company
- **Toni Grobstein** (1990-) NASA Lewis Research Center
- **Susan Housh** (1990-) Dow Chemical U.S.A.
- **Dennis D. Huffman** (1982-) The Timken Company
- **S. Jim Ibarra** (1991-) Amoco Research Center
- **J. Ernesto Indacochea** (1987-) University of Illinois at Chicago
- **Peter W. Lee** (1990-) The Timken Company
- **William L. Mankins** (1989-) Inco Alloys International, Inc.
- **David V. Neff** (1986-) Metaullics Systems
- **Richard E. Robertson** (1990-) University of Michigan
- **Elwin L. Rooy** (1989-) Consultant
- **Jeremy C. St. Pierre** (1990-) Hayes Heat Treating Corporation
- **Ephraim Suhir** (1990-) AT&T Bell Laboratories
- **Kenneth Tator** (1991-) KTA-Tator, Inc.
- **William B. Young** (1991-) Dana Corporation

Previous Chairmen of the ASM Handbook Committee

- **R.S. Archer** (1940-1942) (Member, 1937-1942)
- **L.B. Case** (1931-1933) (Member, 1927-1933)
- **T.D. Cooper** (1984-1986) (Member, 1981-1986)
- **E.O. Dixon** (1952-1954) (Member, 1947-1955)
- **R.L. Dowdell** (1938-1939) (Member, 1935-1939)
- **J.P. Gill** (1937) (Member, 1934-1937)
- **J.D. Graham** (1966-1968) (Member, 1961-1970)
- **J.F. Harper** (1923-1926) (Member, 1923-1926)

- **C.H. Herty, Jr.** (1934-1936) (Member, 1930-1936)
- **D.D. Huffman** (1986-1990) (Member, 1990-)
- **J.B. Johnson** (1948-1951) (Member, 1944-1951)
- **L.J. Korb** (1983) (Member, 1978-1983)
- **R.W.E. Leiter** (1962-1963) (Member, 1955-1958, 1960-1964)
- **G.V. Luerssen** (1943-1947) (Member, 1942-1947)
- **G.N. Maniar** (1979-1980) (Member, 1974-1980)
- **J.L. McCall** (1982) (Member, 1977-1982)
- **W.J. Merten** (1927-1930) (Member, 1923-1933))
- **N.E. Promisel** (1955-1961) (Member, 1954-1963)
- **G.J. Shubat** (1973-1975) (Member, 1966-1975)
- **W.A. Stadtler** (1969-1972) (Member, 1962-1972)
- **R. Ward** (1976-1978) (Member, 1972-1978)
- **M.G.H. Wells** (1981) (Member, 1976-1981)
- **D.J. Wright** (1964-1965) (Member, 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Scott D. Henry, Editor, ASM Handbooks; Grace M. Davidson, Production Project Manager; Theodore B. Zorc, Technical Editor; Dawn Levicki, Editorial Assistant; Robert C. Uhl, Director of Reference Publications. Editorial assistance was provided by Joseph R. Davis, Kelly Ferjutz, Heather Lampman, Kathleen M. Mills, Nikki D. Wheaton, and Mara S. Woods.

Conversion to Electronic Files

ASM Handbook, Volume 18, *Friction, Lubrication, and Wear Technology* was converted to electronic files in 1997. The conversion was based on the Second Printing (March 1995). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Scott Henry, Grace Davidson, Randall Boring, Robert Braddock, Kathleen Dragolich, and Audra Scott. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Introduction to Friction

Jorn Larsen-Basse, National Science Foundation

FRICTION is the resistance to movement of one body over body. The word comes to us from the Latin verb *fricare,* which means to rub. The bodies in question may be a gas and a solid (aerodynamic friction), or a liquid and a solid (liquid friction); or the friction may be due to internal energy dissipation processes within one body (internal friction). In this article, the discussion will be limited to the effects of solid friction.

Two of the most significant inventions of early man are friction-related: He learned to use frictional heating to start his cooking fires, and he discovered that rolling friction is much less than sliding friction (that is, it is easier to move heavy objects if are on rollers than it is to drag them along). This second discovery would eventually lead to the invention of the wheel.

Friction plays an important role in a significant number of our daily activities and in most industrial processes. It aids in starting the motion of a body, changing its direction, and subsequently stopping it. Without friction, we could not readily move about, grip objects, light a match, or perform a multitude of other common daily tasks. Without friction, most threaded joints would not hold, rolling mills could not operate, and friction welding would obviously not exist. Without friction, we would hear neither the song of the violin nor the squeal of the brake.

In moving machinery, friction is responsible for dissipation and loss of much energy. It has been estimated, for example, that 10% of oil consumption in the United States is used simply to overcome friction. The energy lost to friction is an energy input that must continually be provided in order to maintain the sliding motion. This energy is dissipated in the system, primarily as heat--which may have to be removed by cooling to avoid damage and may limit the conditions under which the machinery can be operated. Some of the energy is dissipated in various deformation processes, which result in wear of the sliding surfaces and their eventual degradation to the point where replacement of whole components becomes necessary. Wear of sliding surfaces adds another, very large component to the economic importance of friction, because without sliding friction these surfaces would not wear.

The fundamental experimental laws that govern friction of solid bodies are quite simple. They are usually named for Coulomb, who formulated them in 1875 (much of his work was built on earlier work by Leonardo da Vinci and Amontons). The laws can be stated in very general terms:

- Static friction my be greater than kinetic (or dynamic) friction
- Friction is independent of sliding velocity
- Friction force is proportional to applied load
- Friction force is independent of contact area

It must be emphasized that these "laws" are very general in nature and that, while they are applicable in many instances, there are also numerous conditions under which they break down.

Friction is commonly represented by the friction coefficient, for which the symbols μ or *f* generally are used. The friction coefficient is the ratio between the friction force, *F,* and the load, *N:*

$$\mu = \frac{F}{N} \qquad \textbf{(Eq 1)}$$

The friction coefficient typically ranges from 0.03 for a very well lubricated bearing, to 0.5 to 0.7 for dry sliding, and even $\geq$5 for clean metal surfaces in a vacuum. A μ-value of 0.2 to 0.3 allows for comfortable walking; however, walking on ice is very difficult because the μ-value for the ice/shoe pair may be <0.05, and a slippery floor may have a μ-value of 0.15. Nature has provided highly efficient lubrication to another component of walking, the knee joint, which has a μ-

value of 0.02. A. representative list of typical friction coefficients is given in the article "Appendix: Static and Kinetic Friction Coefficients for Selected Materials" in this Volume.

A body of weight *W* on a flat surface will begin to move when the surface is tilted to a certain angle (the friction angle, θ) (Fig. 1). The static friction coefficient is given by

$$\mu_s = \tan\theta \qquad \textbf{(Eq 2)}$$

This represents a simple way to measure μ_s, but force measurements are some generally used to measure both the static and the dynamic, or kinetic, coefficients of friction. The results obtained from these measurements do, however, depend on the nature and cleanliness of the surfaces and also to some extent on the various characteristics of the measuring system. This dependence underscores the basic fact that the friction coefficient is not a unique, clearly defined materials property, as may become evident from the following brief discussion of the basic mechanisms of friction

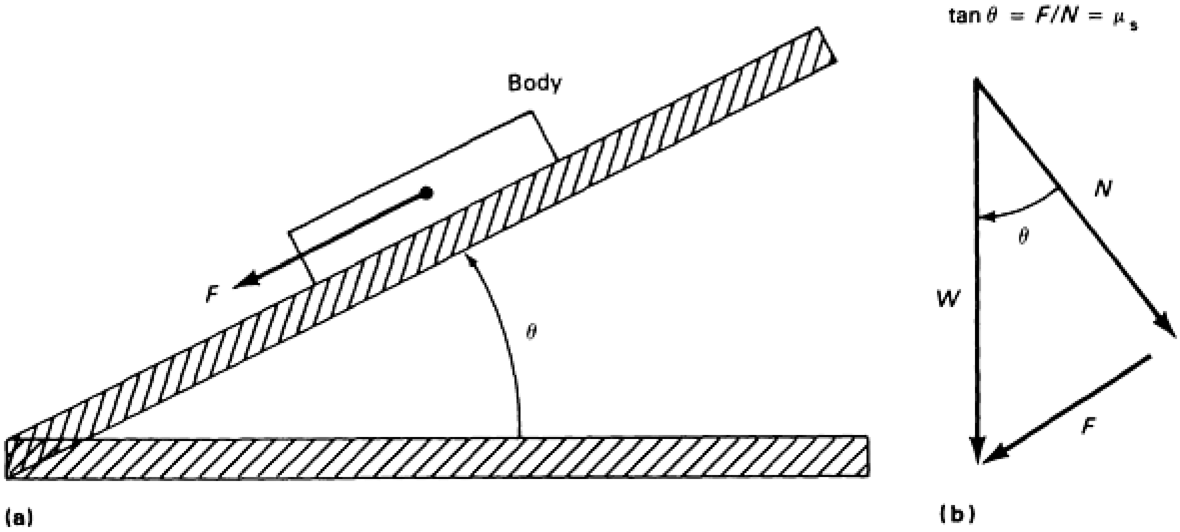

Fig. 1 Inclined plane used to determine coefficient of static friction, μ_s. (a) Tilting flat surface through smallest angle, θ, needed to initiate movement of the body down the plane. (b) Relation of the friction angle to the principal applied forces

Surfaces are not completely flat at the microscopic level. At high magnification, even the best polished surface will show ridges and valleys, asperities, and depressions. When two surfaces are brought together, they touch intimately only at the tips of a few asperities. At these points, the contact pressure may be close to the hardness of the softer material; plastic deformation takes place on a very local scale, and cold welding may form strongly bonded junctions between the two materials. When sliding begins, these junctions have to be broken by the friction force, and this provides the adhesive component of the friction. Some asperities may plow across the surface of the mating material, and the resulting plastic deformation or elastic hysteresis contribute to the friction force; additional contributions may be due to wear by debris particles that become trapped between the sliding surfaces.

Because so many mechanisms are involved in generating the friction force, it is clear that friction is not a unique materials property, but instead depends to some extent on the measuring conditions, on the surface roughness, on the presence or absence of oxides or adsorbed films, and so on. In spite of this complexity, the values of μ obtained by different methods and by different laboratories tend to fall into ranges that are representative of the material pair in question under reasonably similar conditions. That is, values obtained by different laboratories tend to fall within ~20 to 30% of each other if the testing conditions are generally similar. It is important, however, to understand that the values of μ listed in this Handbook are intended only to provide rough guidelines and that more exact values, if needed, must be obtained from direct measurements on the system in question under its typical operating conditions. Detailed information on friction measurement techniques is available in the article "Laboratory Testing Methods for Solid Friction" in this Volume.

The deformation at asperities and junctions is extremely localized, and very high temperatures may therefore be generated over very short periods of time. At these local hod spots, rapid oxidation, plastic flow, or interdiffusion can take place, and these all affect the wear process. In some cases, sparks may even form. The temperatures obtained depend on how fast heat is generated (that is, on the operating conditions of load and velocity) and on how fast heat is removed (that is, on the thermal properties of the sliding surfaces). These temperatures can be calculated with some degree of certainty, as shown in the article "Frictional Heating Calculations" in this Volume.

Friction oscillations may develop when the static coefficient of friction is greater than the kinetic, as is the case for many unlubricated systems. The resulting motion is often called "stick-slip." The two surfaces stick together until the elastic energy of the system has built up to the point where a sudden forward slip takes place. The resulting oscillations may produce equipment vibrations, surface damage, and noise.

Some of the areas of current technological interest and research related to friction include:

- *Friction Measurement:* More accurate ways to measure μ and to predict its value for given conditions without having to test the actual system
- *Friction Sensing:* Use of the various signals that are generated by friction for real-time feedback control of robots, manufacturing processes, lubrication systems, and so on
- *Materials:* Materials and coatings with low friction for operation at elevated temperatures where normal lubricants break down; and materials and coatings with constant, predictable, and sustainable values of μ

Basic Theory of Solid Friction

Jorn Larsen-Basse, National Science Foundation

Introduction

UNIVERSAL AGREEMENT as to what truly causes friction does not exist. It is clear, however, that friction is due to a number of mechanisms that probably act together but that may appear in different proportions under different circumstances. The recent introduction of sensitive and powerful techniques for measuring and modelling surfaces and even manipulating indicating surface atoms is creating a wealth of new information and is elucidating many previously unknown aspects of friction. Much still remains to be done, however, before a complete picture can emerge. In the meantime, this brief review of the various processes involved, as currently understood, is presented to familiarize the reader with the basic concept of friction and with the general approaches that can be used to control or minimize it.

The word "friction" is used to describe the gradual loss of kinetic energy in many situations where bodies or substances move relative to one another. For example, "internal friction" dampens vibrations of solids, "viscous friction" slows the internal motion of liquids, "skin friction" acts between a moving airplane and the surrounding air, and "solid friction" is

the friction between two solid bodies that move relative to one another. We are concerned here only with *solid friction,* which can be defined as "the resistance to movement of one solid body over another." The movement may be by sliding or by rolling; the terms used are "sliding friction" and "rolling fiction," respectively. Most of the discussion that follows deals with sliding friction.

The need to control friction is the driving force behind its study. In many cases low friction is desired (bearings, gears, materials processing operations), and sometimes high friction is the goal (brakes, clutches, screw threads, road surfaces). In all of these cases, constant, reproducible, and predictable friction values are necessary for the design of components and machines that will function efficiently and reliably.

It is useful to clearly separate the various terms and concepts associated with friction, such as "friction force," "friction coefficient," "frictional energy," and "frictional heating." These terms are defined below and in the "Glossary of Terms" in this Volume.

The *friction force* is the tangential force that must be overcome in order for one solid contacting body to slide over another. It acts in the plane of the surfaces and is usually proportional to the force normal to the surfaces, *N*, or:

$$F = \mu N \qquad \textbf{(Eq 1)}$$

The proportionality constants is generally designated μ or *f* and is termed the *friction coefficient.*

In most cases, a greater force is needed to set a resting body in motion than to sustain the motion; in other words, the *static coefficient of friction,* μ_s, is usually somewhat greater than the *dynamic* or *kinetic coefficient of friction,* μ_k.

A body on a flat surface will begin to move due to gravity if the surface is raised to the *friction angle,* θ, where:

$$\mu_s = \tan \theta \qquad \textbf{(Eq 2)}$$

See Fig. 1 in the article "Introduction to Friction" in this Volume.

To overcome friction, the tangential force must be applied over the entire sliding distance; the product of the two is *friction work.* The resulting energy is lost to heat in the in the form of *frictional heating* and to other general increases in the entropy of the system, as represented, for example, in the permanent deformation of the surface material. Thus, friction is clearly a process of energy dissipation.

Nature of Surfaces

Friction is caused by forces between the two contacting bodies, acting in their interface. These forces are determined by two factors besides the load; the *properties* of the contacting material and the *area* of contact. The friction forces are usually not directly predictable because both of these factors depend very much on the particular conditions. For example, the properties may be significantly different than expected from bulk values because the surface material is deformed, contains segregations, is covered by an oxide layer, and so on. Also, the real area of contact is usually much smaller than the apparent area of the bodies because real surfaces are not smooth on an atomic scale. Because of this close dependence of friction on the surface topography and on the properties of the surfaces and the near-surface layers, a brief discussion will be presented of the relevant characteristics.

Tabor (Ref 1) quotes W. Pauli: "God made solids, but surfaces were made by the Devil." Indeed, surfaces are extremely complicated because of their topography and chemical reactivity and because of their composition and microstructure, which may be very different from those of the bulk solid. Surface properties, composition, and microstructure may be very difficult to determine accurately, creating further complications.

Topography

The geometric shape of any surface is determined by the finishing process used to produce it. There will be undulations of wavelengths that range from atomic dimensions to the length of the component. These often result from the dynamics of the particular finishing process or machine used. There may be additional peaks and valleys caused by local microevents,

such as uneven deformation of hard microstructural constituents, local fracture, or corrosive pitting. Even after a surface has been carefully polished, it will still be rough on an atomic scale. It is useful to distinguish among macrodeviations, waviness, roughness, and microroughness (Ref 2) relative to an ideal flat surface (Fig. 1).

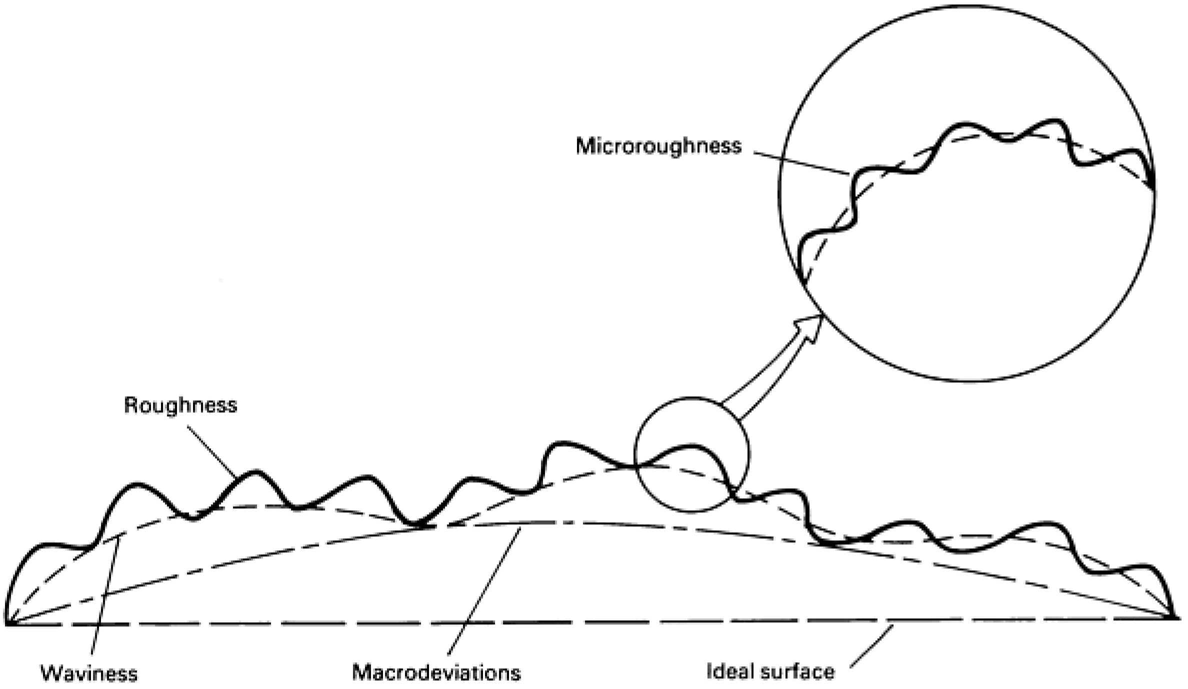

Fig. 1 Schematic showing selected types of surface deviations relative to an ideal solid surface

Macrodeviations are errors from--irregular surface departures from the design profile, often caused by lack of accuracy or stiffness of the machine system.

Waviness is periodic deviations from geometric surface, often sinusoidal in form and often determined by low-level oscillations of the machine-tool-workpiece system during machining (Ref 2). Typically, wavelengths range from 1 to 10 mm (0.04 to 0.4 in.) and wave heights from a few to several hundred micrometers (Ref 2).

Roughness is the deviations from the wavy surface itself, caused by geometry of the cutting tool and its wear, machining conditions, microstructure of the workpiece, vibrations in the system, and so on. Surface roughness changes as a surface goes through the wearing-in process, but may then stabilize.

Microroughness is finer roughness super-imposed on the surface roughness. It may extend down to the near-atomic scale and may be caused by internal imperfections in the material, nonuniform deformation of individual grains at the surface, or corrosion and oxidation processes that occur while the surface is being generated or during its exposure to the environment.

The peaks of surface roughness are called asperities. They are of primary concern in sliding friction and wear of materials, because these processes usually involve contacts between asperities on opposing surfaces or between asperities on one surface and asperity-free regions on the counterface. (The latter case may be unrealistic, but is often useful for modeling purposes.) Microroughness may affect the forces between surfaces, but has relatively little influence on surface deformation.

Roughness Measurement. A typical surface may have more than 10^5 peaks (Ref 3). Thus, it is generally not feasible to measure the height, shape, and location of every single peak on two matching surfaces in order to determine details of the contact. Instead, a simple profilometer trace is often used to measure and represent surface roughness. The stylus of the profilometer is a fine diamond with a fairly sharp tip, 2 μm or less in radius. It is drawn over the surface, and its vertical movement is amplified and recorded. The horizontal magnification is typically 100×, while the vertical magnification may vary from 500 to 100,000× (Ref 3), depending on the necessary resolution.

Because the stylus tip has a finite sharpness, it cannot shows very fine detail and tends to distort some shapes. For example, valley in the surface are shown narrower than they actually are and peaks are shown broader. Also, because only a fairly small portion of the surface can realistically be measured, the profilometer data are not absolute values and should be used only as relative data for comparison purposes. They are best used to compare surfaces produced by the same process--for example, by coarse and fine turning or by coarse and fine grinding.

Traditionally, the analog output of the profilometer is analyzed in terms of the deviation of the profile from the centerline. Two slightly different measures have been used. The roughness average, R_a, is the mean vertical deviation from the centerline and is the value most often used in Europe. The root mean square value, RMS, is the value most commonly used in the United States. It is calculated as the square root of the mean of the squares of the deviations and represents the standard deviation of the height distribution. Typical values for both roughness measures are 1.4 μm (55 μin.) for fine turned surface, 1.0 μm (39.4 μin.) for a ground surface, and 0.2 μm (7.9 μin.) for a polished surface (Ref 3). A table of typical values is given in Ref 2.

Other parameters used to measure roughness include skewness, R_{sk}; height, R_z; and bearing ratio curve.

Modern digitized instrumentation allows more detailed evaluation of the profilometer traces. It is now possible to scan a surface area by repeated but offset traces and to statistically evaluate the data for height distribution, asperity shape, and angle. Full use of the information available from modern instrumentation is still quite rare. The use of fractals to describe surface roughness has had limited success (Ref 4, 5), but much work remains to be done before it is clear whether this technique is more useful than traditional techniques. Additional information is available in the article "Wear Measurement" in this Volume.

Asperity Distribution Model. In contact situations, only the outer 10% of the asperities may be involved. Their height distribution can often be quite closely represented by the tail end of a Gaussian distribution (Ref 3). This distribution was used by Greenwood and Williamson (Ref 6) to derive an expression for elastic contact stresses. They also assumed that all of the asperities had the same tip radius. The Greenwood-Williamson (GW) model of surface roughness is commonly used to analyze contact mechanics of rough surfaces. It is probable, however, that the nature of the asperity height and shape distribution will change significantly once the surfaces begin to move against each other (Ref 7).

Composition

A surface is usually not completely clean, even in a high vacuum. Some of the events that can take place at surfaces are segregation, reconstruction, chemisorption, and compound formation (Fig. 2), as discussed in detail by Buckley (Ref 8).

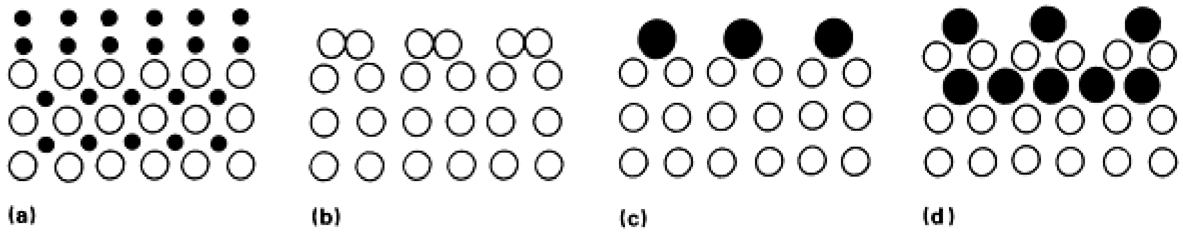

Fig. 2 Effect of composition on surface roughness defects. (a) Segregation. (b) Reconstruction. (c) Chemisorption. (d) Compound formation. Source: Ref 8

Segregation of alloy species to grain boundaries is a well-known phenomenon that may profoundly affect mechanical properties (Fig. 2a). Segregation to the surface may also take place. This generally occurs for small, mobile alloy or impurity atoms, such as interstitial carbon and nitrogen in iron, during processing or heat treatment. In some cases, the segregation of as little as 1 at.% of alloy element to the surface can completely dominate adhesion between contact surfaces (Ref 8). Significant changes in friction properties have been observed for ferrous surfaces with segregation of carbon, sulfur, aluminum, and boron, and for copper surfaces with segregation of aluminum, indium, and in (Ref 8). The nature of the changes friction due to surfaces segregation depends on the nature of the changes that the specific segregation in question causes in surface mechanical properties, adhesion, oxide film formation, and so on. For example, if certain metallic glasses containing boron are tested at increasing temperature, μ increases first with temperature, from

about 1.0-1.5 at room temperature to 1.8-2.5 at 350 °C (660 °F). Above 500 °C (930 °F), μ drops drastically (to about 0.25), a change that has been associated with the formation of boron nitride on the surface (Ref 8).

Reconstruction takes place when the outermost layers of atoms undergo a change in crystal structure (Fig. 2b). Examples include evaporation of silicon from a SiC surface upon heating, leaving behind a layer of carbon (Ref 8), and conversion of diamond surface layers to graphite or carbon during rubbing (Ref 9). Reconstruction may result in substantial changes in friction coefficient, but the fact that reconstruction has taken place may be evident only after careful characterization of the surface layers.

Chemisorption readily occurs on clean surfaces (Fig. 2c). Adsorbed species include water molecules from atmospheric moisture and carbon and carbon compounds also derived from the atmosphere or from lubricants used during operation or manufacture. The adsorbed species may also be components of various salts originating from the environment of from human handling of the component. The amount of adsorbed species, the degree of surface coverage, and the nature of the adsorbed molecule can substantially affect the adhesion between two surfaces, thereby directly or indirectly influencing friction behavior. For example, when a monolayer of ethane is introduced on a clean iron surface, the adhesive force drops from a value of greater than 400 dynes to 280 dynes (Ref 8). If the monolayer is acetylene, and force drops to 80 dynes. For a vinyl chloride monolayer, the force drops to 30 dynes--that is, to only 7 to 8% of the value for the clean surface.

Chemical compound formation may take place when surface comes into contact with a different solid, a gas, or a chemisorbed species. Without any tribological contacts, a surface will readily acquire a layer of oxide or hydroxide due to reactions with ambient moisture and oxygen. When two surfaces rub against each other, they may adhere at local spots that can reach elevated temperatures by frictional heating; interdiffusion may then take place, resulting in local compound formation in the surface layers (Fig. 2d). This can strongly affect friction. It is well known, for example, that friction between two metals that can form alloy solutions or alloy compounds with each other generally is greater than if the two are mutually insoluble. This fact has been used by Rabinowicz (Ref 10) to develop a generalized "map" showing which metals can safely slide against one another and which metal couples should be avoided (Fig. 3).

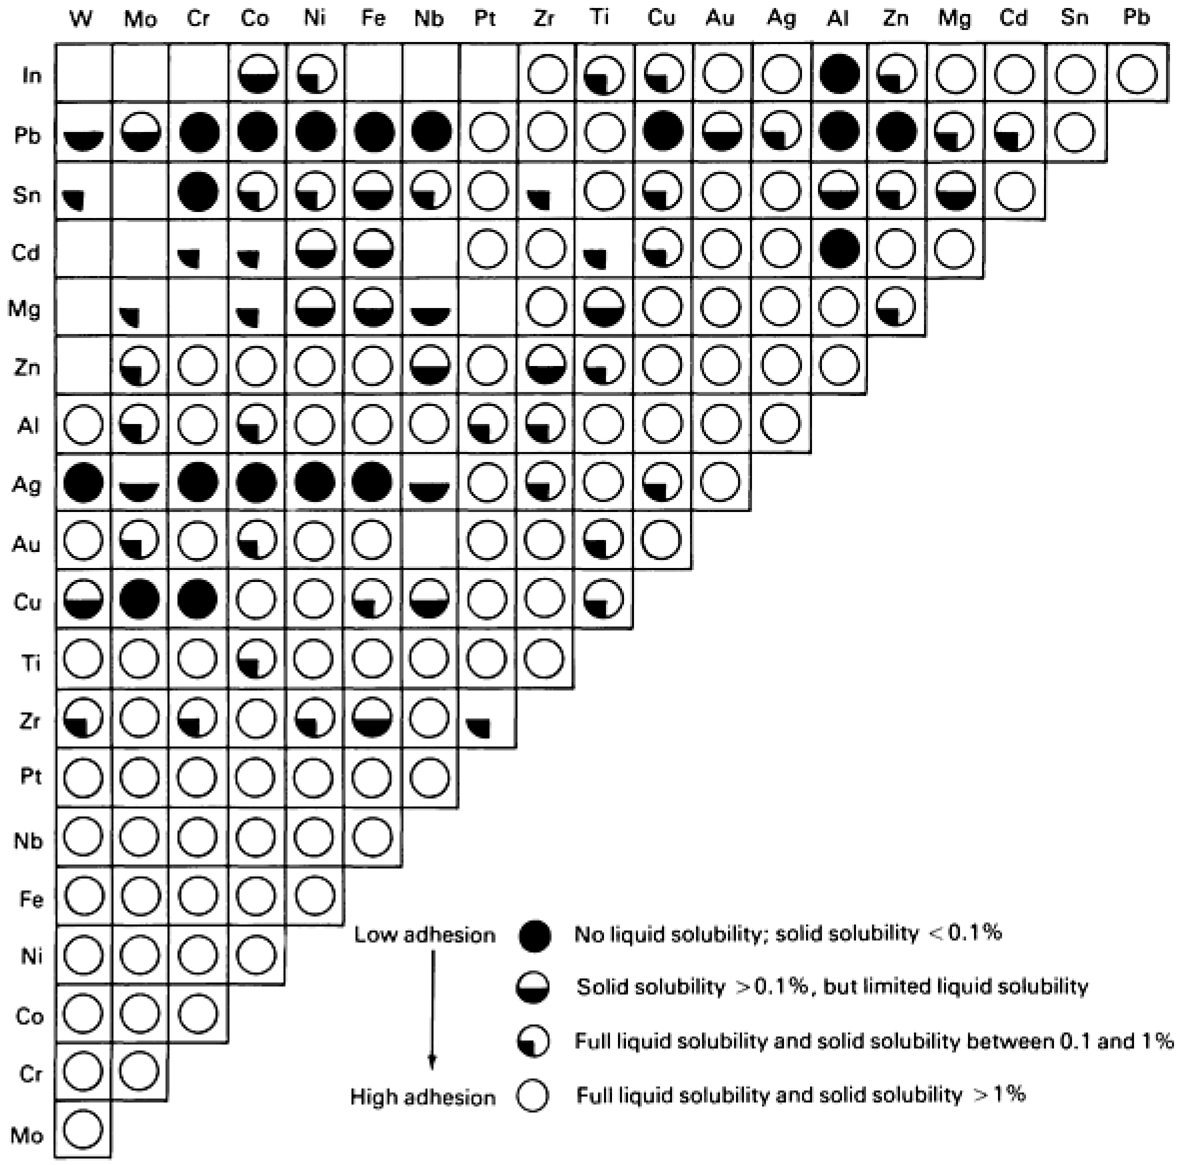

Fig. 3 Compatibility chart developed by Rabinowicz for selected metal combinations derived from binary equilibrium diagrams. Chart indicates the degree of expected adhesion (and thus friction) between the various metal combinations. Source: Ref 10

Surfaces rubbing against each other in the presence of organic compounds may catalyze the formation of polymeric layers, so-called tribopolymers, which may form more or less coherent layers on the surface. These can also affect friction behavior.

Mechanical compound formation is caused by the mechanical allowing of metallic wear particles and surface debris to form solid layers or segments of layers. A layer that forms preferentially on one of the sliding surfaces is often called a transfer layer (Ref 11). The wear particles involved in transfer layer formation are extremely small--of the size of dislocation cells in the heavily deformed surface layers of worm surfaces. These particles are pressed together with one another and with any other small particles present (oxides, oil-additive soaps, and so on) by the very localized, and therefore large, mechanical stresses that act on those asperities in contact with one another. The result is a more or less coherent, very thin transfer layer that may keep the surfaces from coming into direct contact with each other.

Transfer films also form when polymers or carbon rub against metal surfaces, but the formation mechanism may be somewhat different from that for metal-metal couples. The film forms gradually during the first 5 to 10 passes as polymeric or carbon wear particles adhere to the metal surface. The friction usually fluctuates during this stage; when the film is fully developed, the friction takes on a steady and usually low value.

Subsurface Microstructure

The layers immediately below the surface often have a microstructure that is different from the bulk. This is true for machined and ground surfaces, especially if the surface has been heavily worn. The surface layers of metals tend to become heavily deformed during wear, typically to a dept of deformation of about 40 μm (1575 μin.). Shear strains of 1100% and strain rates as high as 10^3/s have been estimated for the outermost layer (Ref 11). Because much of the deformation takes place in compression, otherwise brittle particles may be plastically deformed; for example, cementite lamellae in pearlite may be bent 90° with little or no cracking. The surface layers develop a very heavy dislocation concentration nd a subcell structure. The microstructural aspects of worn metallic surfaces have been reviewed in more detail by Rigney (Ref 11). Figure 4 illustrates some of the surface and subsurface features discussed above, primarily for metals.

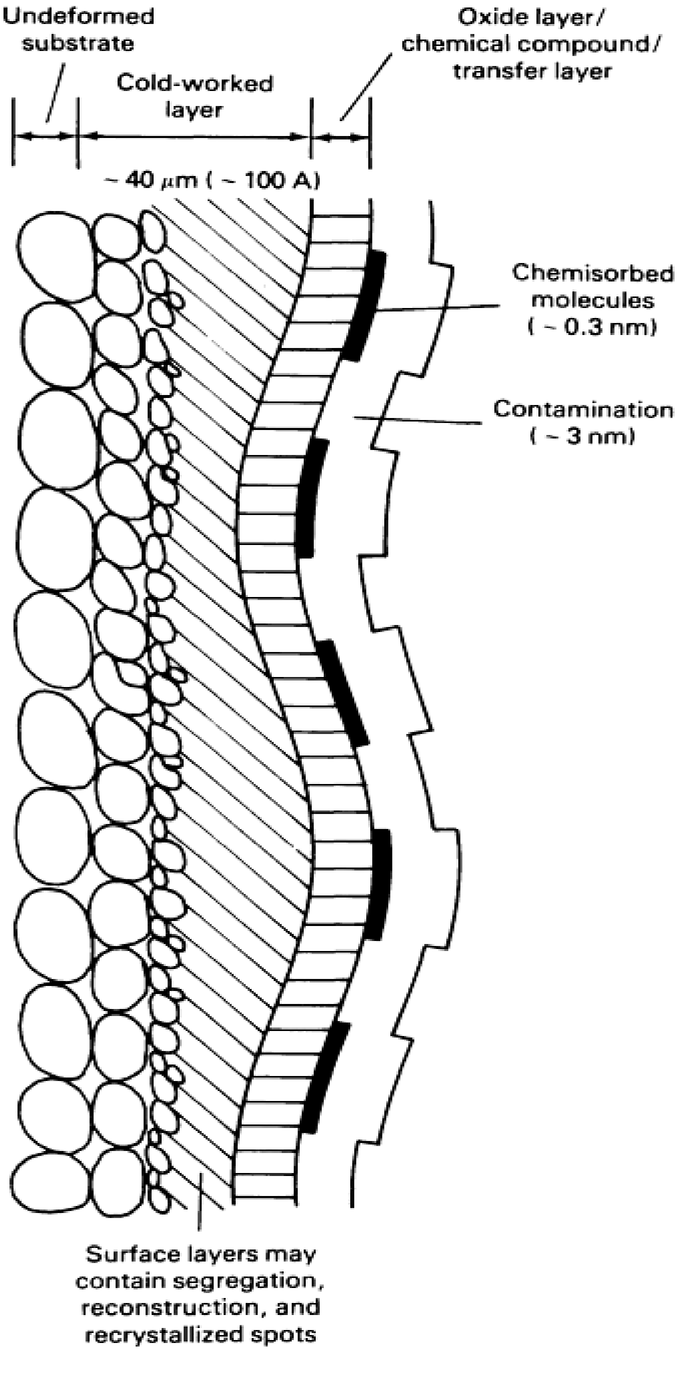

Fig. 4 Schematic showing typical surface and subsurface microstructures present in metals subject to friction and wear. Microstructures are not drawn to scale.

Friction under Lubricated Conditions

The nature, topography, and composition of the surface layers may be important also under lubricated conditions. Many sliding surfaces are lubricated to protect against war and to lower the friction. While most of the discussion here deals with dry sliding friction, it is instructive to briefly consider the transition between lubricated and dry conditions.

In a fully hydrodynamic situation, the lubricant film is sufficiently thick to keep the surfaces completely apart. The friction is then due to viscous dissipation within the lubricant and has little or nothing to do with the nature of the contacting materials. As the two surfaces are brought closer together, the asperities begin to come in contact and the zone of so-called "boundary lubrication" is entered. The degree of separation between the two surfaces can be measured by the ratio of the mean gap distance, *h*, to the composite roughness of the two opposing surfaces, σ. The composite roughness is defined by:

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$$

where σ_1 and σ_2 represent the rms roughness of the two surfaces.

The h/σ ratio is often refereed to as the lambda (Λ) ratio. Generally, for surface whose height distributions are nearly Gaussian, if Λbecomes greater than 3 the conditions are full-film hydrodynamic conditions and asperity interactions are rare. For Λless than 3, asperity rubbing takes place and friction increases as h/σ decreases. If $\Lambda$is less than 1.5, surface deformation may take place and boundary lubrication conditions prevail (Ref 12). In this region, and as the gap is decreased further toward dry sliding, friction depends on what happens in a thin film of lubricant on the surfaces and at asperity contacts. Ideally, the surfaces would be separated by a lubricant film at all times. The ideal film would be one that has low shear strength between molecular layers parallel to the surface (and thus low friction), but which at the same time has strong bonds with the solid and thus prevents the opposing solids from coming into intimate contact with one another. The bonding is affected by the nature and composition of the surface layers; trace elements, such as sulfur in steel, can have significant effects on the formation of these films. Similarly, it is expected that new additive molecules will have to be developed as ceramic triboelements become more common, because the bonds formed with ceramic surfaces are quite different from those between currently used additives and metallic surfaces.

Basic Mechanisms of Friction

The specific physical, chemical, or materials-related microscopic events that cause friction are called the basic mechanisms of friction. A number of different mechanisms of this nature have been proposed over the past several hundred years, and each has had its proponents among scientists and engineers. Interestingly, the situation has changed relatively little, with some modifications, the same general basic mechanisms are still thought to be responsible for friction, and there is still a certain degree of partisanship regarding each mechanism. However, the general consensus seems to be that all the various mechanisms may be involved in the generation of friction but that dominant mechanism in each case depends on the particular situation. For the purpose of this discussion, friction is considered a systems property. It depends on the nature of the two surface, the materials, the environment, the application conditions, and certain characteristics of the apparatus, such as vibrations and specimen clamping.

The microscopic mechanisms that are involved, to varying degrees, in generating friction are (1) adhesion, (2) mechanical interactions of surface asperities, (3) plowing of one surface by asperities on the other, (4) deformation and/or fracture of surface layers such as oxides, and (5) interference and local plastic deformation caused by third bodies, primarily agglomerated wear particles, trapped between the moving surfaces (Fig. 5).

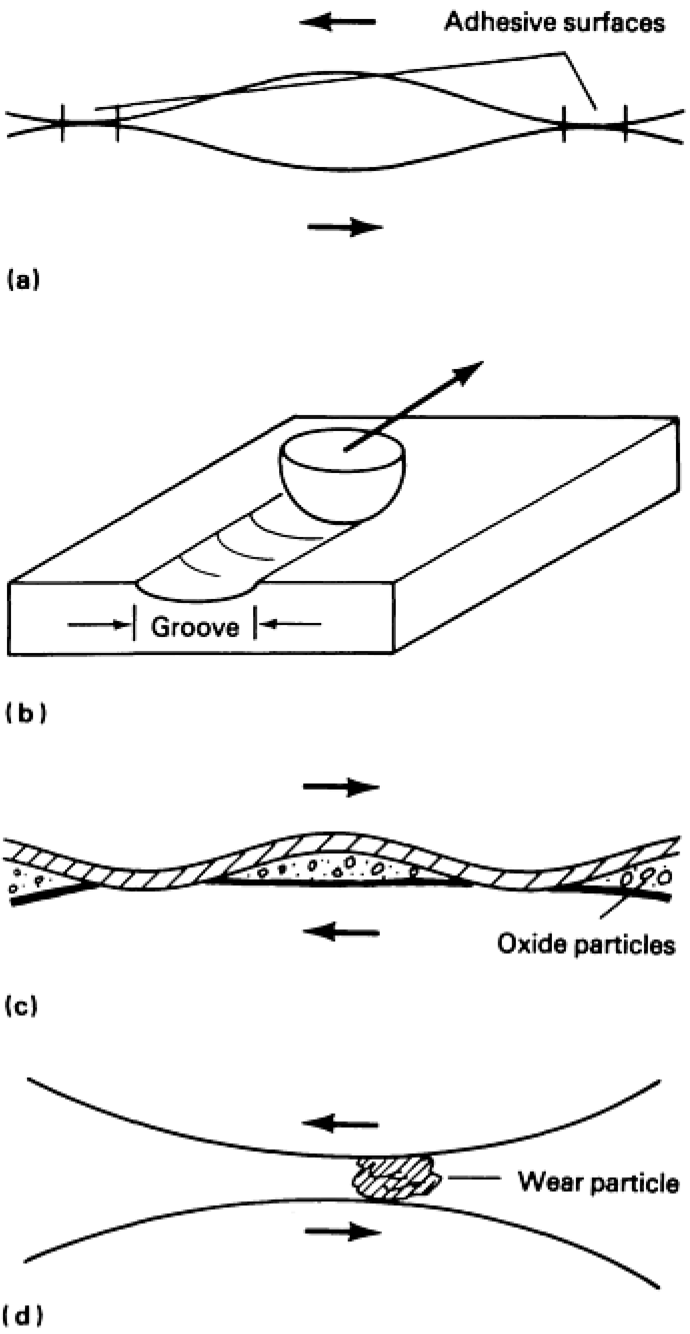

Fig. 5 Mechanisms on microscopic level that generate friction. (a) Adhesion. (b) Plowing. (c) Deformation and fracture of oxides. (d) Trapped wear particle

History

The history of the various attempts to scientifically explain friction has been described by Dowson (Ref 13) and by Bowden and Tabor (Ref 14) and has been briefly summarized by Ludema (Ref 15). The formative years of friction theory coincide with the general development of scientific thought during the 18th and 19th centuries. Basically, there were two schools of thought: a French school, which emphasized mechanical (elastic) interaction of surface roughness or asperities, and an English school, which emphasized "cohesion" or adhesion between the materials.

The French School began with a study published in 1699 by Amontons, who experimentally determined the two main "laws" of friction, often called Amontons' laws:

- The friction force is proportional to the applied load

- The friction force is independent of the apparent area of contact

The same relationships had been observed by Leonardo da Vinci 200 years earlier. Leonardo's studies were basically done before the world was ready for them, and this results were probably not known to the scientific world of Amontons' time. Leonardo's notes and manuscripts were hidden away in private collections and were discovered and printed fairly recently.

Amontons speculated that friction was caused by the interaction of surface roughness peaks. For hard surfaces, he envisioned that the asperities would be forced to slide up and down over one another; for more "elastic" materials, he suggested that the sliding would push aside the surface irregularity peaks.

The Swiss mathematician and theologian Euler, who gave us the symbols *e, i,* and π for common use in mathematics, elaborated on Amontons' theory from an analytical point of view. In 1750, while working in Berlin during a 25-year absence from his post as professor at St. Petersburg, he suggested that friction is caused by a ratcheting effect and that the friction work is the work to lift one body over the asperities of the other. The asperities would have a slope equal to or less than the friction angle. Euler developed the first clearly analytical approach to friction and treated it is an integral part of the mechanics of bodies in motion. He was also the first to use μ for the coefficient of friction and to draw a clear distinction between static and dynamic coefficient of friction, μ_k and μ_s (Ref 13).

The French physicist and engineer Coulomb confirmed Amontons' laws experimentally almost a hundred years after they were first expounded. In 1781, he suggested that friction was caused by mechanical interlocking of asperities and that the actual surface material on the individual asperities was functionless. Although his explanation was wrong, his name lives in quite prominently: the term "Coulomb friction" is still used for dry friction under most conditions (except where heavy plastic deformation is involved, as in metalforming).

The great contribution of the French school was to emphasize that contact occurs only at discrete points. Its major failing was its belief that the contact was determined solely by the original geometry of the asperities (Ref 14) and its exclusion of plastic deformation and asperity shape change from the model.

The English School was actually started by a Frenchman, Desaguliers, whose father was a Protestant priest who fled to England during a period of religious persecution. In a presentation to the Royal Society in 1724, Desaguliers introduced the concept of cohesive force (now called adhesion). He noticed that if two lead balls were pushed together with a light twist, they would stick together and that it took significant force to separate them again. He considered this cohesive force to be a universal phenomenon and suggested that friction can be largely attributed to the adhesion between asperities that come into intimate contact with one another.

Similar ideas were put forth by Tomlinson in 1929 and by Hardy in 1936; however, now they were based on the concept of molecular forces, which had been discovered in the interim and which are very short range in nature. Tomlinson even attempted to explain friction as a basic property derived from fundamental bonding forces working across the interface between the two metals in contact, combined with a partial irreversibility of the parallel force as atoms approach one another during sliding and then separate again.

Research in friction accelerated and reached a firm foundation with the work of Bowden and Tabor in the mid-20th century (Ref 16). Their work focused on adhesion as a major cause of friction, but also showed that more than the outermost layers is involved--that is, that both adhesion and deformation of the substance material are important contributors to the energy dissipation in friction. The adhesion theory of friction is often attributed to Bowden and Tabor, and, while they actually were not the first, they provided much supportive evidence; by including the plastic deformation of surface asperities, they showed that the mechanical properties of the surface material are also important.

In their early work, Bowden and Tabor assumed that the contacting asperities would deform to the point of plastic flow and reach a contact pressure equal to the indentation hardness of the material. The real area of contact, A_r, is then determined from:

$$A_r = \frac{N}{H} \quad \textbf{(Eq 3)}$$

where N is the normal load (in newtons) and H is the flow hardness (in N/m^2). If it is further assumed that friction is due to the shearing of bonds, then the friction force would simply be A_r times the relevant shear stress, τ. In that case:

$$\mu = \frac{F}{N} = \frac{A_r \tau}{A_r H} = \frac{\tau}{H} \quad \textbf{(Eq 4)}$$

This expression satisfies both of Amontons' laws in that contact area and load are eliminated. Because $H \sim 3\sigma_y$, where σ_y is the flow stress and $\tau \sim 0.5$ to $0.6\sigma_y$, a μ of 0.17 to 0.2 should result as a universal value for the coefficient of friction. Indeed, this value is often found for clean metals in air, but as later discovered, much higher values are found in a vacuum when the metals do not have a protective surface oxide film. It was suggested that shearing could also take place below one of the contacting asperities, especially if one of the materials was substantially weaker than the other. In that case, the weaker material would wear (Fig. 6).

Fig. 6 Schematic showing typical adhesive junction pull-off and wear generated by friction in the weaker of two materials

Tabor found qualitative support for the expression $F = A_r\tau$ by a simple experiment (Fig. 7). For the three pairs of slider versus flat:

- *Steel ball on indium flat:* μ= 0.6 to 1.2 because τ of the indium is low, but A_r is large
- *Steel ball on steel flat:* μ= 0.6 to 1.2, because τ is large, while A_r is small
- *Steel ball on steel flat with a thin indium coating:* μ= 0.06, because shearing both τ and A_r, are small. τ is small because shearing takes place in the indium, and A_r is small because the vertical load is supported by the steel substrate. The indium acts as a solid lubricant in this case

Tabor and his Cambridge students have continued work on friction and wear over the past half century. Much of our present understanding is due to their dedicated efforts.

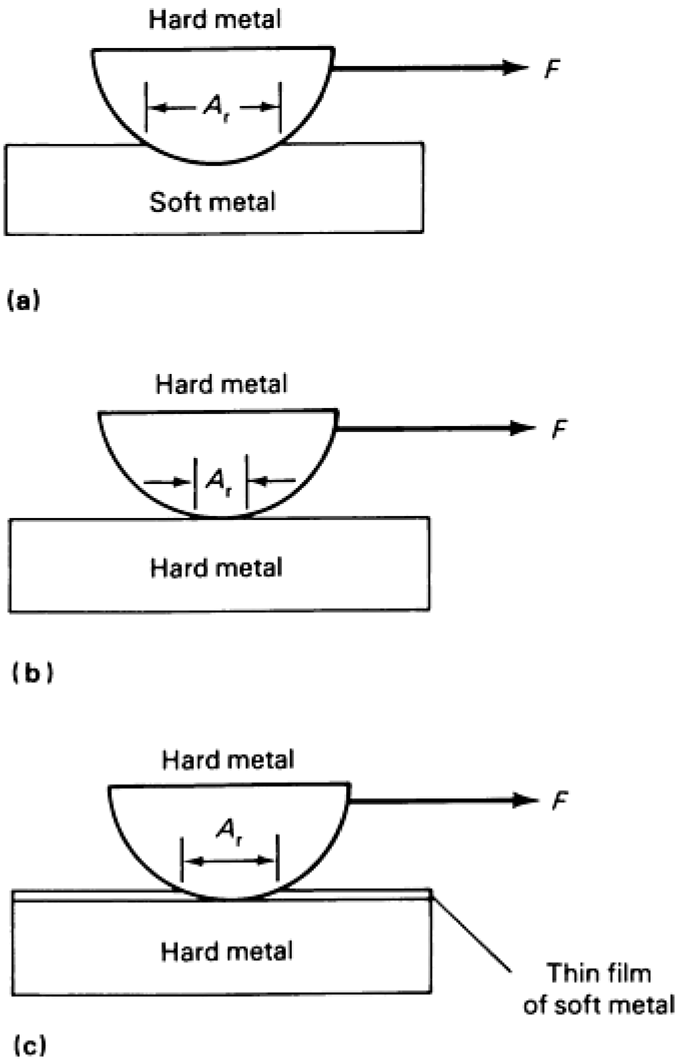

Fig. 7 Relation of friction force ($F = A_r\tau$) to metal substrate hardness. (a) Hard metal in contact with soft metal (small τ and large A_r). (b) Two hard metals of comparable hardness in contact with each other (large τ and small A_r). (c) Two hard metals of comparable hardness separated by a thin-film layer of soft metal deposited on one metal surface (both A_r and τ are small). Deposition of a thin film of a soft metal on a hard metal substrate yields the lowest friction force of the above-mentioned three cases. Source: Ref 16

The overview given in the following sections is not intended to be exhaustive, but rather to acquaint the reader with what many authorities in the field currently consider to be the mechanisms of friction. It is convenient to divide the discussion according to material type, with the understanding that there is considerable commonality among the groups and that most work to date has focused on metals.

Friction of Metals

Adhesion. The interfacial forces caused by adhesion dominate friction when the surfaces are very clean. The contacting surface asperities cold weld together and form intimate atomic bonds across the interface. This can take place at virtually not load, and because the size of the cold-welded area primarily depends on the smoothness of the surfaces and the closeness of their approach, A_r and F can be large. This means that μ can be 5, 20, 100, or even approach infinity. For the higher values, μ clearly loses its conventional meaning. Actually, recent work using molecular dynamics (Ref 17) and atomic force microscopy (Ref 18) has shown that when two surfaces are brought close together at a distance of a few atomic diameters, they will attract each other to form interatomic bonds. In this case, the normal force can be negative (a pull) which means that, strictly speaking, μ is negative. Again, in this situation the concept of friction has lost its conventional meaning.

From an engineering viewpoint, strong adhesion between sliding surfaces becomes important only for very clean surfaces in a very high vacuum. Adhesion problems have been studied extensively by Buckley (Ref 19), whose work has focused primarily on space applications, where the phenomena of adhesion and attendant seizure are extremely important.

High levels of friction in a vacuum environment were previously observed by Bowden and Tabor (Ref 16). They conducted an experiment to illustrate the effect on friction when the vacuum contains small amounts of molecular species that can chemisorb on the surface and thereby lower its tendency to form adhesive bonds. The results are shown in Fig. 8, which illustrates the behavior of pure iron with originally "clean" surfaces sliding against an identical specimen of pure iron. In the initial vacuum, friction was very high and seizure occurred. As oxygen entered the chamber at a low pressure of 10^{-4} mm Hg, μdropped to 2.3. If the oxygen pressure was increased 10-fold to 10^{-3} mm Hg, μdropped slightly to 2.1. It dropped further, to 1.9, as the oxygen pressure was increased to a few millimeters Hg. These μ-values are still very high compared with values that would occur under normal ambient conditions. However, leaving the surfaces exposed to a low oxygen pressure for a long period of time brought $\mu$to about 0.5, which is quite similar to values normally found.

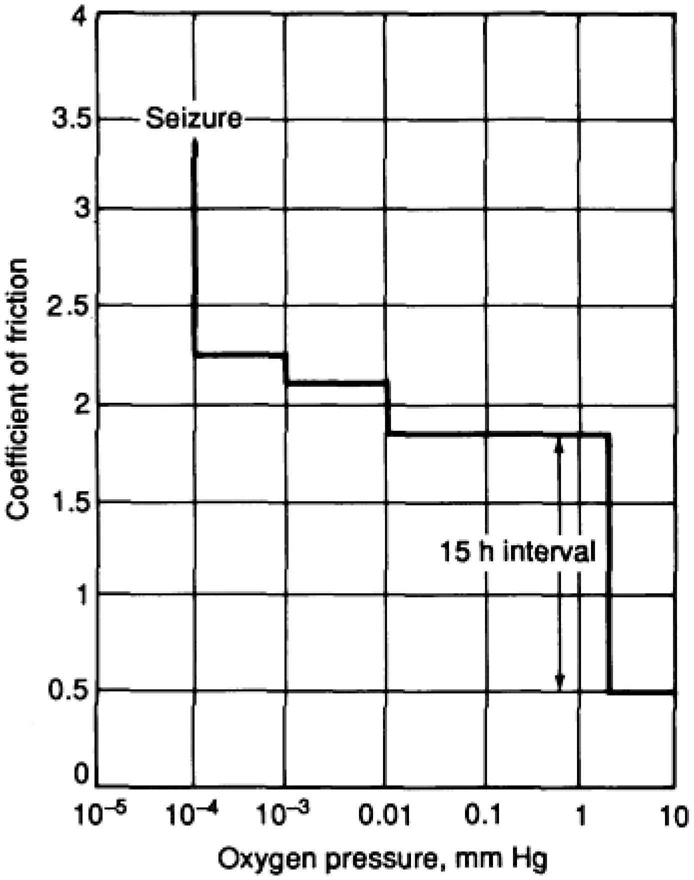

Fig. 8 Influence of oxygen on coefficient of friction of clean iron surfaces. Source: Ref 16

The behavior illustrated in Fig. 8 is not limited to iron sliding on iron, but is representative of the behavior of most metals when they are self-mated. Clean metal surfaces seize, or cold weld to each other, when they are brought together in a vacuum. When they are separated, chunks of material are usually transferred from one surface to the other, even for self-mated couples. When molecules that can adsorb to the surface, such as oxygen or water vapor, are admitted to the system, the friction drops because surface sites become covered with adsorbed atoms or even thin layers of oxide, and thus the surface area available for cold welding decreases. The more reactive a metal is, the more pronounced the effect.

Even materials that do not form oxides in the conventional sense exhibit this type of behavior. An example is diamond (Ref 19). In a vacuum, μ= 0.1, indicating that the diamond surface is protected by adsorbed species. If the two contacting surfaces are rubbed back and forth several hundred cycles in the same track, μincreases to 0.8 to 1, which indicates that the mechanical rubbing action has worn through the protective surface film (Ref 19).

In general, as mentioned previously, most classes of material have lower μ in air than in vacuum because of adsorbed molecules from the ambient air--water, oxygen, carbon dioxide, hydrogen, and so forth. One exception is soft glass, for which μ increases in ambient air. The reason for this behavior is that water molecules tend to chemisorb to the glass and bond the two surfaces together, thereby increasing their friction (Ref 19). If only dry air is used, the effect is not seen.

The amount of adhesion is also affected by the various other possible surface alterations discussed earlier: segregation of solute or impurity atoms to the surface, reconstruction of surface layers due to change in composition, and formation of compounds by chemical or mechanical action. The nature and the effects of all of these depend on the specific situation. For pure, film free surfaces in a vacuum, the adhesive friction depends on the size of the adhesion are, the strength of the adhesive bonds, and, in most cases, on the flow stress of the subsurface material, because that is usually where deformation takes place to accommodate the sliding.

Buckley (Ref 19) has demonstrated that the adhesion between two surfaces depends on the degree of matching between the crystal planes. The highest adhesion and friction forces are observed for matched planes of the same material. Lower values are found for matched planes of materials that are different but that have similar lattice dimensions and also show some mutual solubility. Still lower values are found when the two materials are insoluble in each other. For example, Buckley quotes high-vacuum values of $\mu = 21$ for the self-mated couple copper-copper; $\mu = 4$ for the closely fitting planes of the mutually soluble couple copper-nickel; $\mu = 2$ for copper-cobalt, where solubility exists but where one metal is face-centered cubic (fcc) and the other is hexagonal close-packed (hcp); and $\mu = 1.4$ for copper-tungsten, where no bulk solubility exists.

For matched planes and directions, the lowest values of μ in a vacuum are found for the planes with the highest atomic density--for example, the (111) planes in fcc metals or the basal plane in many hcp metals. These planes also have the lowest surface energy. Mismatched planes and directions yield lower values of μ.

Adhesive friction may also be related to other fundamental properties. One such property is the degree of ***d***-valence bond character of the transition metals (Ref 8, 19) (Fig. 9). Titanium, which has a very high degree of bond unsaturation, shows a strong tendency to bond with almost anything, such as a matching titanium surface or a nonmetal. As the degree of ***d***-bond character increases, the friction coefficient decreases--possibly because the greater the degree of bonding of a metal to itself, the less the bonding across the interface (Ref 19). There may be other possible explanations for this observed behavior. For example, it seems plausible that some or much of the effect could be due to changes in flow stress and flow behavior as the degree of ***d***-bond saturation changes.

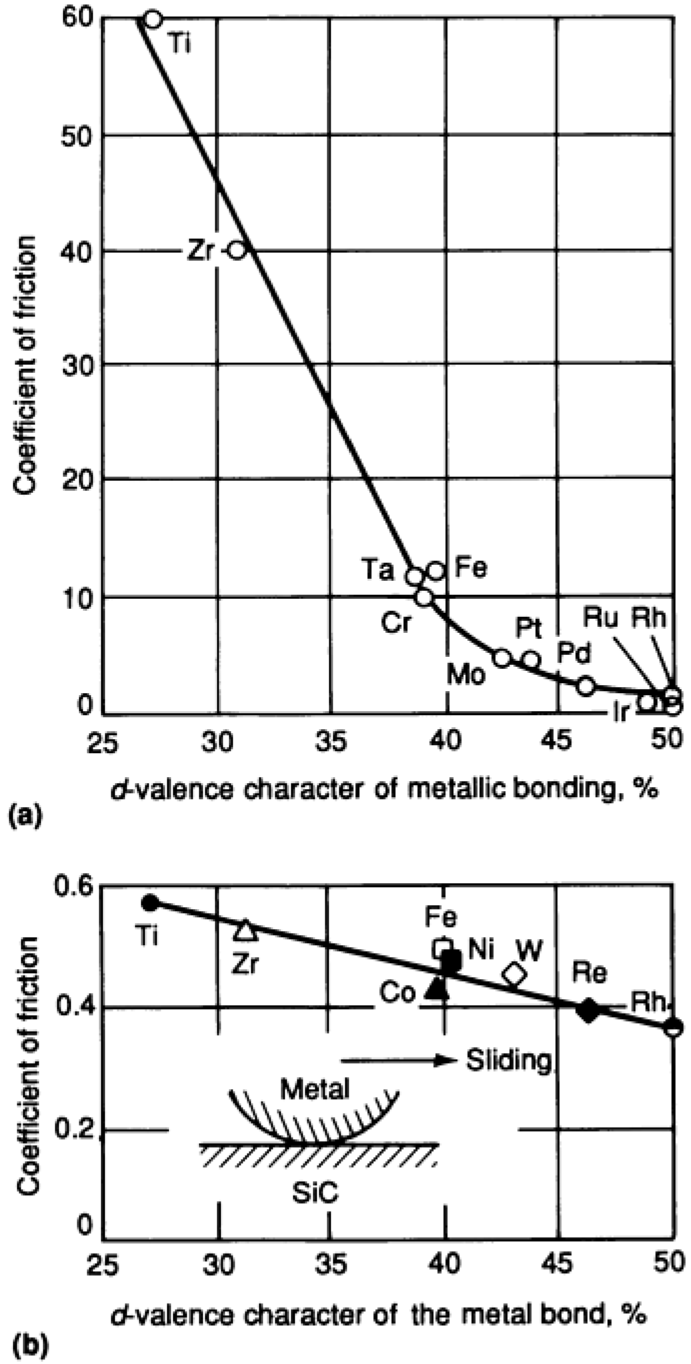

Fig. 9 Plot of coefficient of friction in a vacuum versus *d*-bond character of selected metals. (a) Metals in contact with themselves at very low load and sliding velocity. (b) Metals sliding in contact with single-crystal SiC. Source: Ref 19

Because plastic deformation is associated with friction, in most cases it is expected that even in a vacuum the flow stress of the material will affect μ. This is confirmed, for example, by results of friction tests with changing temperature for metals and alloys that undergo phase transformations. Figure 10 illustrates this for cobalt, which is hcp below 417 °C (783 °F) and fcc above this temperature. Below the transition temperature, μ= 0.35 for cobalt, because the basal hexagonal planes develop a preferred orientation, slips takes place between them, and there is little stain hardening. In this range, cobalt behaves like a solid lubricant. For the fcc structure above the transition temperature, μrises rapidly, possibly because of the significant work hardening of this structure.

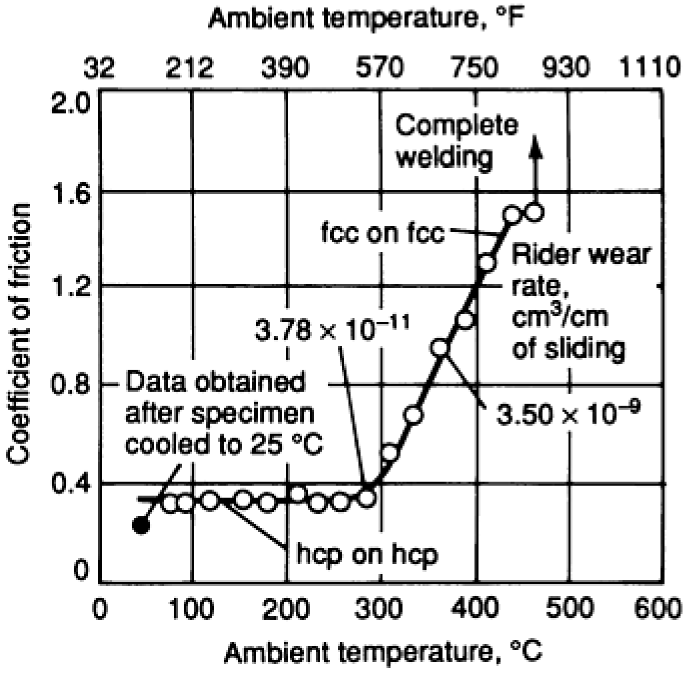

Fig. 10 Plot of coefficient of friction versus temperature as a function of phase transformation in a vacuum for cobalt sliding on cobalt. Sliding velocity, 1.98 m/s (6.5 ft/s). Source: Ref 19

Similar behavior has been observed for thallium, which also undergoes an hcp-fcc transformation. Not all hcp structures show low friction, however. A good example of this is titanium (Fig. 9). It appears that low friction occurs only for those structures that deform exclusively in the basal plane and that show low work hardening because the basal planes slide readily over one another. For lanthanum, which has three crystalline phases, the friction coefficients are in the order $\mu_{hcp} < \mu_{fcc} < \mu_{bcc}$ (bcc, body-centered cubic). Tin and tin-copper solid solutions show the opposite behavior with temperature: there is a drop in μ as the phase transformation from gray tin to white tin takes place upon heating 13 °C (55 °F). In this case, the behavior can also explained on the basis of the deformation properties of the two crystal structures. The high friction is exhibited by the low-temperature phase (gray tin). It has a diamond-type structure and exhibits a high degree of work hardening, while the white tin has a body-centered tetragonal (bct) structure that deforms more readily and that shows less work hardening and consequently lower friction (Ref 19).

In summary, adhesion is a very important component of friction in a vacuum. In extreme cases, it may lead to complete seizure of the two surfaces. The amount of adhesion depends on the nature of the surfaces, on their affinity for each other, and on their affinity for any adsorbates that may be present in the vacuum. The friction coefficient also depends on the flow stress properties of the near-surface material, because this is where deformation to accommodate the sliding most often takes place. In contrast, the effect of adhesion on friction under ambient conditions is more controversial, because it is not as unequivocally demonstrated.

Asperity Deformation. When asperities contact, they undergo elastic and plastic deformation to accommodate the stresses, as proposed by Bowden and Tabor (Ref 16), who divided the friction force into two components: a *plowing* term, F_p, and an *adhesion* term, F_a. The plowing term is due to energy dissipation in plastic deformation when the asperities interact with one another. If one metal is softer than the other, the hard asperities will produce visible grooves in the softer metal surface by a "plowing" action. For rubbers and polymers, the primary energy-dissipation mechanism is internal hysteresis. Most brittle materials can also undergo some plastic deformation in the compressive hydrostatic pressure region in front of and below a moving, plowing indenter or asperity. They also dissipate energy through microcracking.

The adhesion component of friction, F_a, is much more controversial, except when dealing with clean surfaces in a high vacuum, as discussed above. It is difficult to find a measurable force of adhesion between two "normal" engineering surfaces when they are pushed together under "normal" conditions. It has been suggested that this may be due to two factors:

- A large part of the surface is covered with films of oxides, adsorbates, and so forth, and only a few of the highest asperities are able to penetrate these films to form the metal-to-metal bonds needed for adhesion occur
- There is a large, elastically deformed region below the vary small, plastically stressed, adhering volume associated with the few spots of intimate contact. When the load moves, the elastic strain release overwhelms the adhesive bonds and ruptures them; consequently, significant adhesion is not seen in any force measurements

Bowden and Tabor originally suggested that that the reason a friction force would appear when two surfaces were slid parallel to each other, while almost no adhesion was seen if they were pulled apart without sliding, was that the junctions grew because of the horizontal forces and that friction was caused by the adhesion over these larger areas. This junction growth theory still has some supporters (Ref 18, 20), but it is now generally thought that adhesion does not contribute a clearly separate component to friction. Rather, adhesion is thought to be a component of the plastic deformation of asperities, a component that strongly influences the amount and the nature of the deformation. This approach has been reviewed by Johnson (Ref 21) and is discussed in some detail in his book (Ref 22).

The initial assumption that the contacts would be almost exclusively plastic was challenged by Archard (Ref 23), who pointed out that while it is reasonable to assume plastic flow for the first few traversals of one body over another, the same could not be assumed for machine parts that make millions of traversals during a life-time. The tallest asperities may flow plastically at first, but the surface must reach a steady state in which the load is supported elastically. For very rough surfaces, some initial plastic flow would certainly be expected, while for very smooth surfaces, the contact may be mostly elastic.

Greenwood and Williamson (Ref 6) attempted to model the condition at which changeover from elastic to plastic contact takes place. They used a multiasperity model and assumed that the asperities had a Gaussian height distribution and the same tip radius. They also assumed that the elastic deformation and stresses could be calculated from the Hertzian equations. Onset of plastic flow was taken to be the point where the maximum Hertzian pressure reaches about 0.6*H*, where *H* is the indentation hardness. This is in accordance with findings from studies of the indentation hardness of metals (see, for example, Ref 22).

It was convenient to introduce a *plasticity index:*

$$\psi = \frac{E'}{H}\sqrt{\frac{\sigma}{\beta}} \qquad \textbf{(Eq 5)}$$

where ψ is the plasticity index and E' is the effective elastic modulus from the Hertzian expressions, given by:

$$E' = \left(\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\right)^{-1} \qquad \textbf{(Eq 6)}$$

where E_1 and E_2 are the elastic moduli and ν_1 and ν_2 are the Poisson ratios of the two materials. If one material is considerably harder than the other:

$$E' = \frac{E}{1-\nu^2} \qquad \textbf{(Eq 7)}$$

which can be called the "plane stress modulus." If the two materials are identical, E' is half of this.

In Eq 5, *H* is the indentation hardness (in N/m^2), σ is the standard deviation of the asperity height distribution, and β is the radius of the asperity tips. The plasticity index combines mechanical properties (E' and *H* and topographical properties (σ and β) of the solids in contact.

Greenwood and Williamson (Ref 6) found that while ψ may vary from 0.1 to 100 for real surfaces, in practice it falls in a narrow range. Typically, if $\psi > 1$, there is significant plastic flow; if $0.6 < \psi < 1$, there is some elastic and some plastic deformation; and if $\psi < 0.6$, plastic flow is unlikely.

Because load does not enter into the expression, it is clear that surface properties and surface topography, according to this model, play much greater roles in determining whether plastic deformation takes place. It is also clear that if the surface topography is such that plastic flow occurs initially, surface interaction in repeated passes may smooth the surface during run-in, until the standard deviation of the asperity height distribution (σ) decreases and/or the radius of curvature of the asperities (β) increases such that the plasticity index falls into the elastic range of contact.

Interestingly, in the GW model the real area of contract is almost proportional to load, even when the contact is entirely elastic. That is, Amontons' laws can be satisfied by elastic as well as by plastic contact conditions.

Plastic deformation may be of vital importance even when the total area of plastic contact is quite trivial. For example, on oxide-covered contacts, the plastic contacts will be the points where electrical and thermal conduction takes place, and they will also be the origin sites for much of the friction. However, many surfaces probably have no plastic contacts at all or have primarily elastic contacts rather than plastic contacts in each pass.

Somewhat more refined models of surface topography and of the deformation model have been proposed (Ref 24), as has a slightly different plasticity index (Ref 25). These are relatively minor improvements and have been omitted from this discussion for the sake of simplicity.

The effect of friction on the deformation process for idealized single-asperity contact has been described by Johnson (Ref 21) for the case of a two-dimensional asperity (a wedge), which lends itself to slip-line field analysis. The nature of the deformation under a blunt wedge depends on the interface friction between the wedge face and the surface of the metal (see Fig. 11 for a rigid, perfectly plastic material). If the friction is large, a cap of restrained material that does not flow plastically will form below the tip of the wedge. If the friction is zero, no such cap develops and the metal deformation takes place in a narrower zone around the indentation. If the wedge is made to move across the metal surface, it will initially dig deeper into the counterface, because the load will have to be supported on one side only. This is equivalent to the junction growth discussed above. Eventually, the wedge will return to the surface level, riding on its own "bow wave" and pushing a prow of plastically deformed material ahead of it. When the interface friction is high (perfect adhesion), the overall coefficient of friction approaches 1. If the adhesion is zero, pure plowing takes place. The wedge does not dig into the surface as deeply, and the final "bow wave" is much smaller (Fig. 12). In this case, the final friction is $\mu \sim \cot \alpha$, where α is the wedge half-angle.

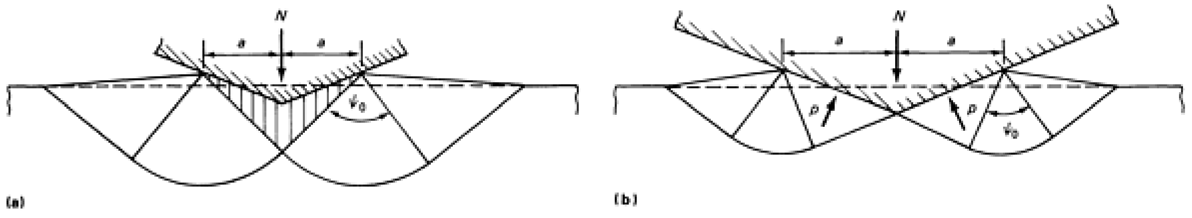

Fig. 11 Indentation of a rigid, perfectly plastic surface by a rigid blunt wedge. (a) With perfect adhesion, a cap of material adheres to the wedge face (shaded area). (b) With zero adhesion, the contact pressure, p_m, acts normal to the wedge face and the volume of deformed material is less. $p_m = 2k(1 + \psi_0)$. Source: Ref 21

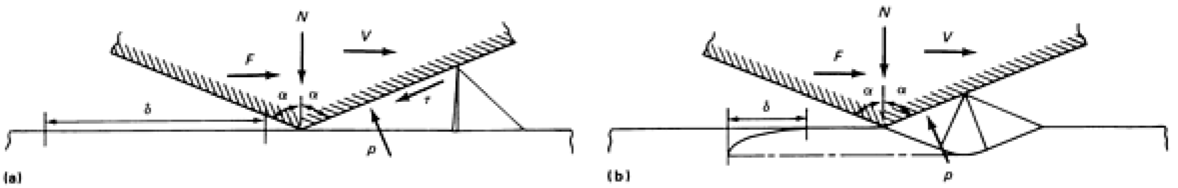

Fig. 12 Steady-state plowing of rigid, perfectly plastic material by a rigid wedge with half-angle, α, of 68°. (a) Perfect adhesion: τ= 0.73, *k* = 0.43*p*, μ= 1.0. (b) Zero adhesion : τ= 0, μ= cot α= 0.40. The plastic shearing of the surface relative to the bulk is shown by δ. Source: Ref 21

This idealized model illustrates the probable role of adhesion in the friction of ductile metals. Both with and without adhesion, the energy dissipation is caused by plastic deformation. Without adhesion, the plastic strains are relatively small , where μ= μ_p and is determined by the surface topography and generally has a value of less than 0.15. The presence of adhesion increase the plastic strains of plowing, causes substantial prow buildup, and yields $\mu\sim$1.0, irrespective of surface topography (Ref 21).

Challen and Oxley (Ref 25) have further investigated this model for various levels of interface strength, that is, for different levels of adhesion between the asperity face and the metal surface. Figure 13 shows their results for three different half-angles, 70°, 80°, and 90°, the last representing a flat punch. The friction coefficient, μ, is plotted versus the normalized interface strength, τ/*k*, where $\tau$is the interface shear strength and *k* is the shear yield stress of the metal. Relatively small changes in τcan change $\mu$from 1.0 to 0.5, a result well known from practical tests on metals in ambient air (see also Fig. 8). The μ-values at τ= 0 may be thought of as representing pure plowing and those at α= 90° as representing adhesion. When true adhesion takes place and there is no slip at the interface, μrises rapidly to a value of 1.0.

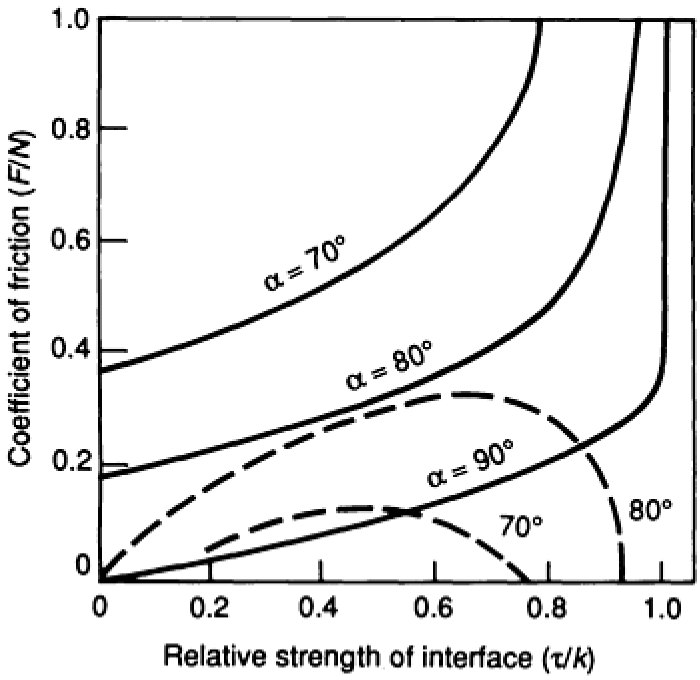

Fig. 13 Plowing by wedges with different half-angles and for various levels of partial adhesion. The "pure plowing" term, μ_p, is given by values of *F/N* when τ= 0; the "pure adhesion" term, μ_a, is given by *F/N* when α = 90°. The total friction coefficient, μ, is given approximately by μ_p + μ_a. The dashed line shows the fraction of total loss dissipated at the interface. Source: Ref 25

One must remember that conditions may be somewhat different in real life compared with the idealized conditions of plane strain indentation of elastic-perfectly plastic materials. The flow under a three-dimensional asperity is somewhat different from that under a wedge, and real surface material usually work hardens during the run-in period. However, the presentation based on the work of Johnson (Ref 21) and Challen and Oxley (Ref 25) illustrates the general phenomena, even if several minor details may be somewhat different under real-life conditions. One must also remember that the local contact areas may be at conditions quite different from those of bulk material. They may be heated by friction to temperatures that cause significant softening or even recrystallization and that may promote local oxidation. Furthermore, the local deformation happens rapidly and over a very short distance, while the resulting strain is large. Consequently, the associated strain rates can be very high. These conditions, coupled with the high hydrostatic pressure, may make it difficult to apply conventional constitutive equations for the material to the deformation that takes place in frictional contacts.

Deformation Energy. Rigney *et al.* (Ref 26, 27) have suggested that metallic friction can be determined on a deformation energy basis alone, from the strain energy that each pass of the slider introduces into the deformed layer. By equating the plastic work in surface deformation with the work done by the friction force, they derived the expression:

$$\mu = \frac{1}{1+n}\frac{\tau_0 \gamma_0}{H} \qquad \textbf{(Eq 8)}$$

where *n* is the work-hardening coefficient in the shear stress/shear strain flow equation:

$$\tau = \tau_0 \gamma^n \qquad \textbf{(Eq 9)}$$

and *H* is the hardness (in N/m^2).

This model has no adhesive component. Thus, current models of friction extend from pure adhesion to pure plastic deformation, with considerable coverage of the middle ground of adhesion plus elastic and plastic deformation. Although the modern models are much more detailed, their basic principles not very different from those of the early French and English schools. This is a tribute to the insight of the early pioneers in the field, but also underscores the complexity of the subject.

Third-Body Effects. An additional friction term based on mechanical deformation has been proposed by Suh (Ref 28, 29). He considers friction to have three components:

$$\mu = \mu_{asp} + \mu_{plow} + \mu_{part} \qquad \textbf{(Eq 10)}$$

where μ_{asp} is a contribution from deformation of the asperities, μ_{plow} is due to plowing effects, and μ_{part} is due to wear particles that remain in the wear zone and may agglomerate, work harden severely, and act as third bodies that deform the contacting surfaces.

The model was supported by findings such as that shown in Fig. 14. Here, the friction of a copper-copper sample rises from a rather low value as the distance of sliding increases (upper curve). If the surface is modulated to provide it with channels into which the particles can fall before they agglomerate and damage the surface, then the rise is not seen, and friction remains quite low (lower curve).

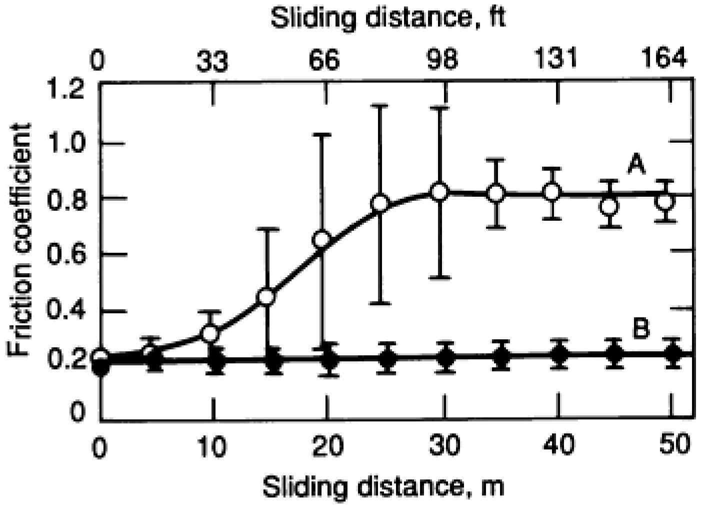

Fig. 14 Plot of coefficient of friction versus sliding distance for two types of copper surfaces. A, copper pin sliding on a copper flat. B, copper pin sliding on a modulated copper surface. Source: Ref 28

The role of trapped debris particles has also been recognized by Godet (Ref 30), who considers most wear behavior at steady state (for example, after 1000 cycles) to be controlled almost exclusively by third-body wear particles between the two surfaces. Adhesion and deformation in plowing and fatigue are still components of the entire process, but mainly because of their roles in formation of the wear particles. Interestingly, in this case friction is basically controlled by wear; the opposite statement--that wear is controlled by friction--is more often heard. Most likely, both statements are partially true.

Friction in metalforming is complex subject worthy of its own article an will be mentioned only briefly here. Because the contact loads during metalforming processes are high, the plastic zones beneath the asperities will merge and overlap and will eventually join with the deformation processes in the workpiece itself. Traditionally, it has been assumed that Coulombic friction controls the interface forces at low loads and that as the load grows to the point where the real area of contact is equal to the apparent area of contact, friction becomes independent of pressure and takes on the value *k,* which is the flow shear stress of the workpiece material (Fig. 15). It has been pointed out that *k,* is not a simple value; it is modified by the hydrostatic pressure and by geometric constraints, so that the final value under real conditions becomes somewhat lower than *k* determined from uniaxial tension tests (Ref 31). Because the situation is complicated by high stresses, high strain rates, frictional heating, surface oxides from heat treating, and so forth, the area of friction in metalworking is one of the least understood and most challenging for future work. An advanced analysis based on slip-line field studies has recently been presented by Kopalinsky *et al.* (Ref 32).

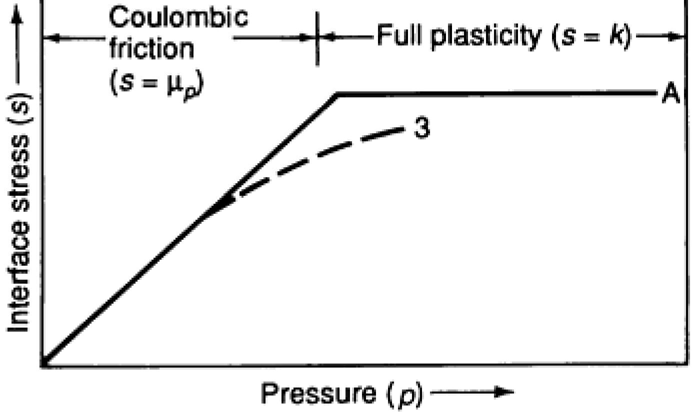

Fig. 15 Friction stress along the die surface in metalforming as a function of the normal pressure in the forming

process. A, ideal conditions. B, actual behavior

There is still some disagreement regarding the actual cause of friction of metals. In general, friction has several components:

$$\mu = \mu_a + \mu_p + \mu_e + \mu_{part} \qquad \textbf{(Eq 11)}$$

where

- μ_a is due to adhesion (or spot welding) between the surfaces. It is very important in high-vacuum applications and for very clean surfaces, and it may take over for certain metals that show seizure under ambient conditions. Under normal conditions, adhesion probably plays only a minor direct role, but it plays a significant indirect role by its effect on the plastic deformation in plowing
- μ_p is plastic deformation and plowing caused by deformation of one surface by hard asperities from the other. The result is formation of permanent grooves in the surface of the softer metal or pushing of a "bow wave" of material across the surface ahead of the indenter
- μ_e is a contribution from the elastic deformation of the material below the plastically deformed regions. It becomes more important as the surfaces are cold worked and smoothed during the run-in period
- μ_{part} is due to third-body particles trapped between the surfaces. These appear after some distance of sliding and are usually agglomerations of small wear particles. Their friction contribution is one of plastic deformation as they indent the surfaces or roll between them

Detailed information is available in the article "Appendix: Static and Kinetic Friction Coefficients for Selected Materials" in this Volume. It is clear that friction is compound property of the system in question and that prediction of friction from first principles is not yet possible.

Friction of Polymers

Friction in polymers is caused by many of the same mechanisms as for metals. There are other mechanisms, too, primarily because of differences in mechanical properties--in particular, the viscoelasticity, strain-rate sensitivity, and low thermal conductivity of polymers. In broad terms, friction is caused by mechanical deformation and surface adhesion, as for metals. The various friction mechanisms for polymers are illustrated in Fig. 16, 17, and 18 and are discussed in the following sections.

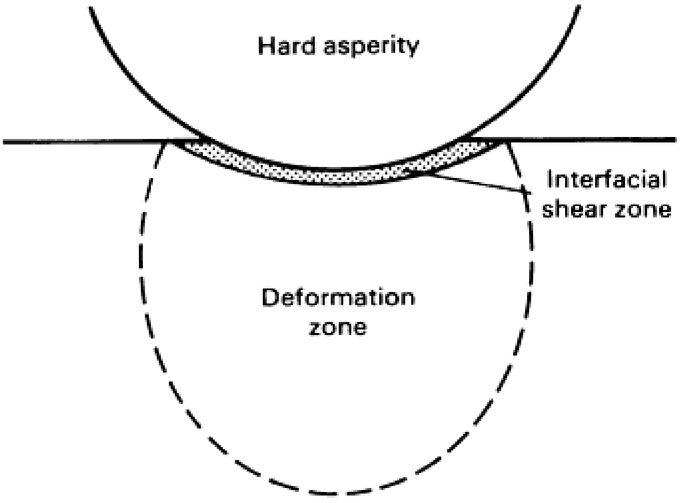

Fig. 16 Schematic showing a model of the friction dissipation zones present in a polymer. Source: Ref 33

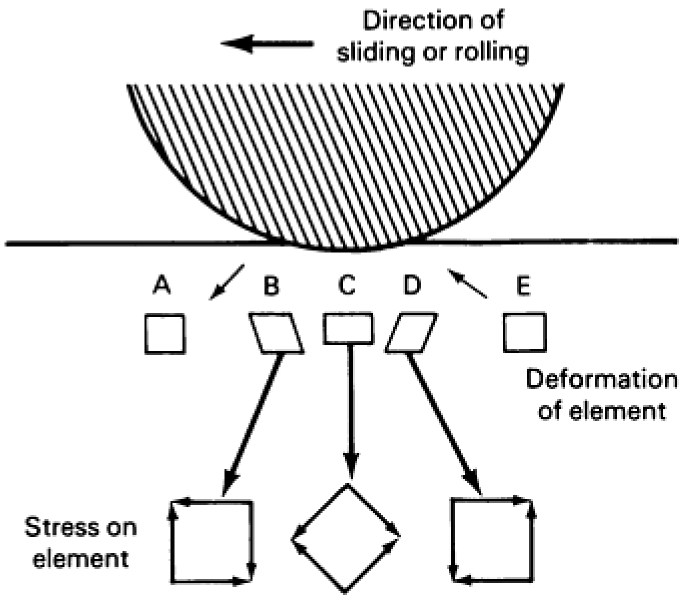

Fig. 17 A smooth, rigid sphere sliding or rolling over a viscoelastic material in the absence of surface adhesion. The progressive changes of stress beneath the contact are indicated for a chosen volume element. Each element undergoes about three cyclic deformations during the passage of the indenter. Source: Ref 33

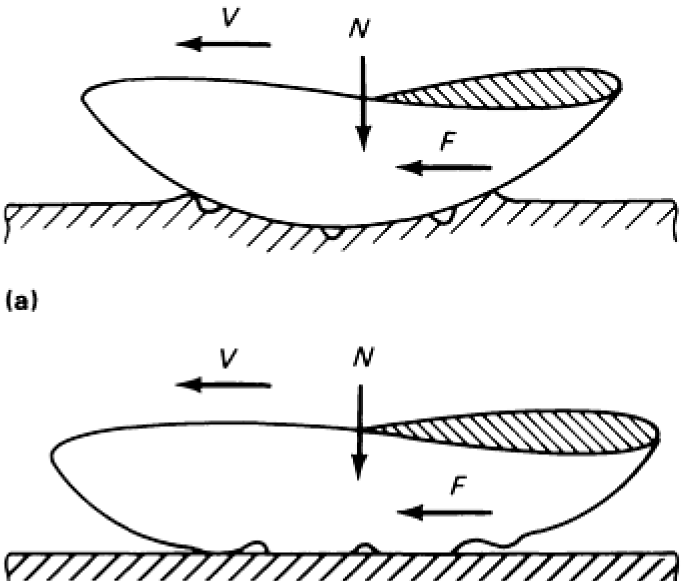

Fig. 18 Formation of Schallamach waves by buckling of the rubber surface at the compression side of contact. (a) For hard slider on rubber flat, waves move from front to back. (b) For rubber slider on hard flat, waves move from back to front. Source: Ref 21

Interfacial Zone Shear. Deformation takes place in a very thin layer (~100 nm) at the interface (Fig. 16). Slip may occur right at the interface itself, but is more commonly found within the polymer. In that case, a transfer layer forms on the other surface, possibly bonded adhesively via the carbon bonds (Ref 8) or held in place chemically by weaker interfacial bonds and mechanically by the surface roughness. Because the shear zone is very thin, it may experience extremely high shear rates with consequent local heating, exacerbated by the relatively low conductivity of the polymer matrix.

Some polymers do not appear to form transfer films, in which case sliding will take place at the interface between the two materials. This occurs primarily in highly cross-linked polymers and in some unlinked polymers below the glass transition temperature (Ref 33). Most semicrystalline polymers form transfer films, however. Typical examples at room temperature are polytetrafluoroethylene (PTFE) and low- and high-density polyethylene (HDPE). For PTFE, HDPE, and ultrahigh molecular weight polyethylene (UHMWPE), strain softening effects tend to lower the friction as sliding progresses. In general, for polymers whose frictional deformation takes place in the interfacial shear zone, friction is controlled by the flow stress at very high strains and strain rates and at somewhat elevated temperatures.

Deformation zone friction is friction caused by energy dissipation in deformation of the material below the indenter in the deformation zone (Fig. 16). This zone is similar in size to the plastically strained zone beneath an indenter on a metal substrate. Polymers have a characteristic ability to deform viscoelastically, in which case an imposed strain is fully recovered, usually with some time hysteresis. Organic polymers cover a full range of viscoelastic behavior, from essentially brittle to essentially ductile behavior, and the relative contribution of the two types of deformation behavior in any particular case depends strongly on deformation rate, temperature, and stress state (Ref 33). For glassy polymers, much of the energy dissipation in the deformation zone will be caused by microcracking, while ductile polymers produce grooving by permanent deformation. There is a transition between microcracking and plastic grooving that depends on sliding velocity, with lower speeds favoring more ductile deformation, as expected. Polymers in this general group include polymethyl methacrylate and polycarbonate.

Many polymers exhibit no permanent deformation after the indenter has passed, because they are viscoelastic and recover the original strain. The friction work is dissipated in the hysteresis of the deformation. Figure 17 shows the deformation patterns below a sliding (or rolling) hard contact. Each volume element undergoes about three cyclic deformations during the passage of the contact (Ref 33). The fraction of deformation energy lost (that is, the energy dissipation and thus the friction) is proportional to tan δ, where δ is the loss angle of the polymer at the deformation frequency. Corrections for local pressure and temperature effects may have to be made, because the conditions beneath the indenter are essentially adiabatic and quasi-hydrostatic pressure (Ref 33). If conditions are made more severe--for example, by increasing the interface friction or by increasing the depth of indentation--the deformation will change from viscoelastic grooving to tearing and plastic grooving. Additional information is available in the article "Solid Lubricants" in this Volume.

Friction of Elastomers

For fully viscoelastic materials, such as rubber and elastomers in general, interfacial friction appears to play an important role in dry sliding by strongly affecting the viscoelastic deformation behavior. Sliding involves generation of so-called Schallamach waves (Fig. 18). These waves are like giant dislocations that form on the compression side of the rubber member and then move through the contact zone toward the tension side. The rubber peels from the counterface and then becomes reattached. The reattachment energy is much smaller than the detachment energy (work of adhesion), so the latter dominates the behavior (Ref 21). The friction force, *F,* is:

$$F = (\Gamma)\, fA/V \qquad \textbf{(Eq 12)}$$

where Γ is the work of adhesion, *f* is the frequency of passage of Schallamach waves, *A* is the contact area, and *V* is the sliding velocity (Ref 21). Additional information is available in the article "Appendix: Static and Kinetic Friction Coefficients for Selected Materials" in this Volume.

Friction of Ceramics

The frictional behavior of ceramics is not well understood. In general, these materials might be expected to exhibit quite low friction, because the contributions from both adhesion and deformation are expected to be fairly low. The contribution from deformation should be relatively low because the hardness is high, and contribution from adhesion should be relatively low because formation of primary bonds across an interface between two ceramic materials requires the proper registry of positive ions on one side with negative ions on the other, and vice versa, a relatively rare condition. Nevertheless, ceramic materials exhibit quite high levels of friction--levels that change drastically as the wear mode changes. The friction is very strongly affected by the formation of surface films of oxides and hydroxides, which often have lubricating properties. Much work needs to be done in this area.

Other Materials

A number of materials exhibit special types of behavior that will be touched on briefly here. This behavior can be understood qualitatively from a detailed knowledge of the deformation behavior and surface chemistry of the materials in question. Additional information is available in the article "Appendix: Static and Kinetic Friction Coefficients for Selected Materials" in this Volume.

Graphite and MoS_2 exhibit low friction because of their layered structures. Each layer contains strong bonds that make it resistant to breakup and thereby enable it to carry substantial load. Weak bonds between the layers enable then to slide readily over one another. These materials and several materials with similar structures are used as solid lubricants.

Ice is a special material from a tribological point of view. Water is one of the very few materials that expands upon freezing. Consequently, ice can be made to melt by the application of pressure. Skates, skis, and sled runners generate their own lubricating film of water as they slide over the ice or snow. The lubricant forms at contacting asperities by a combination of frictional heating and pressure effects. If the ambient temperature drops sufficiently to strongly limit this melting (below about -25 to -30 °C, or -13 to -22 °F), operation of this equipment becomes difficult.

Rolling Friction

This article is primarily concerned with sliding friction, which is the friction that arises as one solid body slides over another. However, it has been known for thousands of years that it is easier to roll surfaces than to slide them. The resistance to rolling is called rolling friction and may be very low; for hard materials it may be as low as 0.001 (Ref 34). A very brief introductory discussion of this topic follows.

The use of rolling, as distinct from sliding, as a means of obtaining low coefficients of friction finds its greatest application in wheels and in ball and roller bearings. It is known that lubricants have little influence on rolling friction and that the resistance to "free rolling" (that is, rolling in the absence of an imposed tangential force) is made up of three components (Ref 22):

- Those arising from microslip and friction at the interface
- Those due to inelastic properties of the materials
- Those due to surface roughness

Microslip at the interface occurs both when the two bodies have different elastic properties and when their curvatures are different, but the effects are insignificant in both cases. Exceptions are found when there is a large area of contact, such as when a ball is rolling in a very deep groove, in which case the coefficient of rolling friction may approach 0.3 (Ref 34). Significant microslip may also occur when the rolling is tractive, that is, when large forces and moments are transmitted between the bodies through the contact zone. In this case the behavior will approach sliding.

Anelastic hyteresis losses dominate rolling friction in free rolling. If no permanent groove is formed from the rolling of a ball over a surface, the material beneath the front of the ball is compressed elastically and the material at the trailing part of the contact zone will expand elastic at the same time. If the material were ideally elastic, there would be no energy loss and the rolling friction would be zero (Ref 34). In reality, the deformation has some inelastic hysteresis and the corresponding energy loss is dissipated within the solids, at a depth corresponding to the maximum shear component of the shear stresses. If the thermal conductivity is low and the elastic hysteresis loss is high, this energy release can lead to failure by thermal stress beneath the surface (Ref 22).

The behavior of metals and ceramics in rolling contact is quite different from that of rubbers and polymers. For the former the anelastic hysteresis is governed by minute dislocation movements and is therefore usually very small, resulting in low rolling resistance. On the other hand, materials (such as rubbers) that exhibit full or partial viscoelastic deformation may have considerable rolling friction, and this friction may be quite sensitive to both temperature and deformation rate. Typical μ_r values for an automobile tire fall in the range of 0.01 to 0.03.

Surface roughness can affect rolling friction in two ways, although the affect usually is minor. First, for very lightly loaded rough hard surfaces, the energy expanded in lifting the body over the irregularities gives a small contribution to the rolling friction. Most of the energy transfer in this situation is by impact between surface irregularities, and the rolling friction due to this causes therefore increases with rolling speed (Ref 22). The second contribution arises from localized deformation. At the local asperities, the contact pressure may be concentrated to the point where permanent deformation

occurs, even if the bulk stress level is within the elastic limit. This can result in a decrease in rolling resistance with repeated traverses as the surface roughness is smoothed out by repeated plastic deformation of the protruding points (Ref 22).

In summary, rolling friction is usually very low, and it is primarily determined by anelastic deformation losses in the material. The greater the hysteresis loop of the deformation, the larger the energy loss in the deformation cycle and the greater the consequent coefficient of rolling friction.

Future Outlook

The basic mechanisms of friction are adhesion and mechanical deformation. Their relative roles are still the subject of much discussion. Frictional energy appears to be lost primarily as energy dissipates through deformation of the surface layers by elastic, plastic, and viscoelastic deformation and/or by microfracture of the surface material and possibly some mode II (shear) fracture of adhesive interface bonds. Adhesion is a primary cause of friction in high-vacuum environments and in instances of seizure. In most cases, however, surface films and contamination limit adhesion to a few small spots, where it can strongly influence the amount and nature of the local friction-generated deformation. Much work needs to be done to elucidate these basic mechanisms and to link minimum friction values (that is, those not determined by the system in question) with basic materials properties--if, indeed, that is possible.

Frictional Heating Calculations

Richard S. Cowan and Ward O. Winer, Georgia Institute of Technology

Introduction

WHEN COMPONENTS IN RELATIVE MOTION are mechanically engaged, the region of contact, which could be dry or separated by a lubricant film, experiences a temperature rise. This phenomenon has been the concern of numerous theoretical and experimental studies because its presence may affect the performance and longevity of the respective surfaces.

While such investigations yield differing effects dependent on the situation, the common observation of a temperature change has been associated with the presence of mechanical energy, which is required to overcome frictional resistance as sliding at the contact interface occurs. The energy, dissipated through conversion into thermal energy, is manifested as a temperature rise. At the microlevel, this increase can be substantial. A localized change in material properties, an enhancement in chemical reactivity, and ultimately, failure of the mechanical system can result.

Attempts to quantify temperature changes have led to the development of straightforward equations associated with the type of contact. Although obscured by such situational uncertainties as the coefficient of friction, real area of contact, time of heat source exposure, and the constancy of material properties, the computational methods outlined in this discussion are focused on the flash temperature; that is, the relative change between the surface temperature and bulk temperature of a component due to frictional energy dissipation at the surface. To a designer, such an analysis provides an indication of what temperature level to expect when surfaces are in contact, provided that the physical and chemical changes that may occur in a surface layer are accounted for.

The authors wish to express their appreciation to the George W. Woodruff School of Mechanical Engineering, at the Georgia Institute of Technology, for the sponsorship of this work.

Frictional Heating Nomenclature

In applying the developments associated with frictional heating, concepts have emerged that can dramatically affect the integrity of an analysis. The user needs to understand how such parameters as temperature, *T;* coefficient of friction, μ; heat partition factor, γ; heat source time, *t;* Péclet number, Pe; and real area of contact, A_r, are interpreted and how they contribute to the heat transfer model employed.

Bulk, Contact, and Flash Temperature. Simply defined as the average temperature of the body prior to frictional heating, the bulk temperature, T_b, remains constant in the body at some distance from the location of frictional energy dissipation. Upon frictional heating, the surface temperature ascends from this bulk temperature to a contact temperature, T_c, at each point comprising the real area of contact. This temperature increase is commonly referred to as the flash temperature, T_f. Therefore:

$$T_f = T_c - T_b \quad \textbf{(Eq 1)}$$

Some members of the engineering community regard flash temperature to be the absolute (actual) temperature of the contact spots. However, this discussion will not use this alternate usage of flash temperature.

Coefficient of Friction. The coefficient of friction, μ, is defined as the ratio of the tangential force required to move two surfaces relative to each other, to the normal force pressing these surfaces together. It is sensitive to a variety of factors, including:

- Material composition
- Surface finish
- Sliding velocity
- Temperature
- Contamination
- Lubrication
- Humidity
- Oxide films

As a result, for any two surfaces, μ may fluctuate over several orders of magnitude, varying with time and location. Because it enters the calculation of flash temperature to the first power, the coefficient of friction provides a major source of uncertainty.

Heat Partition Factor. When two surfaces engage in sliding over a given contact area, the thermal energy generated per unit time, Q, is assumed to be distributed such that part of the heat, namely $Q_1 = \gamma_1 Q$ penetrates body 1, as the remainder, $Q_2 = \gamma_2 Q$, enters body 2. The coefficients γ_1 and γ_2 are known as heat partition factors.

As a function of the thermal properties, bulk temperatures, and relative speeds of the respective components, expressions for γ_i have been developed recognizing that:

$$\gamma_1 + \gamma_2 = 1 \qquad \textbf{(Eq 2)}$$

and that the contact temperature at each point on the interface is identical for both surfaces. Typically, only the maximum or mean surface temperatures within a given contact area are equated for ease of analysis.

Heat Source Time. When a surface contact is exposed to frictional heating, an unsteady situation ensues because the temperature increase becomes a function of time as well as position. The size of the source as well as the thermal properties and speed of the respective materials determine the transient behavior.

The surface receives thermal energy only for the time, t, that the heat source exists. Gecim and Winer (Ref 1) estimate that for a circular contact of radius a, a steady-state temperature is reached in a time such that the Fourier modulus, F_0, of each surface reaches 100. The Fourier modulus is a dimensionless heat transfer grouping:

$$F_0 = \frac{D_i \cdot t}{a^2} \qquad \textbf{(Eq 3)}$$

where D_i is the thermal diffusivity of body i.

Péclet Number. The Péclet number, Pe, is a dimensionless heat transfer grouping defined by

$$\text{Pe} = \rho c_p V L_c / k \qquad \textbf{(Eq 4)}$$

where ρ is the density; c_p is the specific heat at constant pressure; V is the velocity; L_c is a characteristic length; and k is the thermal conductivity (Ref 2). It relates the thermal energy transported by the movement or convection of the medium, to the thermal energy conducted away from the region where the frictional energy is being dissipated.

In computing the Péclet number, L_c is usually expressed as a measure of the contact dimension in the direction of sliding motion. Thus, for relationships presented in this review, the Péclet number can be expressed as:

$$\text{Pe}_i = \frac{V_i \cdot L_c}{D_i} \qquad \textbf{(Eq 5)}$$

where V_i is velocity of surface i, tangential to contact (in m/s); L_c is the contact width for line contact (w), or contact radius for circular contact (a), in the direction of motion (in m); and D_i is the thermal diffusivity of material i (in m^2/s), which is given by:

$$D_i = \frac{k}{\rho \cdot c_p} \qquad \textbf{(Eq 6)}$$

Real Area of Contact. At the microlevel, it is observed that a seemingly smooth surface is composed of a series of asperities. Thus, when contact between surfaces is made under low pressure, the interface is not one coherent area, as assumed by Hertz (Ref 3), but is made up of several small regions where respective surface peaks touch. Generally, the real area of contact (A_r) is only a fraction of the apparent area or contact patch. The real area is considered to be proportional to the normal load, and inversely proportional to the hardness of the softer of the two contacting materials.

The size of and distance between real contact areas within the apparent area will affect the distribution of thermal energy as variations in localized pressure and interactions from neighboring contacts result. This may have little effect on the average apparent contact surface temperature (given that the actual bearing area is small); however, the maximum temperature change from frictional heating at an asperity contact can be significantly, as evidenced by visible hot spots (Ref 4).

Idealized Models of Sliding Contact

Frictional heating calculations are developed on the premise that thermal energy is generated at an area of real contact, and that the energy is conducted away into the bulk of the rubbing members. Thus, the theory requires solution to equations for the flow of heat into each body in such a proportion as to yield equivalent surface temperatures over the contact region.

The following analyses demonstrate the formation of idealized models to represent sliding contact. Expressed in terms of the size of a heat source, the rate of heat flow, and the velocity and properties of the materials in contact, the computations obtained can be used in approximating practical conditions of a similar nature.

General Contact Analysis. The sliding contact may be considered as two solid bodies, of which one or both move at uniform speed past a band-shaped heat source (Fig. 1). This source has a heat flux distribution, *q*, with an average value of q_{av}.

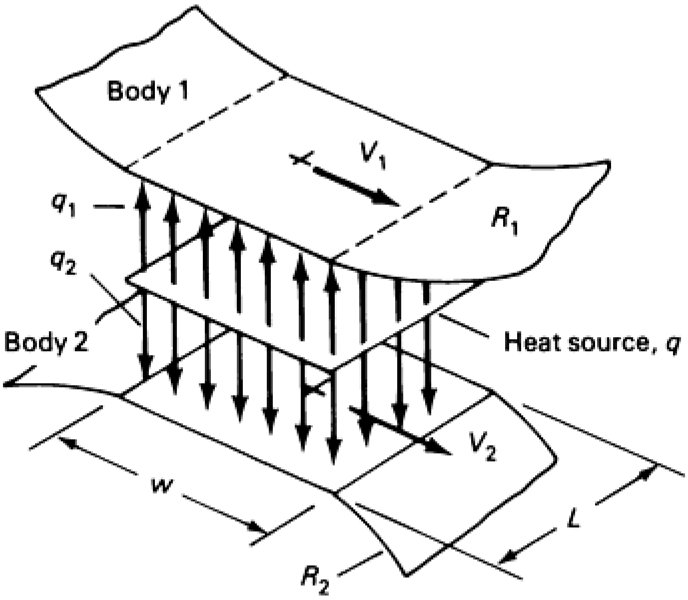

Fig. 1 Schematic showing key parameters that affect heat distribution in an ideal sliding contact model. V_1 and V_2, velocities of surface 1 and surface 2, respectively, both velocities being tangential to contact and normal to contact length; *q*, heat flux distribution; q_1 and q_2, portion of heat distribution that penetrates surface 1 and surface 2, respectively; R_1 and R_2, radius of curvature of surface 1 and surface 2, respectively; *L* and *w*, length and width, respectively, of heat source

The maximum contact temperature, T_c, will occur at the surface of either body. It may be simply computed from:

$$T_c = T_{f_i} + T_{b_i} \qquad \textbf{(Eq 7)}$$

where T_{f_i}, the maximum flash temperature of body *i* (in °C), is superimposed on its respective bulk temperature, T_{b_i}.

Considering that one or both bodies will move relative to the heat source, the maximum flash temperature (in °C) for a moving surface has been related to the parameters described as:

$$T_f = F \cdot \frac{\gamma \cdot q_{av}}{b} \cdot \sqrt{t}$$ **(Eq 8)**

where t represents the time during which any point on the surface is exposed to heat (Ref 5). Variable b denotes a thermal contact coefficient equal to the square root of the product of the specific heat (c), density (ρ), and thermal conductivity (k) of the material. Coefficient F is dependent on the form of the heat flux distribution, q, over the width of the heat source. For a square heat source with uniform distribution in which $q = q_{av}$, F is equivalent to $2/(\pi^{1/2}) = 1.13$, closely approximating a semielliptical distribution where $F = 1.11$ (Ref 6). Furthermore, the product $\gamma \cdot q_{av}$ represents the portion of heat entering the body where γ is the heat partition factor. The average total heat flux, q_{av} (in W/m^2), generated by friction between the two loaded surfaces can be expressed as:

$$q_{av} = \mu \cdot p_{av} \cdot V_r$$ **(Eq 9)**

where μ is the coefficient of friction, p_{av} is the average pressure according to Hertzian contact theory, and V_r denotes the relative sliding velocity between the two surfaces.

Should one of the bodies of Fig. 1 be stationary or moving such that there is sufficient time for the temperature distribution of a stationary contact to be established, the maximum flash temperature of the body is determined as a function of its thermal conductivity, k, and the heat flux distribution, q. Table 1 summarizes an assortment of maximum flash temperature relationships for point and line contacts based on a uniform heat flux distribution, $q = q_{av}$.

Table 1 Selected maximum flash temperature relationships for line and point contacts based on uniform heat flux distribution

Type of contact	Surface relative to heat source	Maximum flash temperature, T_f(a)
Line (L, length; w, width)	Stationary	$\frac{Q}{\sqrt{\pi}Lk}$
	Moving	$1.13 \frac{Q}{Lk} \sqrt{\frac{D}{Vw}}$
Circular (a, radius)	Stationary	$\frac{Q}{\pi ak}$
	Moving	$0.508 \frac{Q}{ak} \sqrt{\frac{D}{Va}}$

(a) Q, thermal energy generated per unit time; k, thermal conductivity; D, thermal diffusivity; V, velocity

Examples of frictional heating, with both bodies or only one body in motion, are discussed in the sections "Line Contact Analysis with Two Bodies in Motion" and "Circular Contact Analysis with One Body in Motion" in this article.

Line Contact Analysis with Two Bodies in Motion. Using the model of Fig. 1, the total heat flux developed from the two moving bodies in line contact must be partitioned (see the section "Heat Partition Factor" in this article). Blok estimated this by equating the maximum flash temperature of each surface using Eq 8, assuming equivalent bulk temperatures and a time of contact, t, equal to w/V_i, where w is the width of the heat source and V_i is the velocity of body i (Ref 6). As a result, the portion of heat withdrawn by surface 1 is:

$$\gamma_1 = \frac{n}{n+1}$$ **(Eq 10a)**

where:

$$n = \frac{b_1 \sqrt{V_1}}{b_2 \sqrt{V_2}} \qquad \textbf{(Eq 10b)}$$

As the two components have equal bulk temperatures T_b, the contact surface temperature (in °C) of either body can be simply expressed as:

$$T_c = T_f + T_b \qquad \textbf{(Eq 11)}$$

Should both bodies be moving such that the Péclet number of each surface is at least 2, the combination of Eq 8 and 9 for use in Eq 11 yields T_f (in °C):

$$T_f = 1.13 \cdot \mu \cdot \frac{W}{L\sqrt{w}} \cdot \left(\frac{|V_1 - V_2|}{b_1 \sqrt{V_1} + b_2 \sqrt{V_2}} \right) \qquad \textbf{(Eq 12)}$$

where μ is the coefficient of friction, w is the contact width (in m), L is the contact length (in m), W is the normal contact load (in N), V_1 and V_2 are velocities (in m/s) of surfaces 1 and 2, tangential to contact and normal to contact length, respectively, and b_1 and b_2 are thermal contact coefficients of bodies 1 and 2 ($W \cdot s^{1/2}/m^2 \cdot °C$); in which b_i is:

$$b_i = \sqrt{k_i \bullet \rho_i \bullet c_i} = k_i/\sqrt{D_i} \qquad \textbf{(Eq 13)}$$

Note that k_i, ρ_i, c_i, and D_i are the thermal conductivity, density, specific heat per mass, and thermal diffusivity of body i, respectively. Representative values of common materials are found in Table 2.

Source: Ref 7

(a) Materials are anisotropic and values vary with crystallographic orientation.

(b) Single-crystal synthetic material.

(c) Typical properties of bearing-quality materials. Ceramics are hot pressed or sintered. These properties are representative and depend on detailed composition and processing.

If both bodies are of the same material, the thermal contact coefficients are equal. Thus, $b_1 = b_2 = b$, and Eq 12 becomes:

$$T_f = 1.13 \cdot \left(\mu \frac{W}{L}\right) \cdot \left|\sqrt{V_1} - \sqrt{V_2}\right| \cdot (b\sqrt{w})^{-1}$$ **(Eq 14a)**

where T_f is in °C.

By utilizing Hertzian contact theory (Ref 3) to relate load and contact geometry to pressure:

$$T_f = 2.49 \cdot \mu \cdot p_H^{3/2} \cdot \left|\sqrt{V_1} - \sqrt{V_2}\right| \cdot \left(\frac{R}{E_v}\right)^{1/2} \cdot b^{-1}$$ **(Eq 14b)**

or:

$$T_f = 0.63 \cdot \mu \cdot \left(\frac{W}{L}\right)^{3/4} \cdot \left|\sqrt{V_1} - \sqrt{V_2}\right| \cdot \left(\frac{E_v}{R}\right)^{1/4} \cdot b^{-1}$$ **(Eq 14c)**

in which:

$$E_v = E/(1 - v^2)$$ **(Eq 15a)**

where E is Young's modulus (in N/m^2) and v is Poisson's ratio, and

$$R = \left[\frac{1}{R_1} \pm \frac{1}{R_2}\right]^{-1}$$ **(Eq 15b)**

where R is the equivalent radius, in meters, of convex to convex (+) or concave (-) undeformed surfaces; and p_H is the maximum Hertzian contact pressure (in N/m^2). Note that the coefficients 1.13, 2.49, and 0.63 are associated with a uniform heat flux as discussed in the section "General Contact Analysis" in this article.

Should the components have different bulk temperatures, T_{b_1} and T_{b_2}, let:

$$T_c = T_f + T_b = T_{f_1} + T_{b_1} = T_{f_2} + T_{b_2}$$ **(Eq 16)**

thus permitting, where T_c is in °C, Eq 12, 14a, 14b, or 14c to still be used for determining T_f, provided T_b in Eq 11 or 16 is replaced with:

$$T_b = T_{b_1} + (T_{b_2} - T_{b_1}) \cdot (n + 1)^{-1}$$ **(Eq 17)**

where T_b is in °C and n is determined from Eq 10b. It should be noted that the corrected heat partition factor in this case becomes:

$$\gamma_1 = \frac{n}{n+1} + \left(\frac{1}{n+1}\right)\left(T_{b_2} - T_{b_1}\right) \cdot \frac{\sqrt{\pi}}{2} \cdot \left(\frac{L}{\mu W}\right) \cdot \frac{b_1 \sqrt{w V_1}}{|V_1 - V_2|} \quad \text{(Eq 18)}$$

For the situation in which surface *i* is stationary (Pe < 2), Blok (Ref 8) suggests that the maximum flash temperature, in °C, is:

$$T_{f_i} = \frac{Q_i}{\sqrt{\pi} \cdot L \cdot k_i} \quad \text{(Eq 19)}$$

where Q_i is the rate of heat supplied to body *i.* Coupled with the moving body relationship of Eq 8, a frictional heating assessment can be made via the method discussed in the section "Circular Contact Analysis with One Body in Motion" in this article.

Circular Contact Analysis with One Body in Motion. Figure 2 illustrates a convenient model for flash temperature estimation (Ref 7), where a protuberance on body 1 forms a circular contact area of radius *a* with the flat surface of body 2. While this model is useful in representing two general surfaces forming an apparent area of contact, it is typically associated with the real area of contact formed by a pair of spherical asperities. This does not involve any loss of generality because the static contact of two rough surfaces is, to within a good degree of approximation, equivalent to the contact of a smooth surface and a rough surface with a composite roughness (Ref 9).

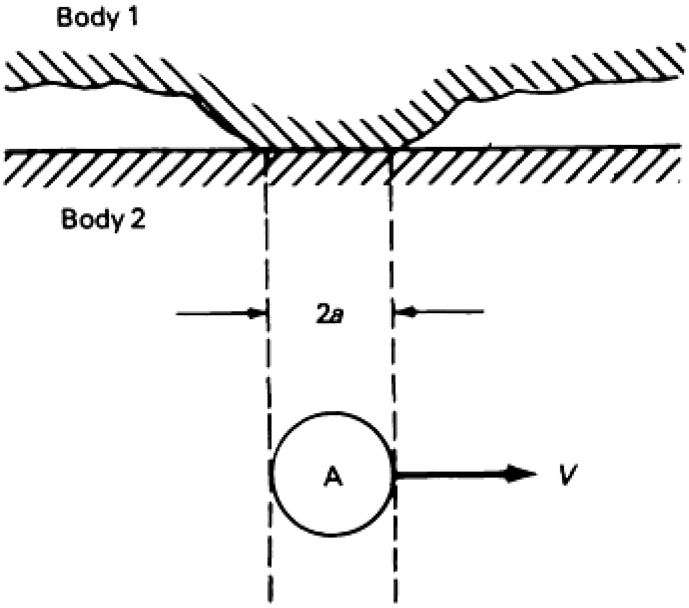

Fig. 2 Schematic showing key parameters required to estimate flash temperature using a circular contact model with a single contact area. Body 1 is stationary, while body 2 moves relative to the contact area. See text for discussion. Source: Ref 7

Body 1 is assumed to be stationary, whereas body 2 moves relative to the heat source or contact area with velocity V_2. Considering a uniformly distributed heat flux, $q = q_{av}$, over the contact width $2a$, Eq 8 can be used to establish the maximum flash temperature of the moving surface. By using a thermal-electrical resistance analogy, Holm (Ref 10) determined that the maximum flash temperature (in °C) of the stationary surface is:

$$T_{f_1} = \frac{Q_1}{\pi \cdot a \cdot k_1} \quad \textbf{(Eq 20)}$$

where Q_1 represents the rate of heat supplied to the stationary body of thermal conductivity k_1.

By equating the maximum flash temperatures of the respective surfaces in contact through Eq 8 and Eq 20, and assuming equivalent bulk temperatures with a time of contact t, equal to $2a/V_2$, the fraction of the total heat entering the stationary body 1 is:

$$\gamma_1 = \frac{k_1}{k_1 + 0.627\, k_2 (V_2 \cdot a/D_2)^{1/2}} \quad \textbf{(Eq 21a)}$$

Hence, from Eq 20, the maximum flash temperature(in °C) for use in Eq 11 is:

$$T_f = \gamma_1 \cdot \mu \cdot \frac{W \cdot V_2}{\pi \cdot a \cdot k_1} \quad \textbf{(Eq 21b)}$$

where W is the normal contact load (in N), k_i is the thermal conductivity of body i (in W/m · °C), D_2 is the thermal diffusivity of body 2 (in m^2/s), and V_2 is the velocity of surface 2 (in m/s).

Should the components have different bulk temperatures, T_{b_1} and T_{b_2}, the maximum contact temperature, T_c (in °C), can be established using Eq 16, 21a, and 21b, provided:

$$T_b = T_{b_1} + (T_{b_2} - T_{b_1}) \cdot (s + 1)^{-1} \quad \textbf{(Eq 22a)}$$

where:

$$s = 1.60 \cdot (V_2 \cdot a/D_2)^{-1/2} \cdot k_1/k_2 \quad \textbf{(Eq 22b)}$$

Although this situation utilizes Eq 21a for γ_1, the portion of heat withdrawn by surface 1 is adjusted as follows:

$$\gamma_1 = \frac{s}{s+1} + \left(\frac{1}{s+1}\right)\left(T_{b_2} - T_{b_1}\right) \cdot \frac{\pi \cdot a \cdot k_1}{\mu W V_2} \quad \textbf{(Eq 23)}$$

The analyst is reminded that should both surfaces be moving (Pe $\geq$2), the theory for the moving surface is applied to both bodies as described in the section "Line Contact Analysis with Two Bodies in Motion" in this article.

Average Flash Temperature Estimation via Heat Partitioning. Upon frictional heating, the average surface temperature over a given real area of contact, $\overline{T}_c$ (in °C) can be expressed as:

$$\overline{T}_c = \overline{T}_{f_i} + T_{b_i} \quad \textbf{(Eq 24)}$$

where $\overline{T}_{f_i}$ reflects the average surface temperature increase of body i from its bulk temperature, T_{b_i}. For a stationary body (case 1), subjected to a uniform circular heat source of radius a, Holm (Ref 10) reports that the average flash temperature (in °C) is:

$$\overline{T}_{f_1} = \frac{Q_1}{4\, a \cdot k_1} \qquad \textbf{(Eq 25)}$$

where Q_1 represents the rate of heat supplied to body 1 of thermal conductivity k_1. For a component (case 2), moving with velocity V_2 past the uniform circular heat source, the average exposure time will be $(a \cdot \pi)/(4 \cdot V_2)$ (Ref 11). Applying this parameter to Eq 8, the average flash temperature (in °C) is:

$$\overline{T}_{f_2} = \frac{Q_2}{\pi a k_2} \sqrt{\frac{D_2}{V_2 \cdot a}} \qquad \textbf{(Eq 26)}$$

where Q_2 represents the rate of heat supplied to body 2 of thermal conductivity k_2 and diffusivity D_2.

In the model of Fig. 2, surface 1 is assumed to be stationary. By assuming equivalent bulk temperatures, the average flash temperatures of the respective surfaces in circular contact may be equated. Through Eq 25 and 26, the fraction of the total heat entering the body 1 will be:

$$\gamma_1 = \frac{k_1}{k_1 + 0.785\, k_2 \,(V_2 \cdot a/D_2)^{1/2}} \qquad \textbf{(Eq 27a)}$$

Hence, from Eq 25, the average flash temperature for use in Eq 24 is:

$$\overline{T}_{f_{1,2}} = \gamma_1 \cdot \mu \cdot \frac{WV_2}{4a \cdot k_1} \qquad \textbf{(Eq 27b)}$$

Average Flash Temperature Estimation via Contact Size. Archard (Ref 12) considered special cases where the contact size is determined by either elastic or plastic deformation utilizing the model of Fig. 2. Surface 1 is assumed to be stationary, with both bodies composed of thesame material. If the deformation is plastic, the contact radius, a (in meters), is:

$$a = \left[\frac{W}{\pi \cdot p_M}\right]^{1/2} \qquad \textbf{(Eq 28a)}$$

where p_M is the flow pressure or hardness of the material (in N/m^2) and is about three times the yield strength of the material in uniaxial compression (Ref 13). If the deformation is elastic:

$$a = 0.91\left[\frac{W \cdot R}{E_v}\right]^{1/3} \qquad \textbf{(Eq 28b)}$$

where R is the undeformed radius of curvature of body 1 (in meters); and $E_v = E/(1 - v^2)$, where E_v is in N/m^2, and E is Young's modulus and v is Poisson's ratio.

Assuming both bodies are of the same material and bulk temperature, Archard suggests that at very slow speeds (Pe < 0.2), the total rate of heat flow, Q, is divided equally between both bodies; thus, $Q_1 = Q_2 = (\frac{1}{2})Q$. At very high speeds (Pe > 200), practically all the heat is supplied to the moving body 2; thus $Q_2 = Q$. Therefore, at high and low speeds, the following relationships result for an average flash temperature, $\overline{T}_f$ (in °C), given Eq 25, 26, 28a, and 28b:

- Plastic deformation, low speed (Pe < 0.2):

$$\overline{T}_f = \mu \frac{\sqrt{\pi p_M}}{8k} W^{1/2} \cdot V_2 \qquad \textbf{(Eq 29a)}$$

- Plastic deformation, high speed (Pe > 200):

$$\overline{T}_f = 0.31 \mu \frac{(\pi p_M)^{3/4}}{(k\rho c)^{1/2}} W^{1/4} \cdot V_2^{1/2} \qquad \textbf{(Eq 29b)}$$

- Elastic deformation, low speed (Pe < 0.2):

$$\overline{T}_f = 0.13\mu \left(\frac{1}{k}\right)\left(\frac{E_v}{R}\right)^{1/3} \cdot W^{2/3} \cdot V_2 \qquad \textbf{(Eq 29c)}$$

- Elastic deformation, high speed (Pe > 200):

$$\overline{T}_f = 0.36\mu \left(\frac{1}{\sqrt{k\rho c}}\right)\left(\frac{E_v}{R}\right)^{1/2} \cdot W^{1/2} \cdot V_2^{1/2} \qquad \textbf{(Eq 29d)}$$

-

By equating the stationary and moving flash temperature relationships of Table 1 for a given contact geometry, transition Péclet numbers of 2.5 and 4.0 result. This suggests that, for ease of analysis, a body of Pe < 2 may be considered "low speed" or fixed. For values in the range of 2 $\leq$Pe $\leq$200, a representative value for $\overline{T}_f$ may be obtained by taking an average of the low-speed and high-speed flash temperatures calculated using the appropriate deformation condition in Eq 29a, 29b, 29c, and 29d.

Correlation of Experimental Data with Calculated Values

Griffioen, Bair, and Winer (Ref 14) have measured surface temperatures using an infrared scanning camera. In operating from rolling to sliding, with loads resulting in Hertzian contact pressures of 2.0 GPa (290 ksi), data have been obtained under starved and lubricated conditions.

Temperature fluctuations as high as 2000 °C (3600 °F) were observed in an unlubricated contact between a silicon nitride pin and a sapphire disk that was subjected to a load of 8.9 N (0.91 kgf) with a sliding speed of 1.5 m/s (4.9 ft/s). Temperatures of this magnitude suggest that the local material undergoes extensive property changes, thus complicating any frictional heating calculations employed.

Measurements confirmed the power dependence of the flash temperature on normal contact loads as noted in the results of the section "Average Flash Temperature Estimation via Contact Size" in this article (that is, for low speeds [Pe < 0.2], the temperature rise was proportional to $W^{2/3}$ and at high speeds [Pe > 10], the temperature rise was proportional to $W^{1/2}$).

The power of dependence on sliding speed was found to be less than that in theory (0.7) versus 1.0 for Pe < 0.2 and 0.21 versus 0.5 for Pe > 10). This may have been the result of one or more of the following factors:

- In the experiment, there was lubricant surrounding the contact zone, which may cause more cooling than accounted for in theory
- Presence of a lubricant layer may cause an unaccounted-for temperature difference between the surface and lubricant in which the energy dissipation occurs

- Coefficient of friction decreased with sliding velocity whereas theory assumes it to be constant

The measured maximum temperature of the moving surfaces in the sliding-lubricated case agreed well with the calculated values. When both surfaces were moving, the measured maximum temperature correlated well with the calculated average temperature.

Factors Limiting the Accuracy of Calculations

Attempts to improve the accuracy of calculations associated with frictional heating have occurred utilizing a variety of analytical methods, with suppositions built upon the basic concepts of the section "Idealized Models of Sliding Contact" in this article. From the fundamental contributions of Jaeger (Ref 15), to the unique approximations of Ling (Ref 16, 17), Francis (Ref 18), Lim and Ashby (Ref 19), and others, sliding contact analyses have progressed, although they are limited by the complexities of the equations that result. Consequently, the generalizations that follow can be of significance when addressing alternative designs.

Effect of Transient Temperature. Using the model of Fig. 2, the contact of a stationary circular asperity (surface 1) of radius *a* creates a heat source with the moving surface of a relatively larger body (surface 2). Because the primary interest is the temperature in the immediate vicinity of the contact, the rest of the surface is assumed to be insulated.

From the governing differential equations (Ref 1), Fig. 3 was developed to show that the surface temperature behaves as a function of time, *t*. Presented in nondimensional terms of temperature (*kT/qa*), position (*r/a*), and time ($F_0^{1/2}$), the figure confirms that a steep temperature rise near the center of the source is established rapidly (for example, $F_0^{1/2}$ ~1). (Note that F_0, the Fourier modulus, is equal to $D_i \cdot t/a^2$ as discussed in the section "Heat Source Time" in this article.) At $F_0^{1/2}$ ~5, the center temperature is ~95% of the steady-state temperature, whereas the temperature at a distance *r/a* = 5 is only 50% of its steady-state value. Steady-state in the vicinity of the source is reached at $F_0^{1/2}$ ~10. Similar results were reported by Barber (Ref 20) and Greenwood (Ref 21) using asymptotic analysis.

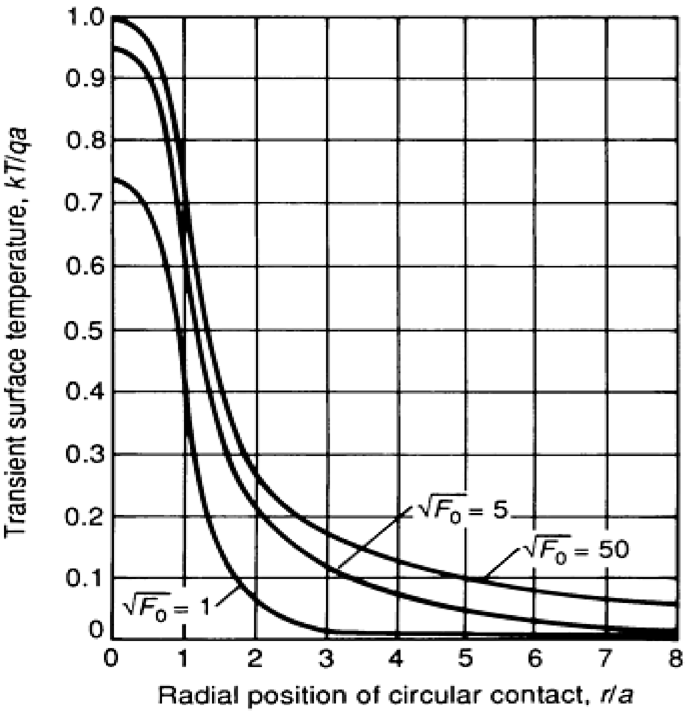

Fig. 3 Plot of surface temperature versus radial position of circular contact as a function of time. Time is

expressed in terms of Fourier modulus, F_0. Source: Ref 1

Recalling that the circular contact analysis discussed in the section "Circular Contact Analysis with One Body in Motion" in this article was based on a steady-state heating duration, results could differ if the mean effective time for the moving surface is equal to the time (in seconds) the heat source exists. That is:

$$t = (F_0 \cdot a^2)/D_2 \qquad \textbf{(Eq 30)}$$

Substituting this heat source time into Eq 8, and equating the mean temperatures of the moving and fixed surfaces, the heat partition factor γ_1, associated with the total frictional heat input to the fixed surface becomes a function of F_0. For $F_0 \sim 0$ (Ref 11):

$$\gamma_1 = \frac{k_1}{k_1 + k_2\sqrt{D_1/D_2}} \qquad \textbf{(Eq 31)}$$

Effect of Surface Layer. A surface film with different thermal and mechanical properties than those of the substrate will affect the frictional heating behavior at a sliding contact. It will not only affect the coefficient of friction, but may also affect the dissipation of thermal energy. By modeling a rotating layered cylinder, Gecim and Winer (Ref 22) closely approximated the thermal condition of the semi-infinite body (surface 2) of Fig. 2. Subjected to a "small" heat source, while incorporating a film depth δ, the body is assumed to be moving at a rate sufficient for Pe > 100.

Figure 4 was developed from the governing differential equations (Ref 22) to show how the surface temperature may behave as a function of the thermal contact coefficients of the substrate (b_s) and film (b_f). Presented in nondimensional form, the plot gives an indication of the surface temperature rise with the film, T_{f_w} to that without the film, $T_{f_{wo}}$. (Note that $T_{f_{wo}}$ is computed utilizing the models discussed in the section "Idealized Models of Sliding Contact" of this article.) The horizontal axis is associated with the product of the dimensionless film thickness and the square root of the Péclet number. Expressed as $(\delta/R_0) \cdot [(VR_0)/(2 \cdot D_f)]^{1/2}$, R_0 represents the surface radius (with film), V the surface velocity, and D_f the thermal diffusivity of the film.

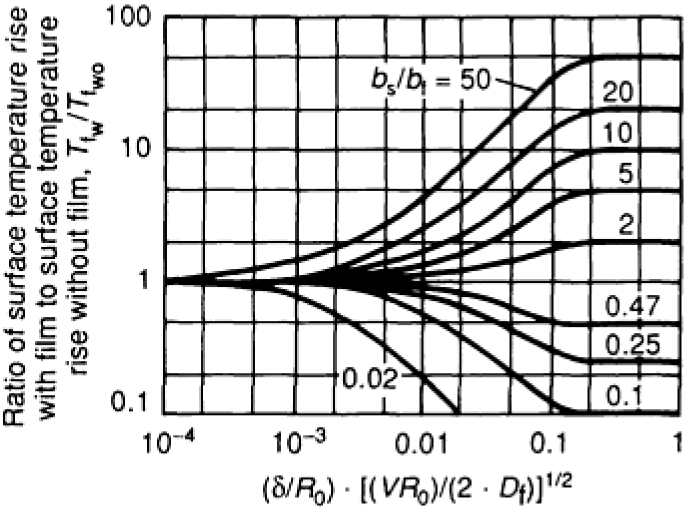

Fig. 4 Surface layer temperature graph showing effect of substrate (b_s) and film (b_f) thermal contact coefficients on surface temperature. Angular contact width, Φ_0, is 0.05 rad. Source: Ref 22

For an angular contact width Φ_0 = 0.05 rad (which is typical of a cam, gear, or rolling-element bearing contact), results suggest that for the thin-film/low-speed condition, thermal penetration goes well below the film into the substrate; thus, film thermal resistance becomes insignificant, and the temperature ratio approaches unity. For the thick-film/high-speed

case, the temperature rise is confined within the film; hence, the flash temperature is inversely proportional to the thermal contact coefficient of the film alone. As a result, the temperature ratio approaches the ratio of the thermal contact coefficients, b_s/b_f. Recall from Eq 13 that $b = (\rho \cdot c \cdot k)^{1/2}$, where ρ is the density; c is the specific heat; and k is the thermal conductivity of the appropriate material.

Limitations of Calculations. As suggested in this work and by the reviews of Blok (Ref 23) in 1970 and Kuhlmann-Wilsdorf (Ref 24) in 1987, frictional heating calculations are quite imperfect because they are typically not well defined and vary greatly in time and place. This occurs no doubt because of the lack of knowledge about many of the underlying assumptions.

A number of factors affect the presence of thermal energy from frictional resistance. Such parameters as velocity and normal load are measurable. However, material properties are constantly changing, particularly when exposed to high temperatures and heavy loads. Changes in the coefficient of friction, which enters the flash temperature computation to the first power, must be considered. Difficulties also arise when attempting to quantify the real area of contact, given its relationship to the sharing of load among contact spots that vary in size, number, and hardness.

Laboratory Testing Methods for Solid Friction

K.G. Budinski, Eastman Kodak Company

Introduction

THE MEASUREMENT OF FRICTION FORCE and the calculation of the coefficient of friction are often warranted for many tribosystems. Such testing is particularly critical for brakes, clutches, and similar power- and motion-control mechanisms where the friction force must be known and controlled. If the friction characteristics of a system are somehow changed, the results can be disastrous. For example, continuous braking of an automobile on a steep incline can lead to "glazing" of the brake pad material: the surface overheats and chars, forming a material with friction characteristics different from those of the bulk, and the resulting friction coefficient may be much lower than the design coefficient of friction. Consequently, the brakes may not work at the extremes of operating conditions. Thus, manufacturers of brake and clutch facings must know the friction characteristics of their material against the counterfaces it will meet under all operating conditions. This holds true for manufacturers of many different products that experience friction, including flooring and tires.

In machine design, friction characteristics must be known for friction drives, for sizing motors, for determining work forces, and for designing any part of a machine where changes in forces between sliding members could affect operation. Friction is not a measure of wear or the tendency to wear; therefore, it does not determine service life. Frictional heating sometimes causes a machine part to fail, but this usually occurs when circumstances create abnormal friction effects. To emphasize the importance of friction in machine design, it is estimated that one-third to one-half of the world's energy production is wasted through friction (Ref 1).

This article will describe the numerous techniques used to measure friction. The objective is to provide sufficient information so that a person who has never conducted a friction test can do so. Following a brief description of the historical development of friction testing, the tests and equipment currently available for friction testing and the precautions that must be taken to ensure valid test results are discussed. The final sections of this article describe how to report data and how these data may be entered into a database.

Historical Development of Friction Testing Techniques

Research into the history of tribology suggests that Greek philosophers were familiar with the concept of friction. However, Leonardo da Vinci originated the basic precepts of friction, the basic laws, and the tests used to measure and

study friction (Ref 2). Da Vinci's sketches of friction testing apparatus (Fig. 1) were made circa 1495. He used these devices to show that friction force is dependent on the force pressing two bodies together and that it is independent of the apparent area of contact between the two bodies. Da Vinci essentially introduced the concept of a friction coefficient. He found that the ratio of the friction force (*F*) to the pressing force (*N*) was about $\frac{1}{4}$; consequently, he suggested that $F = \frac{1}{4} N$. The value of $\frac{1}{4}$ is fairly accurate for the materials that da Vinci tested (wood, stone, hemp rope, bronze, and so forth) under conditions of low speed and low normal forces.

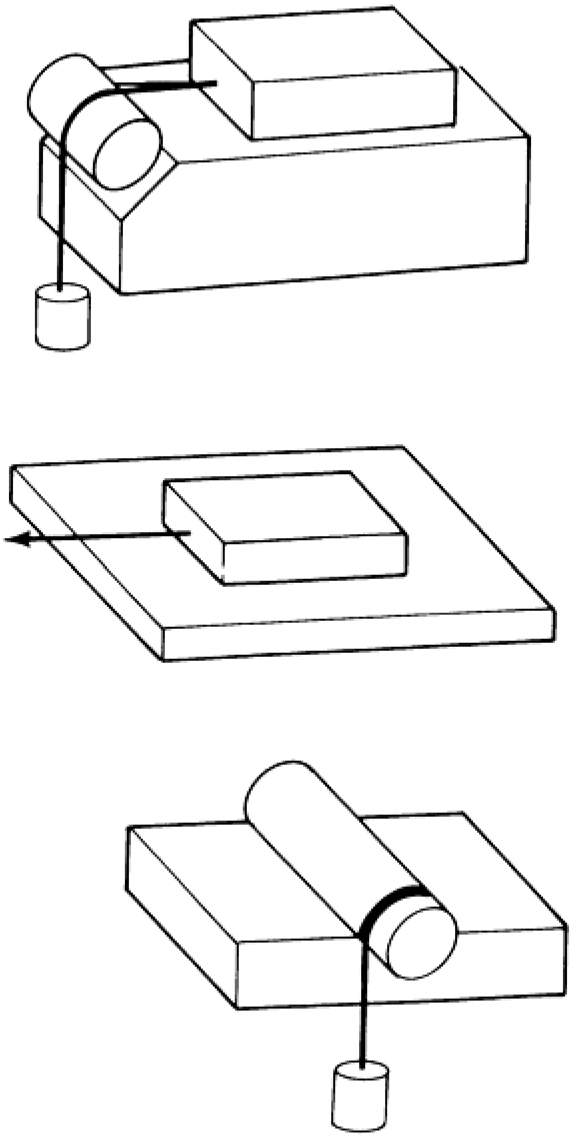

Fig. 1 Schematics of friction-measuring devices based on early work of Leonardo da Vinci

In about 1750, the mathematician Euler developed the concept of an actual friction coefficient: $\mu = F/N$. He also introduced the concept of static friction, which states that when a block is on an inclined plane, the tangent of the angle at which motion starts is the static coefficient of friction:

$$\mu_s = \tan \theta \qquad \textbf{(Eq 1)}$$

From this point on, two types of friction (static and kinetic) and two friction coefficients (the static μ_s and the kinetic μ_k) had to be considered. The static coefficient was measured in the inclined plane test, and the Kinetic was measured using

one of da Vinci's devices. Essentially the same situation exists today, except that electronic force-measuring systems may allow determination of static and kinetic friction forces on the same device in the same test.

Research in the early 19th century on the effect of lubricants on friction suggested that friction in lubricated systems depends more on the nature of the lubricant than on the nature of the materials that are in sliding contact (Ref 2). Later in that century, the Petrov equation was developed, which related the friction coefficient of a lubricated journal-bearing couple to the viscosity of the lubricant and the operational conditions of the bearing (diameter, velocity, length, and normal force). As shown in Fig. 2, this equation states that:

$$\mu = \left(\frac{4\pi r^2 l}{c}\right)\left(\frac{\eta N}{P}\right) \quad \textbf{(Eq 2)}$$

where *r* is the shaft radius, *l* is the bushing length, η is the viscosity of the lubricating fluid, *N* is the shaft velocity, *c* is the film thickness, and *P* is the normal force.

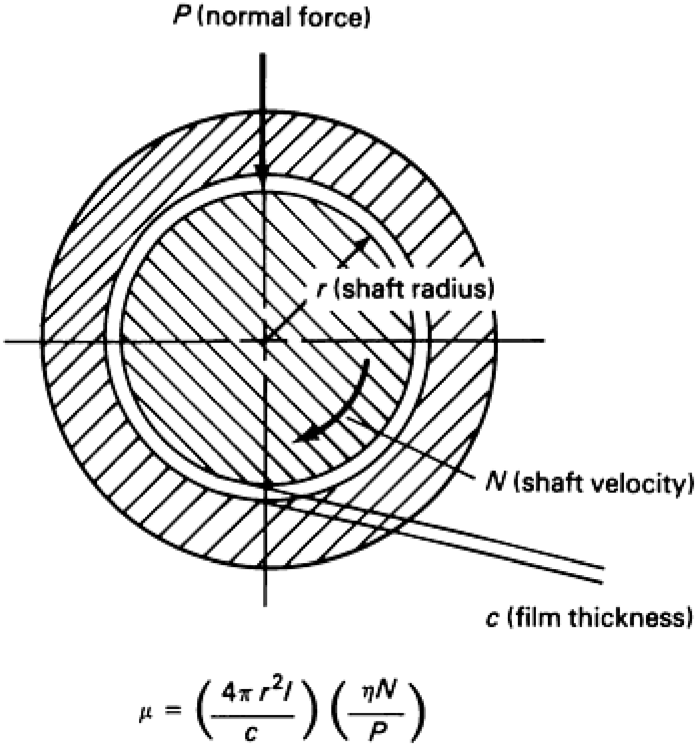

Fig. 2 Petrov equation for the coefficient of friction of a lubricated tribosystem. See text for details.

A significant amount of reseach on rolling friction was also conducted during the 19th century. It was learned that the friction of tires on surfaces is a function of the surface hardness, but a separate test for rolling friction did not emerge. By the start of the 20th century, the friction tests shown schematically in Fig. 1 were the most commonly used, and the situation remains nearly the same today.

Friction Models

There have been many models proposed for use in calculating coefficients of friction from system properties (Ref 3, 4, 5, 6, 7, 8, 9, 10, 11, 12); however, with the exception of the Petrov equation, most are not widely accepted. The Petrov equation suggests that friction in a lubricated system is a function of the system conditions and the nature of the lubricant. Using this model, which appears to work for the case of plain bearings, lubricant properties rather than friction are measured. The most accepted model for determining the coefficient of friction between solid surfaces is probably that proposed by Bowden and Tabor (Ref 5):

$$\mu_k = \frac{S}{H} \quad \textbf{(Eq 3)}$$

where μ_k is the kinetic friction coefficient, *S* is the shear strength of asperity junctions, and *H* is the bulk hardness of the softer material in the couple.

The Bowden-Tabor model is an extension of the asperity contact theory, which originated around 1930. Proponents of this theory believe that the tribological interaction between conforming solids is controlled by what happens at the point(s) where asperities on one surface make contact with asperities on the other surface. The term "asperity" usually refers to the microtopological features of a surface. Surface roughness is the most common surface property studied in conjunction with the asperity contact theory. The problem with this theory is that the equation assumes that the strength of the surface asperities is known. This information is not available and is not easy to determine experimentally. Most users of this model employ the bulk properties of the material (bulk shear strength). However, sliding conditions can obviously affect the strength of surface asperities. For example, at any sliding interface there is heating due to friction forces. This heat could affect the properties of asperities, and lower-strength materials--especially plastics--will obviously be affected (Ref 9, 11, 12). Also, it is well known that strain rate affects mechanical properties, and surface asperities may behave differently and different sliding speeds (coinciding with different strain rates).

The deformation theory of friction proposed by Bikerman (Ref 4) suggests that friction force is a function of path length and the work of deformation of surface asperities during relative motion:

$$f = \mathrm{k}wd \quad \textbf{(Eq 4)}$$

where k is a constant that depends on the mechanical properties of the two solids, *w* is the width of disturbed material, and *d* is the depth of disturbed material. This model seems intuitively correct. It simply states that the friction force is the force required to deform materials on the surface of a sliding member. This is essentially the same as the Bowden-Tabor model, but, in this case, everything is unknown. A potential user of the model knows neither the area of deformation nor the material constant.

Many other models have been proposed for calculating the coefficient of friction, but they invariably involve the use of information that is not readily available in handbooks or databases. The alternative is actual measurement of friction coefficients.

Friction Testing Techniques

Every high school physics class usually performs laboratory tests on an inclined plane to demonstrate the concept of sliding friction. The inclined plane, as demonstrated by da Vinci, remains one of the more commonly accepted techniques for measuring friction. Other techniques used to measure coefficients of friction are also modifications of concepts developed by da Vinci. Popular methods for measuring friction forces are shown in Fig. 3.

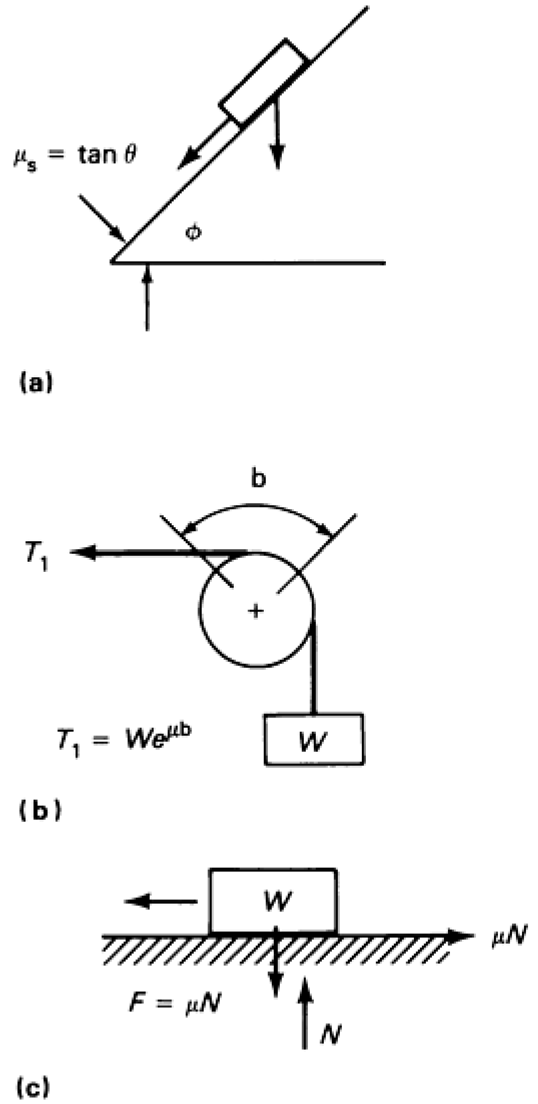

Fig. 3 Schematics of current friction-measuring concepts

In the inclined plane test (Fig. 3a), one member of the couple of interest is placed on the plane and the plane is tilted until the object starts to move. The tangent of this critical angle is the static coefficient of friction, μ= tan θ.

The problem with this technique is that it does not simulate many real-life tribosystems. Machine designers do not design systems that involve only inclined planes. Friction is a system parameter. A single material does not have a coefficient of friction; even a material pair does not necessarily have a coefficient of friction. Only when a material is mated with another material (or more than one material) and some type of sliding motion is present in the system can the coefficient of friction be measured. To be valid, a friction test should simulate the system of interest.

Figure 3(b) is classified as a "capstan test" because its principle is employed in capstans used to hold lines under tension. This friction test has utility when the system under study involves a belt, cable, rope, or web sliding over a roll or cylindrical surface. It simulates slip of plastic films on rolls during manufacturing operations, slip of belts on drive sheaves, or other practical engineering systems involving this type of tribosystem. It can be used to determine both static friction and kinetic friction, and transducers can be used to measure T_1 and W. In highspeed web handling, common practice is to place load-sensing idler rolls on either side of a system of interest (Ref 13). These rolls come in many sizes and often detect tension through strain gages mounted at the base of a cantilevered beam that supports the roll.

When using this type of system, it is important that the slip over the test roll simulate the service conditions. If a web is being transferred at 10 m/s (33 ft/s), the slip of the web on an idler (nondriven) roll will not be 10 m/s (33 ft/s), but some

fraction of this (usually less than 10%). The actual slip at a roll can be measured by instruments on the web (footage meter) and on the roll (tachometer). The difference between the two measurements yields the slip, and friction tests should be performed at this slip speed. It is also important to ensure that the surface textures on the cylinder (roll) and web duplicate the conditions in the system of interest.

The system illustrated in Fig. 3(c) can be any system where motion of one member is produced by a load cell. Pulling a block on a flat surface with a load sensor yields the friction force *F* in the basic friction equation, $F = \mu N$.

In wear studies, it is common practice to restrain a member with a load cell; the friction coefficient is calculated from this measured forced (Fig. 4). This is probably the most common method of measuring friction force. Although there are countless variations of this test, most devices use a force sensor that is essential a calibrated spring. This spring has a spring constant that determines the sensitivity of the system; there is probably some damping associated with the system. A free-body diagram of a sled friction tester is shown in Fig. 5.

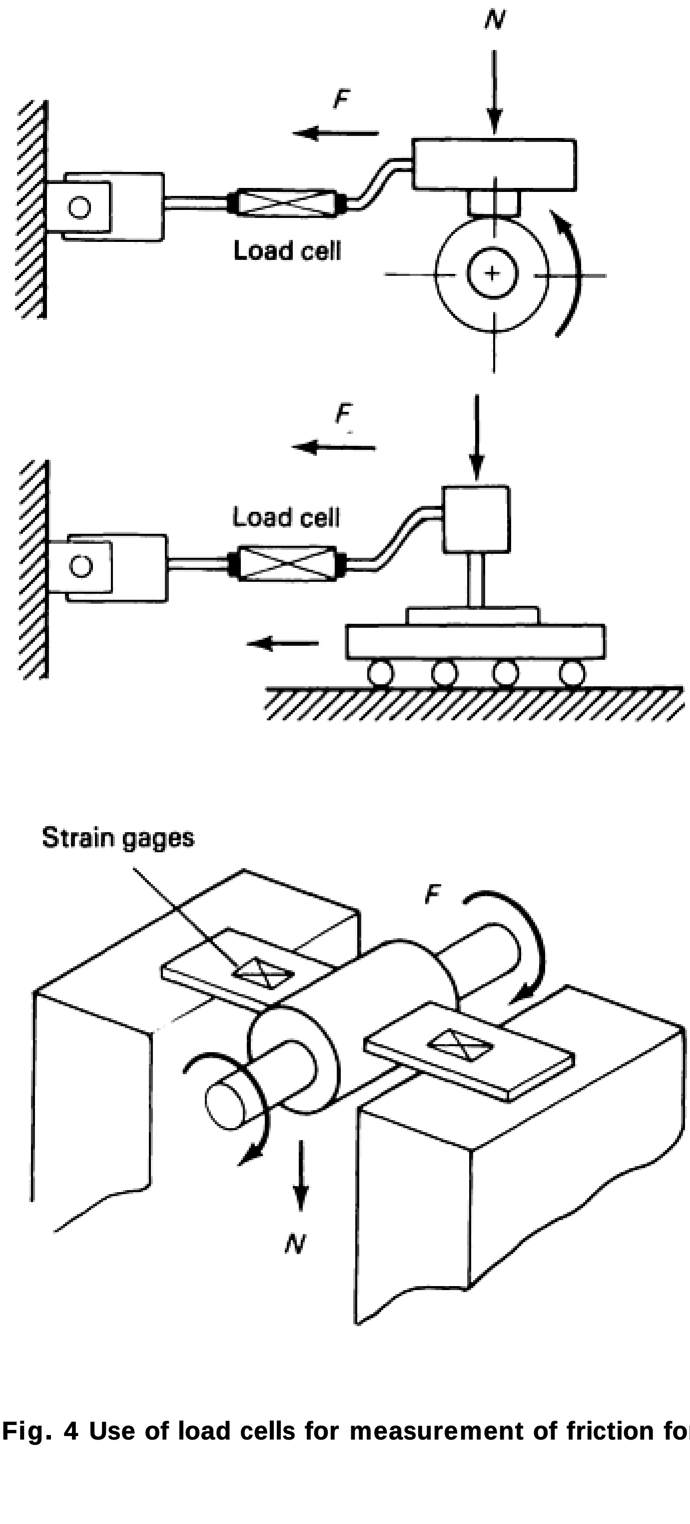

Fig. 4 Use of load cells for measurement of friction force

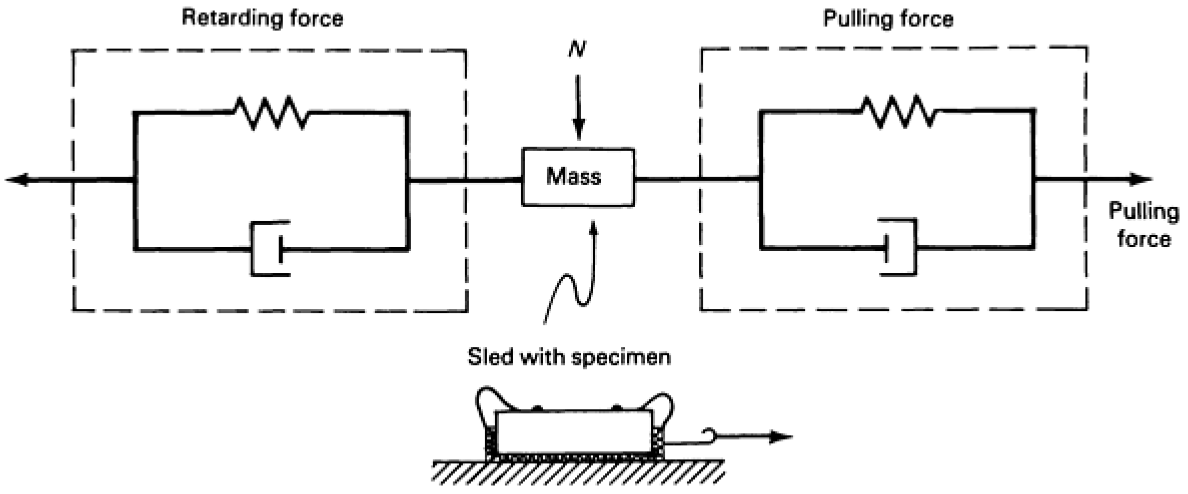

Fig. 5 Free-Body diagram of a sled friction tester

Certain system parameters can affect the results of a friction study. All that is measured is the friction force, *F,* by means of an electrical signal or a mechanical device. Both types of sensors have elastic and damping characteristics that can affect the measurement. The major concern is static friction. If the pulling system shown in Fig. 5 were replaced by a steel rod, which would have much smaller time-dependent strain behavior, the system model could be simplified as shown in Fig. 6. The measured force would still involve the elastic properties of the steel rod (spring *a*), but any time-dependent component of the friction force would come from the system under study, that is, the elasticity, *a,* and viscous behavior, *b,* of the surface contacts.

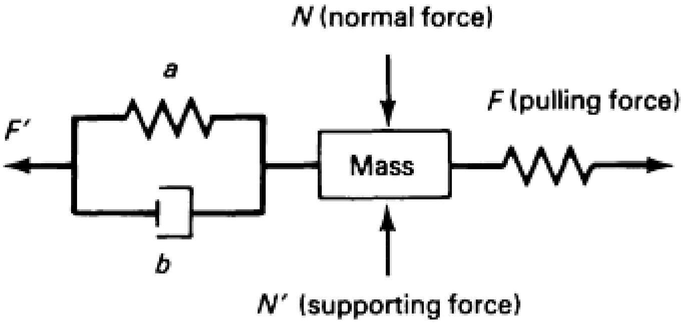

Fig. 6 Free-body diagram of a sled friction tester with a nonelastic driver

Friction Nomenclature

Terms such as "static friction," "kinetic coefficient of friction," "stick-slip behavior," and "lubricated friction," commonly used in tribology, are discussed below. Additional friction terms are defined in the "Glossary of Terms" in this Volume.

Static Friction. This term was originally defined by Amontons in 1750. In current practice, the coefficient of friction is defined in ASTM G 40 (Ref 14) as the "dimensionless ratio of the friction force between two bodies to the normal force pressing these bodies together." The static coefficient of friction is defined as the "friction coefficient corresponding to the maximum force that must be overcome to initiate macroscopic motion between two bodies." Amontons stated that in an inclined sliding-plane system, this number is equal to tan θ, the angle of inclination of the plane. This is still the case. When friction force is continuously monitored during a sliding test, a force-versus-time curve similar to the one shown in Fig. 7 is produced.

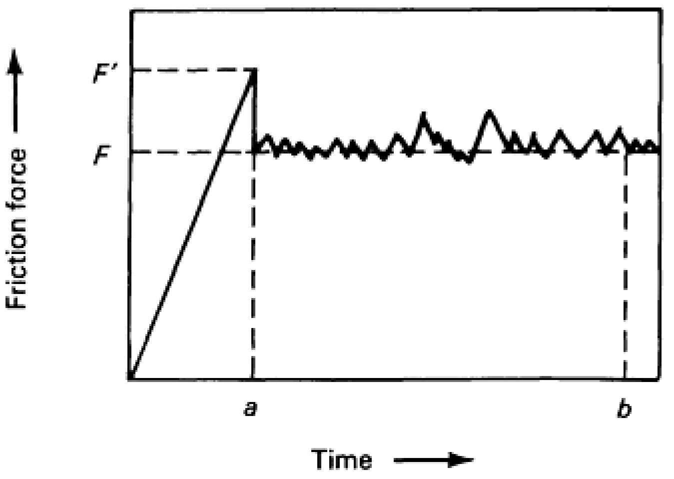

Fig. 7 Friction force recordings that are constant with time

If the force sensor detects an internal spike at the start of the test, such as *F*' in Fig. 7, this force is used to calculate the static coefficient of friction. The force *F* is used to calculate the kinetic coefficient of friction. An important consideration in a friction test is wether the internal force spike (*F*' - *F*) is due to the sliding system or is the result of elastic or viscoelastic behavior in the force-measuring system. Researchers who study static friction purposely produce motion on the movable body with a highly elastic system; for example, in a sled test, the line that pulls the sled is made of nylon or a similar low-modulus (*E*) material. If the pulling line were made of steel, there would be a significant buildup of "line stretch" before motion started. If there is a buildup of spring deflection, as in the model in Fig. 6, there will be an inertia spike caused by the basic rule of physics (force = mass × acceleration, or $F = ma$) when motion starts. The force reading *F* will sense a component from a higher acceleration *a* than would be seen if there was no buildup of spring deflection (line stretch) before motion commenced. In other words, an initial spike in a friction test can arise from spring effect or sticking of the two surfaces, or it can arise from inertial effects from the system used to produce motion:

$$F_{S_{measured}} = F_{sticking} + F_{inertia} \quad \textbf{(Eq 5)}$$

The $F_{sticking}$ between surfaces can result from reactions between surfaces, from interlocking surface features, or from other more subtle phenomena such as van der Waals forces, cohesion of surface films, and even microscopic solid static junctions between surfaces.

Static friction can be real or can be a product of the measuring system. Recommended practice for dealing with static friction in testing is to make the test model the system under study. If an initial force spike is observe, there will probably be one in the service application. If a system under study involves elastic components, a high-elasticity force-measurement system should be used.

Kinetic Coefficient of Friction. Addressing the remainder of the force-versus-time curve, the question arises as to what value should be used in measuring kinetic friction. Taking the example in Fig. 7, there are force variations that are normal in almost any sliding couple. The curve may even increase or decrease with time, as shown in Fig. 8.

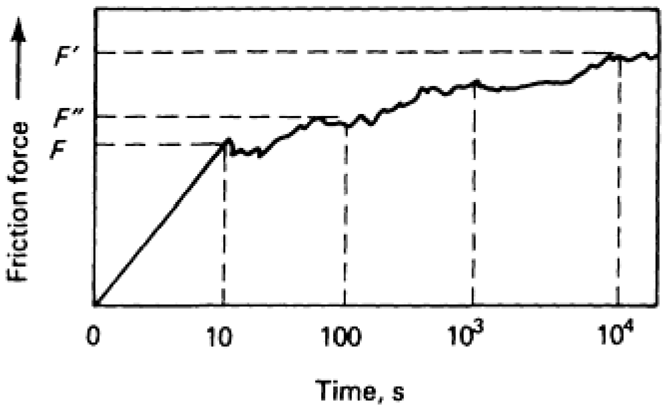

Fig. 8 Friction force recording that varies with time

ASTM G 40 (Ref 14) defines kinetic coefficient of friction as the "coefficient of friction under conditions of macroscopic relative motion between two bodies." This definition does not specify whether force *F* or *F*' or an alternate measurement shown in Fig. 8 should be used. This aspect of friction testing is left to the investigator, but it is recommended that the force number that typifies the system under study be used. If the goal of the study is determination of the friction coefficient of a part sliding down a track, and it takes 30 s for the part to do so, the force values should be averaged for that increment of time: (*F*" - *F*)/2 + *F*. If the study is concerned with friction during steady-state wear of a system after break-in and during normal running, it would be advisable to use the force readings after 10 h or even 100 h of sliding. Enough tests must be run to determine the steady-state force. If the system will wear in service, it may be desirable to measure the friction coefficient in a wear test. Wear debris between sliding members will undoubtedly affect the friction characteristics of the system.

In some standardized laboratory tests, it is customary to record the coefficient of friction after specified intervals of sliding. This provides a friction-versus-time profile and may be preferable to a fast test involving one stroke of a test device. Some investigators use computer acquisition of friction data, programming the computer to average kinetic friction over any time increment. Some test devices simply take the maximum force rendered in a test and use this as the force for static coefficient. This practice is not recommended, as the maximum force may be at the end of the test (see Fig. 8). Again, the system to use is the one that best simulates the actual system under study, but the investigator must always determine which force should be used for friction calculations.

Stick-Slip Behavior. At one time or another, everyone has encountered a squeaky door hinge that creaks when the door is opened slowly. This is likely a manifestation of stick-slip behavior. ASTM G 40 (Ref 14) defines stick-slip as "a relaxation oscillation usually associated with decrease in coefficient of friction as the relative velocity increases." In more descriptive terms, stick-slip is the jerky motion that sometimes results when one object is slid on another. If a mass is being pulled by a line, the mass will stick, then rapidly move, then restick, and so on. Under such conditions, a friction-versus-time recording may resemble that shown in Fig. 9.

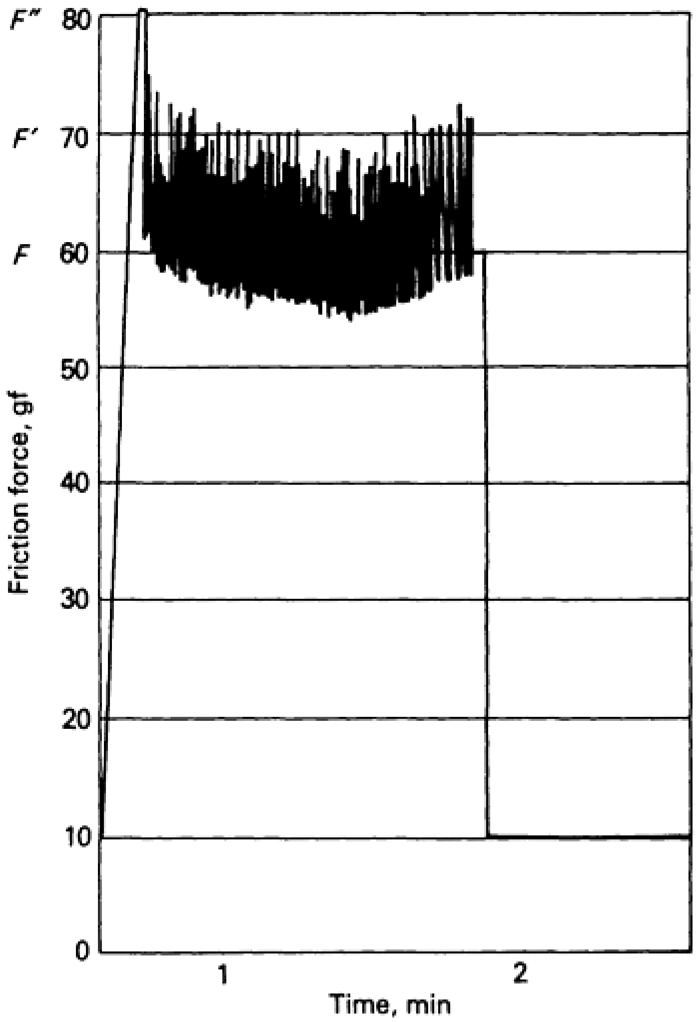

Fig. 9 Friction force recording for a system displaying stick-slip behavior

There may or may not be a friction force spike to suggest a static coefficient of friction. Stick-slip behavior in a sliding system is indicated by an obvious jerky motion, which can be recorded in a friction force versus time trace. Noise in sliding systems often results from stick-slip behavior.

One way of dealing with the coefficient of friction in a system that exhibits stick-slip behavior is to calculate the minimum and maximum coefficients by using *F* and *F*' in Fig. 9 and then noting when stick-slip occurs. In Fig. 9, *F*" could be used to calculate the static coefficient of friction. Some investigators simply ignore the numbers and state "stick-slip behavior," meaning that the kinetic coefficient of friction is not particularly meaningful for the system under study because the system produces erratic motion under the test conditions.

Sometimes stick-slip behavior results from the testing system. As discussed previously, a high-stiffness-movement system attached to the sliding member may eliminate this phenomenon. In general, if stick-slip occurs in a system under study, the test should include means of eliminating this type of behavior.

There is disagreement over the mechanism of stick-slip behavior. Some researchers believe that it occurs when the kinetic coefficient of friction is higher than the static coefficient of friction. Some say it occurs when the friction-versus-velocity plot has a negative slope (Ref 15). This is what friction recordings apparently indicate about the process, but this is not really the mechanism. Intuitively, the mechanism is probably the spring behavior of the system shown in the model in Fig. 5.

The contacts between two bodies exhibit elastic behavior, and there may be some viscoelastic behavior depending on the materials involved. In laboratory sled tests, it appears that stick-slip occurs when a sufficiently high spring force builds up

in the nylon pulling line. The specimen then moves rapidly to unload the spring (pulling line); it comes to rest when it reaches the spring deflection (line stretch), and the process begins again. What causes a material to do this is a function of the nature of the contacting materials, including adsorbed films, surface topography, the chemical nature of the surfaces, conformability, and contact stress.

Lubricated Friction. If sliding members are fully separated by a film of lubricant (oil, water, gas, and so forth), the friction coefficient of the system is essentially the friction coefficient of the fluid. When boundary lubrication exists, the surfaces are partially in contact, and the coefficient of friction of the system is a function of the combined properties of the fluid and surfaces. When dry-film (solid) lubricants are used, the friction coefficient of the system may be related to the properties of the dry-film lubricant slipping on itself or to those of an uncoated solid on the lubricant film. Lubrication with graphite, molybdenum disulfide, or fluorocarbons is an example of this (see the article "Solid Lubricants" in this Volume).

With fluid separation, the friction coefficients can be several orders of magnitude lower than for systems that involve solid contact. The Stribeck-Hersey curve shown in Fig. 10 allows calculation of the coefficient of friction from lubricant properties ($\eta N/P$), where η is the viscosity, N is the velocity, and P is the pressure (load). Empirical measurement of friction in film-separated systems is complicated by the need to maintain the fluid separation. With oils and greases, it usually involves testing at high velocities. If circumstances allow, the use of a friction coefficient calculated from the fluid parameters is infinitely easier.

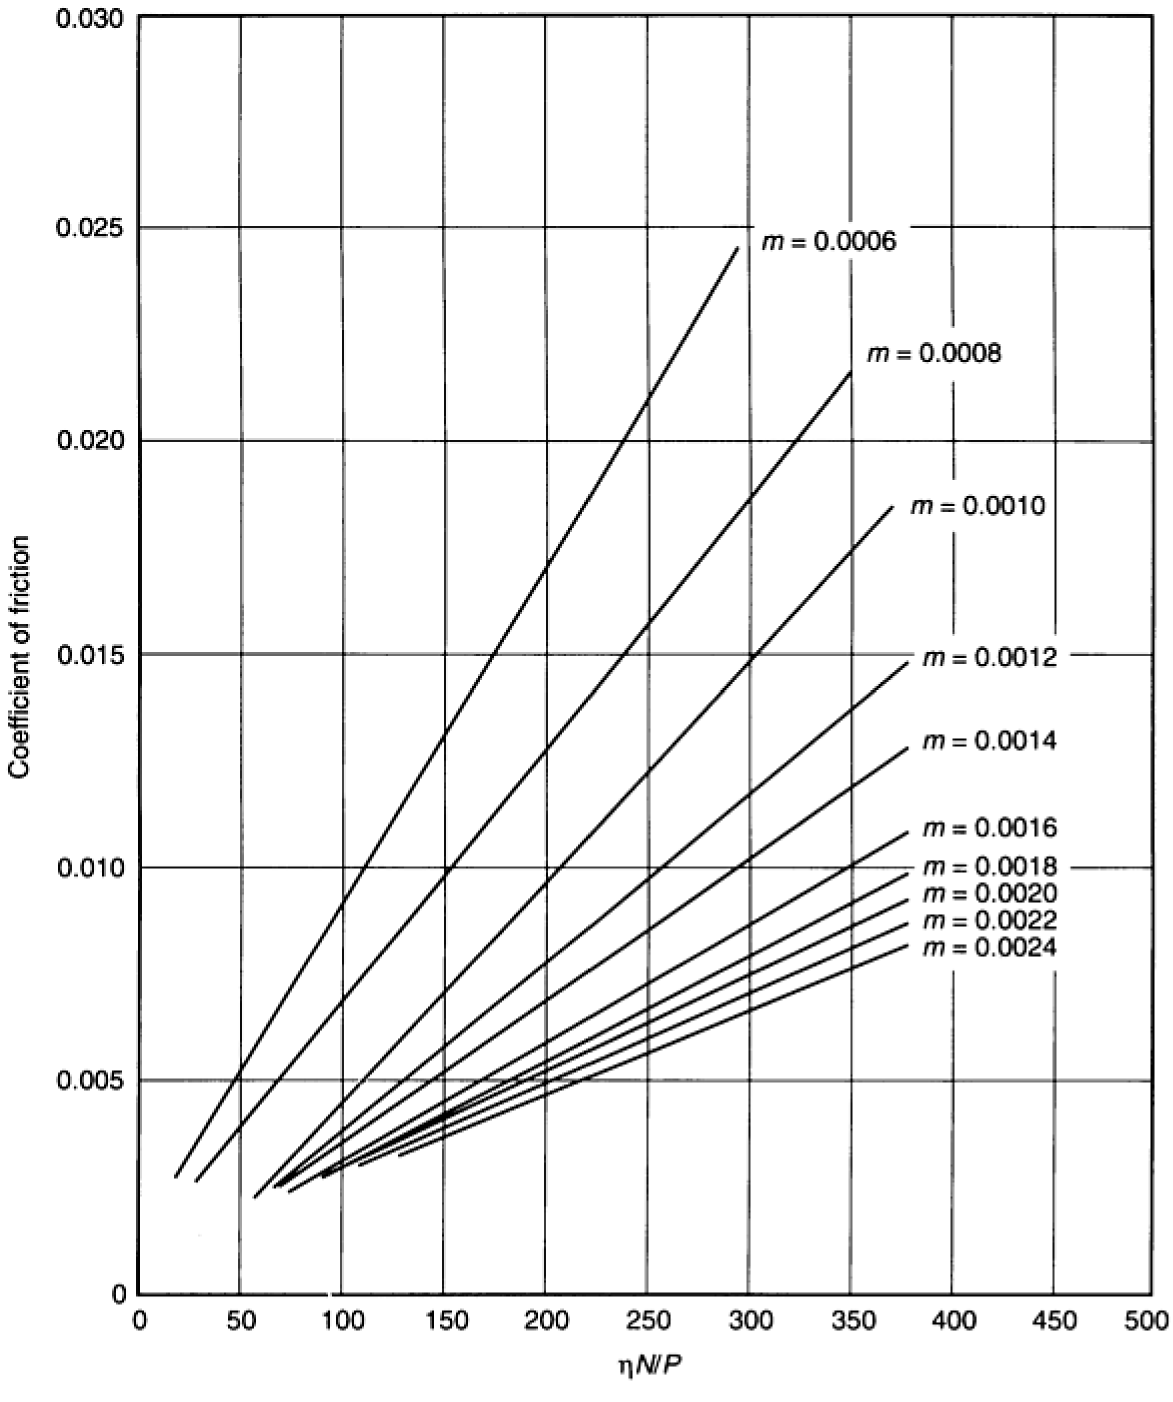

Fig. 10 Example of a Stribeck-Hersey curve for determining the friction coefficient from lubricant properties

Standard Friction Tests

A number of organizations have developed standard tests for measuring coefficient of friction. These tests vary greatly in type and purpose.

ASTM Standards and Specifications. Table 1 lists tests that have been standardized by ASTM. Some are directed toward a particular application or material, while others are for general evaluation of materials. The B-9 Committee standards deal with the types of composite friction materials used for clutches and brakes. The C-5 Committee standard is essentially a checklist of considerations for conducting coefficient of friction tests on carbon/graphite types of materials.

These considerations apply to most friction studies, and this standard is a suitable reference for any novice in the field of friction.

Table 1 Selected solid friction tests per ASTM standards

Note: Used with permission of the G-2 Committee on Wear and Erosion

Standard (committee)	Title	Material couple (measured parameters)	Test configuration
B 460 (B-9 on metal powders)	Dynamic Coefficient of Friction and Wear of Sintered Metal Friction Materials under Dry Conditions	Friction materials versus metal (μ_k versus temperature)	B 461 (B-9 on metal powders)	Frictional Characteristics of Sintered Metal Friction Materials Run in Lubricants	Friction materials versus metal (μ_k versus number of engagements) (μ_k versus velocity)	B 526 (B-9 metal powders)	Coefficient of Friction and Wear of Sintered Metal	Friction materials versus gray cast iron (μ_s and μ_k)	C 808 (C-5 on carbon/graphite)	Reporting Friction and Wear Test Results of Manufactured Carbon and Graphite Bearing and Seal Materials	Carbon versus other materials (μ_s and μ_k)	Any apparatus
D 1894 (D-20 on plastics)	Static and Kinetic Coefficients of Friction of Plastic Films and Sheeting	Plastic film versus stiff or other solids (μ_s and μ_k)	D 2047 (D-21 on polishes)	Static Coefficient of Friction of Polish Coated Floor Surfaces as Measured by the James Machine	Flooring materials versus shoe heels and soles (μ_s and μ_k)	D 2394 (D-7 on wood)	Simulated Service Testing of Wood and Wood-Base Finish Flooring	Wood and wood-base flooring versus sole leather (μ_s and μ_k)	D 2714 (D-2 on lubricants)	Calibration and Operation of Alpha Model LFW-1 Friction and Wear Testing Machine	Steel ring versus steel block (lubricated with standard oil) (μ_k)	
Standard (committee)	Title	Material couple (measured parameters)	Test configuration
D 3028 (D-20 on plastics)	Kinetic Coefficient of Friction of Plastic Solids and Sheeting	Plastic sheets or solids versus other solids (μ_s and μ_k)	D 3108 (D-13 on textiles)	Coefficient of Friction, Yarn to Solid Material	Textile yarns versus solids (μ_k)	D 3247 (D-6 on paper)	Coefficient of Static Friction of Corrugated and Solid Fiberboard	Self-mated cardboard (μ_s)	D 3248 (D-6 on paper)	Coefficient of Static Friction of Corrugated and Solid Fiberboard (inclined plane method)	Self-mated cardboard (μ_s)	D 3334 (D-13 on textiles)	Testing of Fabrics Woven from Polyolefin Monofilaments	Self-mated woven fabric (μ_s)	D 3412 (D-13 on textiles)	Coefficient of Friction, Yarn to Yarn	Continuous filament and spun yarns self-mated (μ_s and μ_k)	 $\mu = [\ln(T_2/T_1)]/\theta$ where: μ = coefficient of friction θ = wrap angle, rad T_1 = input tension, gf (or mN) T_2 = output tension, gf (or mN)

Standard (committee)	Title	Material couple (measured parameters)	Test configuration
D 4103 (D-21 on polishes)	Preparation of Substrate Surfaces for Coefficient of Friction Testing	Vinyl and wood tiles (preparation only)	Any apparatus
E 303 (E-17 on traveled surfaces)	Measuring Surface Frictional Properties using the British Pendulum Tester	Rubber versus pavement (BPN, British Pendulum Number)	E 510 (E-17 on traveled surfaces)	Determining Pavement Surface Frictional and Polishing Characteristics using a Small Torque Device	Rubber versus pavement (TN, torque number)	E 670 (E-17 on traveled surfaces)	Side Force Friction on Paved Surfaces using the Mu-Meter	Tires versus pavement (μ) ($F_{dry} - F_{wet}$)	E 707 (E-17 on traveled surfaces)	Skid Resistance of Paved Surfaces using the North Carolina State University Variable Speed Friction Tester	Rubber tire versus pavement (variable speed number)	F 489 (F-13 on footwear)	Rating of Static Coefficient of Shoe Sole and Heel Materials as Measured by the James Machine	Leather and rubber sole and heel material versus walking surfaces (μ_s)	
Standard (committee)	Title	Material couple (measured parameters)	Test configuration
F 609	Test Method for Static Slip Resistance of Footwear, Sole, Heel or Related Materials by Horizontal Pull Slipmeter (HPS)	Footwear materials versus walking surfaces (μ_s)	F 695-81 (F-13 on footwear)	Evaluation of Test Data Obtained by Using the Horizontal Slipmeter or the James Machine for Measurement of Static Slip Resistance of Footwear, Sole, Heel, or Related Materials	Footwear materials versus walking surfaces (reliable ranking of footwear for slip resistance) (μ_k)	F 732 (F-4 on medical and surgical materials)	Reciprocating Pin-on-Flat Evaluation of Friction and Wear Properties of Polymeric Materials for Use in Total Joint Prostheses	Materials for human joints (μ_k)	
Note: Used with permission of the G-2 Committee on Wear and Erosion

The D-20 Committee friction test for plastic film versus other solids is a general type of test. A plastic film is placed on a platen, and then a sled, faced with a material of interest, is pulled on the surface. Although not covered in the standard, this same test works well for coated metal, sheet metal, and paper. The test uses a nylon pull line; thus, the previously mentioned system-elasticity considerations apply.

The D-21 Committee standard is very specific to floor finishes. It uses an apparatus (the James machine) that simulates the friction contact between shoe heels and soles and flooring. This same device is used for the friction tests developed by the F-13 Committee on footwear. The D-7 Committee standard on flooring addresses the friction coefficient of flooring and sole leather. All of these tests use a sample pulled by a chain. This reduces system elasticity and stick-slip behavior.

The D-2 Committee test on the block-on-ring machine is really a calibration test for the machine and is not intended for comparison of materials or lubricants. However, the apparatus described in the standard is widely used for wear testing. The test specimen is held by a friction-force transducer. ASTM G 77 describes the use of this machine for wear testing, and this standard can be used to conduct sliding wear tests on a wide variety of materials. The coefficient of friction measured in a wear test on this machine will be for worn surfaces. The lowest normal force that can ordinarily be applied in this machine is 45 N (10 lbf). The normal force is sufficient to generate damage in most materials. The only way that friction can be measured on unworn surfaces on this machine is to minimize revolutions of the counterface ring.

The rig illustrated for use in the D 3028 test standard is commonly called a "frictionometer." One test specimen is a 100 mm (4 in.) diam by 6.4 mm (0.25 in.) thick disk and the other is a 2.5 mm (0.1 in.) wide disk with an outside diameter of 20 mm (0.8 in.). The larger disk can rotate up to 200 rev/min. The smaller nonrotating disk is spring-loaded against the larger disk. The spring force is variable, and the spring provides the normal force between the two disks. The test is normally run in an accelerating and decelerating mode. The rotational speed of the larger disk is increased up to the desired terminal velocity; the speed is then slowly reduced to zero. As the friction force changes, the position of the nonrotating disk changes. At the start of a test, it may be at the 12:00 position. When the friction increases, it may move to the 1:00 position, then to the 2:00 position, and so forth. This position change is sensed by the location of a pointer on a protractor-type scale, and a coefficient of friction is determined from the number that is indicated on the scale. Friction force is measured mechanically--essentially by the rotation of a pendulum weight.

The frictionometer is easy to use, is capable of sliding speeds up to 6 m/s (20 ft/s), and can be adapted to measure the friction of a film versus the nonrotating disk. This device is especially useful for measuring the friction between plastics and metals under light loads and high velocities. This device is somewhat confusing in that the friction coefficients measured during increasing velocity often do not match the friction coefficients measured during the decreasing velocity

portion of the test. This may be due to some mechanical attribute of the machine, or it may be what actually happens at the surface.

The D 3108 test for yarn versus "solid materials" uses the capstan formula for measuring friction. If there is zero friction between the yarn and the sheave with the pointer on it (Table 1), the yarn tensions T_1 and T_2 will be the same. As the friction increases, the pointer sheave will rotate. The degrees of rotation are measured, and this number is used to calculate the coefficient of friction. This device is essentially dedicated to yarns and similar materials sliding over a curved surface at relatively high speeds (100 m/min, or 325 ft/min).

The D-6 Committee tests (D 3247 and D 3248) are sled and inclined plane tests, respectively, using classic measurements and equipment. These standards apply to self-mated cardboard. The D 3334 test is a similar classic inclined plane test for measuring static coefficient of friction. It applies to self-mated woven polyolefins, but could be used for other fabrics.

The D 3412 test, which is an extension of the D 3108 test, allows testing of self-mated yarns. The yarn is wrapped tightly on a cylinder. A single strand of yarn is then wrapped 180° around the yarn-wrapped cylinder; one end is attached to a load cell, the other to a dead-weight mass. The yarn-covered cylinder is rotated, and the friction coefficient is calculated using the capstan formula.

Specification D 4103 is not a friction test, but rather a specification for preparing vinyl and wood surfaces for friction testing. This is the same procedure used to prepare polish-coated (waxed) samples of wood and vinyl for the D 2047 "walking" machine friction test.

The E 303 test measures the friction of rubber versus concrete and similar paving materials. A block of rubber is attached to a pendulum similar to those used in impact tests. There is a preset amount of interference between the rubber and the sticky counterface. The pendulum is released; the arm swings, strikes the counterface, and the follow-through swing after the rubber strike is measured. The higher the friction, the more energy adsorbed and the shorter the back-swing after impact.

The E 510 test measures the effect of pavement finishes on the traction of tires. The desired finish is put on a sample of concrete, and two "go-cart"-size rubber tires are driven on it. The concrete disk is kept stationary by a torque-measuring arm. The end result is a number that relates to the coefficient of friction between the tires and the pavement.

The E 670 test is not a laboratory test, but instead requires pulling a trailer-type device fitted with three full-size tires. Two of the tires are at an angle different from the direction of tow. As a result, the tires skid when towed. Water is also directed at the pavement/skidding tire interface. The coefficient of friction between the pavement and the skidding tires is measured by the force that the trailer exerts on the trailer hitch of the pull vehicle. This procedure allows fullsize tires to be tested on a wide variety of pavement surfaces.

An alternate test of the E-17 Committee on traveled surfaces is a pendulum (E 707) that calls for water to be applied to the pavement sample and a small rubber tire attached to the pendulum. The test result is a variable speed number, but this number is a real measure of the friction between the tire and the pavement.

Specifications F 489, F 609, and F 695 are similar to the tests used for floor finishes; however, their purpose is to evaluate shoe soles and heels. The tests were developed by the F-13 Committee on footwear and use the James machine, which simulates walking.

Test F 732, developed by the F-4 Committee on medical and surgical materials, uses a reciprocating flat-on-flat material couple and is intended to simulate motion in human joints. The test is used to evaluate candidate couples for prosthetic devices. It is run submerged in bovine blood to simulate body conditions. The usual couples are plastic-to-metal, but many other systems have been tested.

Non-ASTM Standards. Other organizations such as the American National Standards Institute (ANSI) have also developed friction test standards. If a material under study is commonly under the jurisdiction of a particular standards organization, that organization's applicable standards should be used. For example, the photographic film industry frequently adopts ANSI and International Organization for Standardization (ISO) standards. There is an ANSI test for the static coefficient of a film in contact with a metal surface. Whenever possible, standard tests should be used. They have been agreed upon by peer groups and subsequently approved by representatives from many industries. Using such standardized tests increases the likelihood of producing valid results when compared with in-house tests.

Performing a Valid Test

The procedural considerations that should be addressed to ensure that valid data are derived from a friction test will be discussed in this section. Investigators often run a friction test that is convenient to use but that has no resemblance to the system under study. Friction is a system property, and systems must be modeled carefully (same materials, same treatments, and so forth). Other factors that can affect the validity of a friction test include sample preparation, method of friction measurement, and interpretation of data.

System Modeling. Essentially three types of geometries prevail in systems where friction is a concern. These include:

- Flat-on-flat
- Conforming surfaces (belt on a drum, plain bearings, and so forth)
- Hertzian contact

These systems are illustrated in Fig. 11. It could be argued that when wear occurs, all surfaces become conforming. This is true for all systems but those where the triboelements remain Hertzian in contact. For example, railroad wheels wear significantly in service, but they still contact the track in a Hertzian manner by line or point contact. With regard to wear of the sliding surfaces, this may be the most important aspect of modeling a tribosystem. If the system under study will wear, and it is the desired goal of the study to determine the friction characteristics under conditions of steady-state wear, friction should be measured in a wear test. If the system of concern will not change with time, a friction test that does not involve wear can be conducted. Figure 12 shows how wear can affect friction forces. Figure 12(a) illustrates the friction force variation with time for a system that does not experience any wear or changes in behavior when wear occurs. If, for example, paper is conveyed over a fixed roller with a smooth finish, it is highly likely that the friction force will remain the same as the roller wears by polishing abrasion, and the friction force will be constant with time, as will the nature of the tribosystem. The roller constantly wears, but the surface is always polished. The wear debris is carried away with the product, and nothing in the system changes. This statement must be qualified by noting that the environment (humidity, temperature, and so forth) may cause friction to change with time. Environmental effects are discussed later in this article.

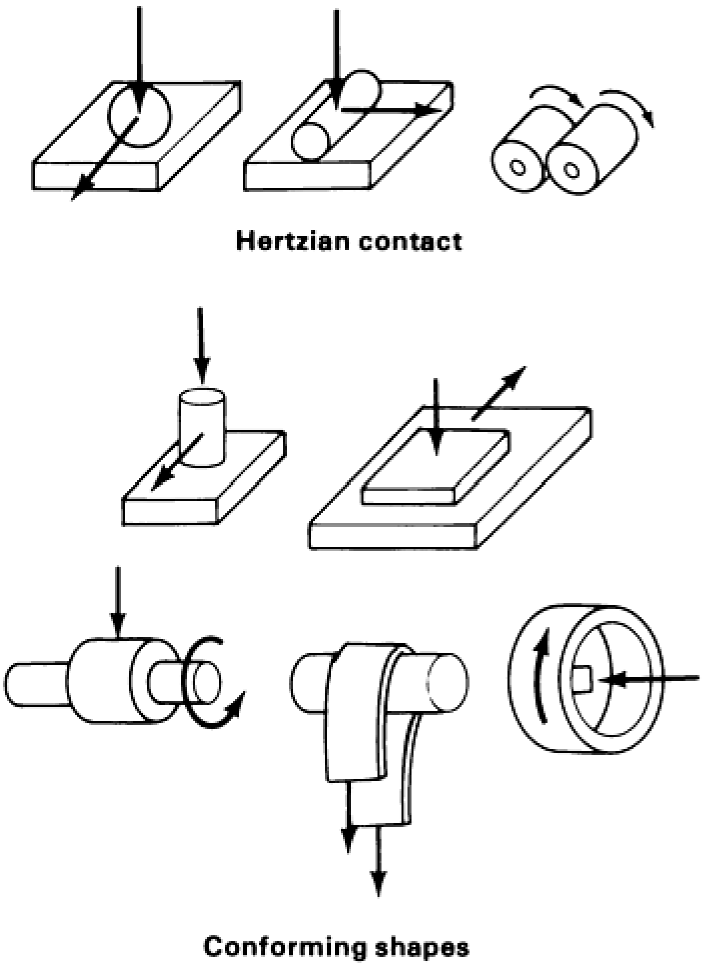

Fig. 11 Friction test specimen configuration options

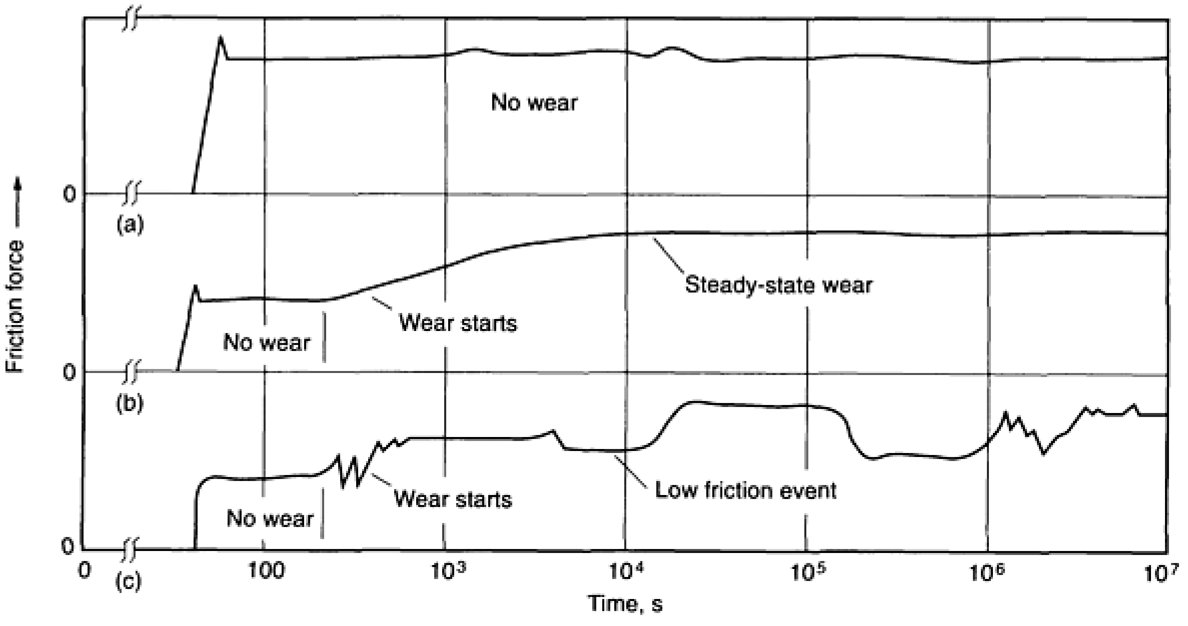

Fig. 12 Effect of system wear on friction force. (a) System that does not experience any wear or changes in behavior when wear occurs. (b) System where friction force increases with time until reaching a steady-state condition. (c) System where friction force varies with each event in the wear process

Figure 12(b) illustrates a tribosystem where the friction force increases with time and then reaches steady state. This type of behavior might occur in a system experiencing severe wear. Friction is low when both members have their original surfaces. When the original surfaces start to wear, friction increases, and from that point on, the worn surfaces remain the same. It is comparable to a machining operation in that material is constantly being removed, but the cutting forces remain constant.

Figure 12(c) illustrates a system where the friction force varies with events in the wear process. This type of behavior often occurs in a tribosystem where wear debris remains in the system. Depending on how it separates the surfaces, wear debris can have a lubricating or nonlubricating effect on the system. The friction will be constant when the triboelements have their original surfaces; when they wear, there will be a friction event followed by another when both surfaces become coated and are separated by wear debris. Because wear is a statistical process, some other event may take place to remove the separating wear debris, and still another cycle or friction event will occur. This phenomenon is seen in many machines. The machine may run quietly for a year, but then a squeal occurs that lasts for two weeks and then stops. The noise may come back in two months, or it may never return. It is quite possible that significant fluctuations in friction force with time are the result of environmental events. For example, it is well documented that the friction characteristics of photographic films are significantly affected by relative humidity. Photographic emulsions are gelatin based. Many gelatins have mechanical properties that are directly proportional to their water content. Mechanical properties vary with humidity, and these property changes in turn affect friction characteristics. Temperature has a similar influence on many materials, particularly plastics.

The illustrations shown in Fig. 12 are presented in order to emphasize that it is important to closely model the system under consideration. The test should simulate the mode of contact and the environment, and the length of time that the system is tested should be typical for the intended service. If new materials are being screened for friction characteristics, short-term and long-term tests should be conducted to explore friction events that change with time. If a service problem is being studied, the test should simulate the important aspects of the service, the environment, the type of contact, and the materials. It is not necessary to exactly duplicate the sliding speed and load unless they are likely to change some properties of the test materials (temperature, chemical environment, and so forth).

Material Documentation. Problems concerning repeatability of a friction test with time can be related to subtle or major changes in the nature of one of the tribocomponents. For this reason, it is important to provide adequate documentation of the materials in a tribosystem where friction measurement is the goal. As shown in Table 2, the necessary documentation varies with the type of material (metal, plastic, ceramic, or composite).

Table 2 Material parameters that should be documented to ensure repeatability when testing tribosystems

Metals
Chemical composition
Manufacturer's name and address
Manufacturing process [wrought (cold finished or hot finished), cast, extruded, etc.]
Generic designation
Trade name (if applicable)
ASTM or similar designation
Condition of heat treatment
Surface finish
Surface treatments
Grain direction
Microstructure
Plastics
Polymer species (If a blend, state ratio of blended polymers)
Fillers, lubricants, and so forth (percentage)
Manufacturing process (injection molded, extruded, cast)
Generic name
Applicable specifications (MIL, ASTM, and so on)
Trade name and manufacturer's number
Manufacturer's name and address
Process used to generate wear surfaces, orientation of wear surfaces to original shape (wear surfaces flatwise on as-molded flatwise plate, wear surfaces are end grain in extruded shape, and so on)
Lubricants on the surface or in the material
Surface texture of wear surfaces (R_a, lay, waviness)

Heat treatments applied
Composites
Detailed description of composite components (filament winding details, number of plys, components in laminate)
Generic name and applicable specifications on composite components
Trade names of components
Manufacturer's name and address
Method of manufacture
How wear surfaces were generated
Orientation of wear surfaces to reinforcement
Heat treatments
Surface texture (R_a, lay, waviness)
Surface treatments, lubricants, mold releases, and so forth
Ceramics
Basic type and composition
Percent theoretical density
Manufacturer's name and address
Trade name
Manufacturing process (HIP, vacuum sintering, chemical vapor deposition, and so on)
Method used to generate wear surfaces (grinding, polishing, and so on)
Texture of wear surfaces (R_a, lay, waviness)
Heat treatment
Surface treatments
Grain size
Microstructure
Morphology (degree of crystallinity, phases present, crystal structure)
Lubricants/impregnants

More items undoubtedly could be added to Table 2, but the point to be made is that all of the variables that have been mentioned thus far could have an effect on sliding friction. If the surfaces are lubricated, the tester must add related details of the type of lubricant and its distribution on the sliding surfaces. It is imperative that documentation on all members in the tribosystem be included. It is quite easy to cite examples where each of the factors listed in Table 2 has affected friction results in laboratory tests; more importantly, these factors influence friction properties in service. Heat treatment, structure, and so forth can affect mechanical properties; surface films affect sliding forces; surface texture affects early friction; a cast polyester will have different mechanical properties than a tentered and drafted polyester web; a hot isostatically pressed silicon carbide will have differentmechanical properties than pressed and sintered material. The tester should be meticulous about material documentation.

Surface Condition. Few tribologists will argue with the statement that friction can be affected by surface condition. If the loads are light enough, only the outer one or two monolayers on the surface may take part in sliding interactions. In lubricated systems, surface roughness plays a role in determining whether the surfaces are separated. Full-film separation will not occur unless the film thickness is greater than the surface roughness. Even with hydrodynamic lubrication, there are some investigators who claim that the system friction is affected by the surface roughness and lay (Fig. 13). In the normal range of roughnesses on rolling-element bearings and plain metal bearings (0.1 to 1 μm R_a), it is likely that surface features do not significantly affect lubricated sliding. In nonlubricated sliding, the effect of roughness can be negligible to significant, depending on the system (Ref 16). With normal machined surfaces with a roughness less than about 1.5 μm, the effect will be slight. Roughness becomes a meaningful factor when the roughness interactions result in mechanical locking effects. This usually happens only with very rough surfaces. Sometimes, very smooth surfaces cause adhesion--for example, gage blocks or plastic webs on smooth surfaces. Conversely, in some applications such as high-speed sliding of yarns and filaments over stationary guide pins, the friction coefficient is low when the pin surfaces are rough (0.5 to 2 μm R_a) and becomes very high when the pins become polished from wear.

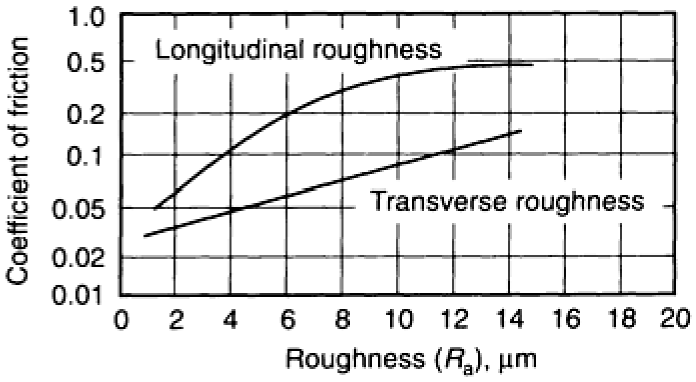

Fig. 13 Effect of surface roughness on the friction coefficient of a lubricated sliding system. Adapted from Ref 16

A valid wear test considers the effect of surface texture. For many systems, the effect is not significant. If, however, surface texture is considered a variable for a given wear study, a few quick tests using the high and low of the expected range of surface texture will determine whether this is a parameter to be pursued in a friction study.

Surface films are important in most tribosystems, especially unlubricated systems. The recommended practice in friction testing is to leave the films in place if they are likely to occur in the tribosystem of interest. If they are not part of the system of interest, they should be removed by cleaning. Valid wear results require that a cleaning procedure be used that will remove contaminants and not leave another contaminating film. The cleanest surface is the as-machined or as-ground surface (without coolants and the like). These types of surfaces prevent cleaning-solution contamination problems. If metal surfaces must be cleaned of contaminating films, then a refluxed solvent system should be used. Plastics are difficult to clean with solvents because of the risk of chemical alteration of the surface. Commercial glass-cleaning solutions have been employed to clean plastic test surfaces with favorable results. Ceramics can also be cleaned by these solutions. Sometimes even water-based cleaners can chemically alter a ceramic surface. The safest technique for removing contaminants on ceramics is dry lapping or similar abrasive finishing.

Absorbed films from the atmosphere can be another source of contamination. To cite an example, many plastics were tested in a comprehensive laboratory as a track material for conveyance of plastic parts. Test results indicated that an ultrahigh-molecular-weight polyethylene had the lowest friction. Hundreds of feet of this track were installed in the manufacturing plant, but within a month the track was pulled out and replaced because of an environmental factor that had not been considered during laboratory testing. Although there were no problems with the track during the week when there was a three-shift operation, after the weekend, parts would stick to the track with great frequency. Only after several hours downtime and frequent "nudging" of the parts would the system begin working properly. Further study indicated that when the track material was allowed to sit idle for a period of 48 h, some type of film formed that deleteriously altered the friction characteristics.

This example points out the importance of carefully duplicating the system environment, even to the extent of allowing surfaces to sit idle in production environments. Many manufacturing plants have an atmosphere that can leave a condensate on a surface. If this is likely to occur in a tribosystem under study, then it should be made part of the friction testing.

Test Parameters

Friction test parameters, such as speed and load, should be as close as possible to actual conditions. Sometimes, however, it is difficult to simulate these parameters in a laboratory environment. The speeds and loads may be out of the range of the lab equipment, or testing at actual conditions may take too long. A valid friction test does not require that speeds and loads be exactly duplicated. Friction coefficients are relatively insensitive to speed and loads up to the point where these parameters affect the properties of the test surfaces. Speed will affect friction results on most metals when it is sufficiently high to soften the surface and alter mechanical properties. With plastics, this temperature may be only a few hundred degrees Fahrenheit. With metals, the critical temperature is close to the stress-relief temperature for a given alloy.

Sliding speed for a friction test can range from 10 mm/s (0.4 in./s) for an inclined plane test to 100 m/s (325 ft/s) for high-speed yarn friction tests. For optimum results, test equipment should yield a wide range of sliding speeds. If the actual operating speed is unusually high or low, unique friction conditions may be produced that can be simulated only by test speeds in the range of concern. For example, a laboratory study was conducted on plastic and competitive plain bearings for a compact-disk drive scanner that had to slide (bushings versus hardened steel shafts) in a linear motion at a speed of 1.6 μm/s (0.00006 in./s). This slow speed caused many materials to display stick-slip behavior. When higher speeds were used, this did not occur. Under such conditions, the speed of the tribosystem should be duplicated as closely as possible.

The same type of reasoning should be applied to test loads. If a system under study uses loads of only a few grams, this should be duplicated. If the system under study is subject to extreme forces, such as those that occur in threaded fasteners, there is little recourse other than to use these very high forces. When studying bolt friction, most investigators use actual bolts and nuts and a washer equipped with a strain gage for measurement of bolt tension. This is because of the difficulty in obtaining a bench-top friction tester that can apply a 45 kN (10,000 lbf) normal force.

As a rule of thumb, if it is not possible to simulate the service load, then the highest load that does not exceed the compressive strength of either member in the test couple should be used. This is particularly applicable to Hertzian loading situations. If the compressive strength of the material is exceeded, the friction test only yields the forces to plastically deform the surfaces. Test speeds and loads that produce significant wear should be avoided unless that is part of the tribosystem under study.

As previously mentioned, friction force may not be constant throughout a test, and questions may arise as to the value that should be reported. The most meaningful data are the minimum, the maximum, the mean, and the standard deviations. This allows the use of statistical analysis to determine wether friction coefficients for various systems are really different. Erratic systems such as that described in Fig. 12(c) will be treated with statistics. In friction tests were the goal is to find a couple with the smoothest motion, a suitable test parameter for ranking materials is the standard deviation of the friction force. This shows the variability of the friction forces for the various systems. In fact, for all friction tests it is recommended that statistical tests be used. The simplest test of differences is illustrated in Fig. 14. If the mean of test data is plotted with error bars coinciding with plus or minus two standard deviations, a visual test of differences can be made. If the error bars overlap, the test results are not statistically different. In Fig. 14, couples B, C, and D have the same frictional characteristics; only couple A differs.

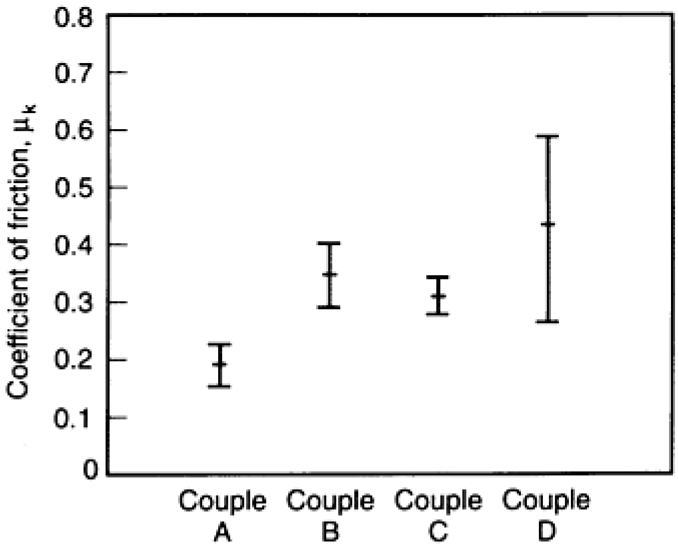

Fig. 14 Graphical use of statistics to show differences in friction coefficients between various material couples

Sample size must also be considered in statistics tests. There are a number of ways to calculate sample size, but most statisticians prefer a large number (for example, 40) of replicate tests. Because most friction tests are very repeatable within a laboratory, this number may be a bit high. Most studies using a bench-top friction tester can have statistical accuracy with as few as 10 replicates per system.

Friction Measurements

There are a number of precautions that must be observed during friction measurements, and most have to do with the measuring equipment. Some of the more commonly used force-measuring systems are illustrated in Fig. 15. Probably the most important consideration with regard to instruments for measuring friction forces is selection of a force-measuring system that is suitably sized for the task. If the tribosystem being tested will produce friction forces of about 4.5 N (1 lbf), it is recommended that a force-measuring system with a capacity of only about 45 N (10 lbf) be used. In other words, a sensor with a capacity not more than 10 times the force to be measured should generally be selected for a given application.

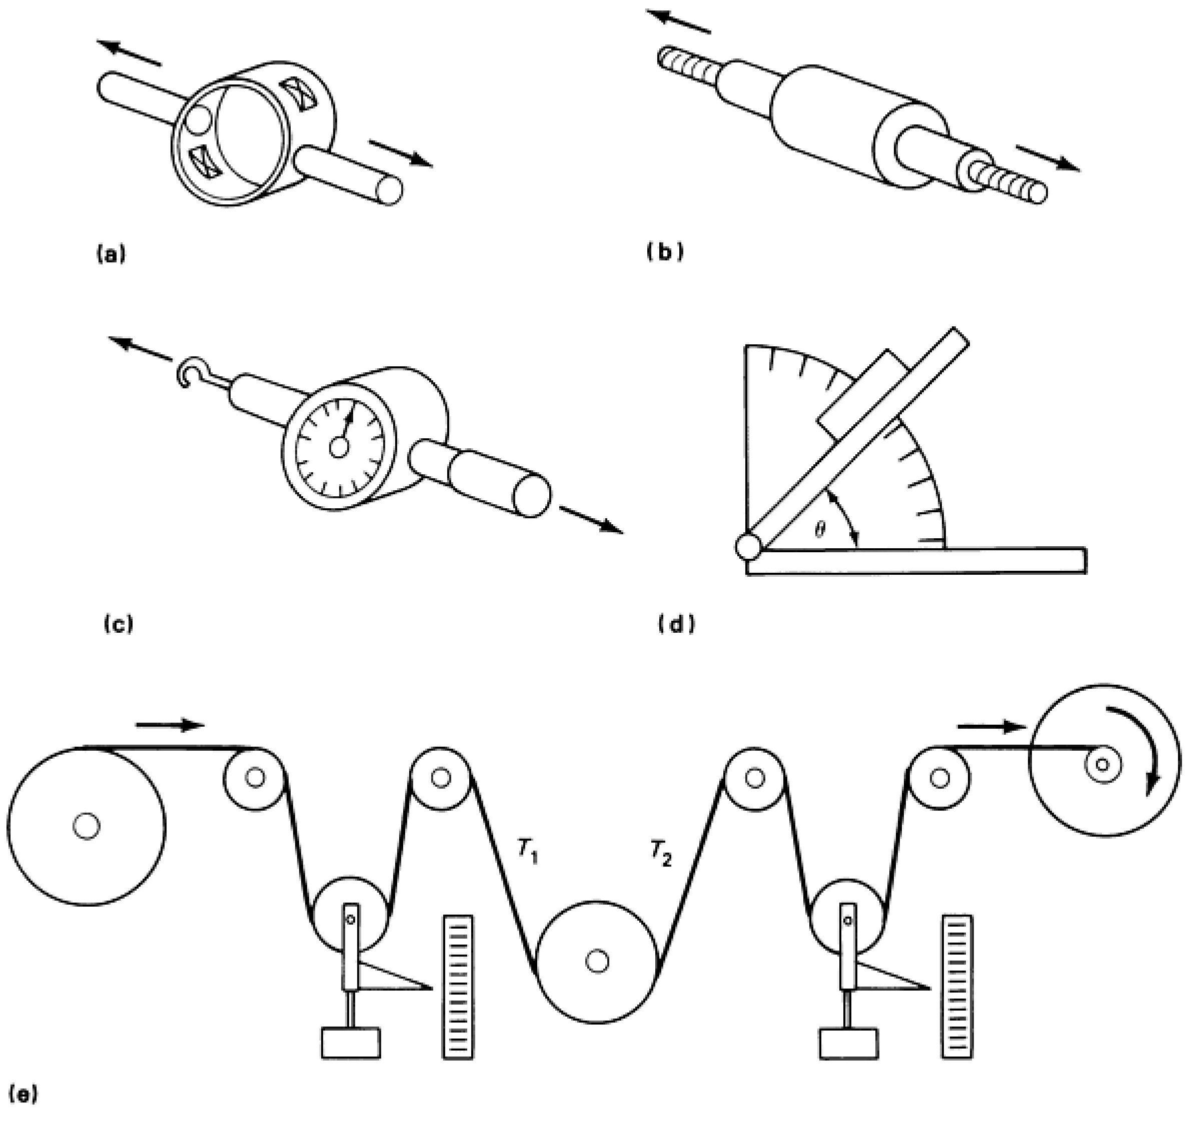

Fig. 15 Friction force sensors. (a) Strain ring with strain gages. (b) Strain gage load cell. (c) Mechanical force gage. (d) Inclined plane. (e) Web tension tester (tension is measured by the position of the weighted sheaves)

The strain ring illustrated in Fig. 15(a) is assembled in the laboratory and features four strain gages adhesively bonded to the ring to form a Wheatstone bridge strain rosette. This type of system can be very accurate, because the ring can be made a heavy or as light as desired. The disadvantages are that such gages are more fragile than purchased gages, and humidity and temperature can affect the adhesion of the gages. This system also requires assembly by a person with some expertise in strain gages.

The commercially available strain-gage load cells shown in Fig. 15(b) are quite durable. Most have some type of internal diaphragm that is instrumented with stain gages. However, these devices can be destroyed by a momentary load greater

than its capacity, necessitating expensive replacement. Many companies offer these gages with mechanical stops to prevent overload damage.

Mechanical force gages (Fig. 15c) work much like strain gages, except that force measurements are made by a spring and sliding system arrangement. The greatest disadvantage of such devices is that they have no recording capability. They are also prone to inaccurate readings by operators.

Friction coefficients measured on inclined planes (Fig. 15d) require only the measurement of the angle at which motion of the test block occurs. The most common technique for measuring this angle is the simple incorporation of a protractor scale in the device. A more accurate system uses an electronic level on the inclined plane. These devices have digital readout capability and are much more accurate than visual assessment of the angle of an inclined plane. One precaution in using this type of device is that the speed at which the plane is raised will affect the breakaway angle. The more reliable inclined plane rigs have a motorized raising device on the table.

The device illustrated in Fig. 15(e) is commonly used to measure the friction coefficient of a moving web over a stationary surface or over a roll where relative slip is occurring. The tension in the web on either side of the test roll will yield the coefficient of kinetic friction when the capstan formula is used. The tension-measuring roll, called a "dancer roll," moves up and down with changes in web tension. The disadvantage of these systems is that they are not very easy to gage electronically, and thus continuous recording mae be difficult. Most dancer rolls are being replaced by cantilever rolls with strain gages incorporated in their mounting brackets.

Whichever force-measuring technique is used, it is most important that the device be sized correctly and that friction forces be recorded over a sufficient period of time to ensure that steady-state conditions exist.

If an electronic device is used to measure and record friction force, the recording system is of concern. The current trend is to use computers to record friction and wear results from test machines. When friction force is digitized, however, the electronic force sensors do not miss any forces; the resulting "hash" in the friction recording may make it difficult to measure averages and ranges and other parameters for statistical data analysis. Although most systems can be electronically filtered, the consensus at the present time is that digitizing of friction forces in friction or wear tests creates too many complications. The filters in strip-chart recorders apparently provide adequate noise filtering and thus reasonable measurements of friction force.

The final precaution that warrants consideration is the system stiffness. If a system is prone to stick-slip behavior or high static friction, a highly compliant force-measuring system should be used. From a practical standpoint, an elastic force-measuring system usually consists of nylon fishing line to pull member A along member B. If a stiff-movement system such as a screw drive is used to produce specimen motion, phenomena such as stick-slip behavior may not be produced. The decision as to whether a high-stiffness (steel) or low-stiffness (plastic) system should be used must be based on the intended application. If the tribosystem of interest is highly elastic, the plastic-movement system should be used. If the system is rigid, the screw-drive system (or a similar system) should be used.

Reporting System Losses

A proposed method for analyzing wear problems is to look at the tribosystem and tabulate all of the system inputs, outputs, and disturbances (Fig. 16). Friction is considered to be a system loss, but certain components of friction should be noted and recorded. From the aspect of system usability, sometimes these system losses are more important than the friction force. For example, in a study on the wear of various cemented carbide couples, it was learned that some carbide couples produced squealing. The friction coefficient was slightly higher than comparable metal-to-metal couples (about 0.5 compared with 0.4) and the wear was very low, but this couple was deemed unacceptable for use because of the noise.

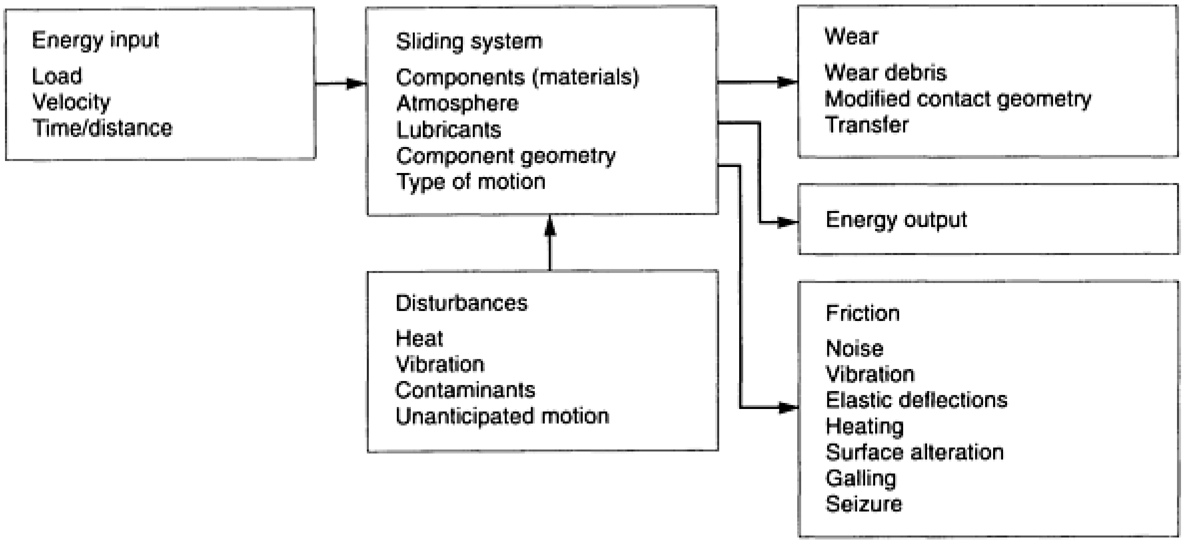

Fig. 16 Systems approach for analyzing friction and wear problems

In Fig. 16, important losses include vibration, elastic deflections, heating, surface alteration, galling, and even seizure. Vibration as an output of a sliding system often indicates that stick-slip behavior is prevalent. Noise is often the result of stick-slip behavior, but a system that exhibits such behavior does not necessarily emanate noise. Although vibration may not be apparent on friction force traces, it may show up on deflection or displacement transducers. This type of behavior from a sliding system is usually undesirable. Accurate measurement of vibration may require the use of accelerometers on one of the members of the sliding system.

Likewise, elastic deflection, which can occur at a sliding interface, may not show up on the friction force recordings; this deflection may mean that the couple under study has unacceptable frictional characteristics. For example, when several elastomers that were undergoing friction tests were slid on a paper counterface, they bent over in the direction of motion; the contact geometry was changed from the point contact of a hemispherical rider to a line contact of a bent hemispherical-ended rod. The friction force was apparently high enough to cause this deflection.

Although heating is an obvious result of friction between sliding members, it is often not measured. The temperature rise is often significant, and it is easy to measure. The mechanical properties of plastics are susceptible to degradation by heating to relatively low temperatures. The temperature rise at a sliding interface is the result of the properties of the materials in contact in addition to the sliding conditions. It will be different for different couples that may have the same friction coefficient. Therefore, for sliding systems that may be affected by frictional heating of the interfaces, a valid friction test should record the temperature rise.

Surface alteration is another important aspect of many wear and friction tests. Whenever wear occurs in a sliding test, the friction coefficient is not that of the test couple alone, but it is the system that comprises the couple as well as wear debris in the interface. When wear testing couples that are not supposed to wear during friction testing, it is important to examine both surfaces for alterations. Damage often may be caused by polishing or scratching. When friction alters the prevailing surface texture, a wear test has been performed, not a friction test. The friction force measured and the coefficient of friction must be reported for a worn surface.

Galling and seizing are the worst possible results of a friction test. Galling is characterized by the formation of microscopic cumulative material transfer during sliding, and seizure (stopping of motion) can be the net result. If a couple seizes, there will be no friction coefficient to report, but merely the fact that the couple seized. If galling occurs, the friction force will often decrease (Fig. 17), but the surfaces will be damaged. This can produce data that misleads a user, who may think that the couple works fairly well because the friction coefficient was low, when actually galling occurred and the material couple is not compatible.

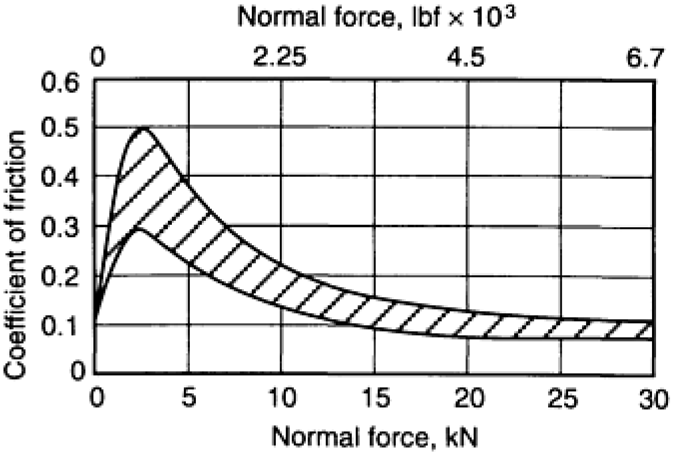

Fig. 17 Typical friction coefficients derived from galling tests (various metal/metal couples)

Friction Databases

The first friction database was compiled by J.T. Desagulies around 1725 (as reported by Dowson in Ref 2). Desagulies tabulated the friction coefficients for the couples of interest at the time. Current handbooks tabulate data for 50 or so materials, with limited documentation regarding test conditions. These tabulations are of little use if the application requires knowing a friction coefficient within an accuracy of ±0.2. Differences in the tribosystem used to make the measurements can, for example, produce a result of 0.1 for a couple on device No. 1 and a result of 0.3 for the same couple tested on device No. 2. It can be stated with a high degree of confidence that measuring techniques will have a significant effect on the friction coefficient of a particular couple in the unlubricated condition. Differences may exist in lubricated systems, but the coefficients will be much lower and an accuracy of ±20% results in a much smaller number. For example, well-lubricated steel couples may have a kinetic coefficient of friction of 0.05 (±20% makes the number 0.04 to 0.06). In other words, existing friction databases have limited utility unless the test conditions used to develop the data are stated and the application conditions are similar.

In order to determine how friction databases should be formulated and used, ASTM Committee G-2 on wear and erosion began developing a standard format for friction databases in 1987. Although this work is ongoing, progress has been made as to the type of data that should go into databases. The minimum results to be reported are:

- Test couple (member 1 and member 2)
- Static coefficient of friction
- Kinetic coefficient of friction

The minimum test condition information includes:

- Apparent pressure
- Normal force
- Velocity
- Temperatures (bulk) of samples
- Test atmosphere
- Lubricant
- Sliding distance (when μ was measured)

Other types of data would also be desirable, but even the ASTM-recommended list is difficult to deal with in database or spreadsheet types of software. The strategy is to have these data in a database so that selective data can be tabulated (see

Table 3). The motivation for establishing friction databases is the elimination of repetitive tests. Even within a single laboratory, it is not uncommon to see the same couples brought in for study several times over a period of several years. Without a database, the tests are rerun each time. The long-range goal is to have published data that can be used by design engineers in the same way that designers use corrosion data generated by countless sources over many years.

Table 3 Friction and wear data of selected plastics tested against polycarbonate containing 12% polytetrafluoroethylene

Plastic[(a)]	Kinetic coefficient of friction, μ_k	Specific wear rate of selected plastic, $K \times 10^{-6}$[(b)]
PC	0.19	7.00
PC + PET	0.19	7.26
PCTG + 30% GF	0.36	9.00
PET + 30% GF	0.27	9.00
PET + 30% GF + mica	0.29	8.00
PC + 10% aramid	0.09	4.00
PA + 10% aramid	0.08	0.80
PA + 15% aramid + 10% TFE	0.07	0.50
LCP wear grade	0.10	2.00
LCP + mineral	0.07	0.60
PC + 40% aramid	0.18	9.00
PC/IPN + 2% aramid	0.15	2.00
PC + 20% aramid	0.20	7.00

(a) PC, polycarbonate; PTFE, polytetrafluoroethylene; PET, polyethylene terephthalene; GF, glass fiber; PA, polyamide; LCP, liquid crystal polymer; IPN, interpenetrating networks; TFE, tetrafluoroethylene.

(b) Parameters: friction force, *F,* 9.86 N (2.20 lbf); velocity, *V,* 0.208 m/s (0.682 ft/s); sliding distance, *D,* 732.0 m (2402 ft)

Friction during Metal Forming

Betzalel Avitzur, Metalforming Inc.

Introduction

FRICTION exists in any metal-forming process. Whenever two solid surfaces are in contact and relative motion, a resistance (friction) to this motion arises. Friction is the last frontier in the study of metal forming. For example, in the process of wire drawing, independent parameters such as reduction and die angle can be measured directly. Friction, however, is not directly measurable, nor is it really an independent parameter. Yet in many metal-forming processes, the effect of friction is as important as that of measurable independent parameters.

During wire drawing, a wire slides over the conical and cylindrical surfaces of a die (Fig. 1). If no lubricant is used, there is direct metal-to-metal contact between the wire and the die. The pressures between the die and the wire are very high (approximately equal to the flow strength, σ_0 of the wire). The relative motion, together with high pressure and high friction resistance, results in the generation of heat. The relative movement of the mating surfaces causes them to be damage by wear. Buildup of foreign matter over the surface of the die is also possible.

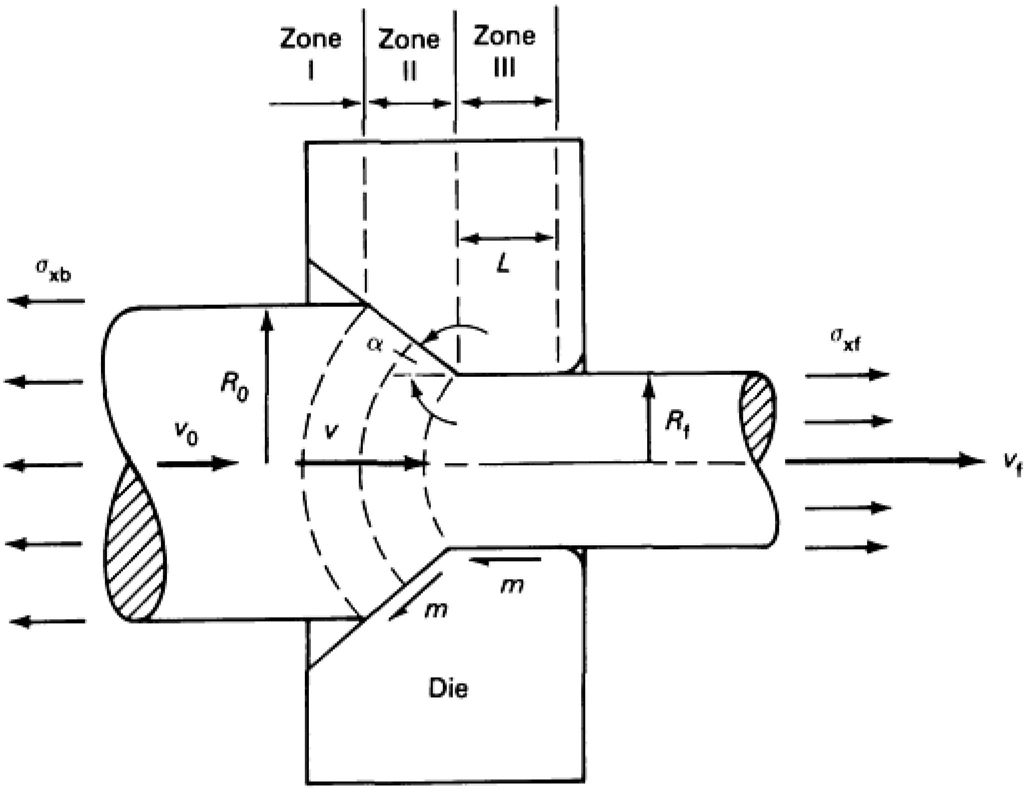

Fig. 1 Schematic of wire drawing or extrusion processes

No surface is geometrically perfect. Surfaces contain irregularities that form peaks and valleys. Thus, contact between the die and the workpiece is maintained over limited portions of the apparent interface. The apparent area of contact is the total area, but the actual area of contact is limited to that between the peaks of the opposing asperities (Fig. 2). If the pressure (*p*) is defined as the total force (*W*) divided by the apparent cross-sectional area (*A*), the local pressure at the points of contact can be much higher (Ref 1). The asperities flatten under the pressure, and the area of flattened asperities adjusts itself to carry the load by plastic deformation of the asperities, even when the bulk of the workpiece is in the elastic state.

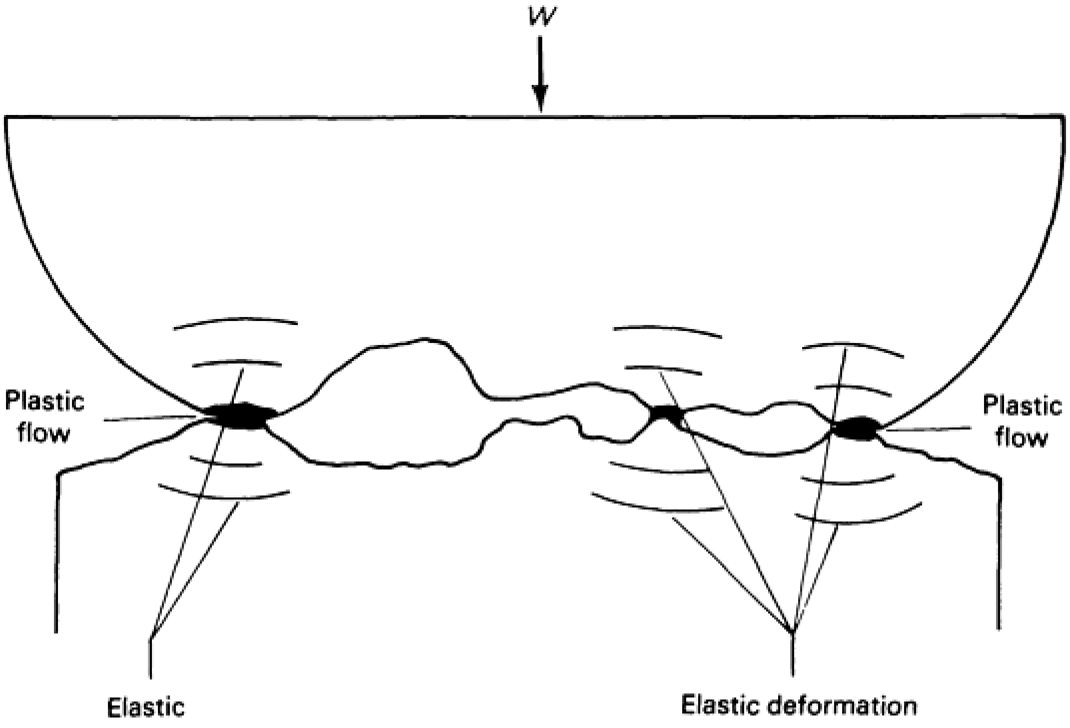

Fig. 2 Schematic of surface irregularities

Surface irregularities and their behavior during sliding, together with the lubricant and surface chemistry, are key factors in the characterization of friction and wear. Figure 3 illustrates some of the various modes of asperity deformation behavior. The steady-state wave model, which is shown schematically in Fig. 3(b), is described in the Appendix to this article. This model provides explicit expressions for the characterization of friction resistance as a function of pressure (Fig. 4a), speed and Sommerfeld number (Fig. 4b), and surface geometry. Terms commonly used in metal-forming operations are defined in Table 1.

Table 1 Nomenclature for friction in metal-forming processes

A	**Cross-sectional area**
f%	Percent forward slip in strip rolling
ℓ_0	Length of the asperity
L	Length of the bearing (land) of the die
m	Constant shear, or friction factor
p	Pressure
r%	Percent reduction in area
R_0, R_f	Original and final radius of a wire
R_O	Radius of the roll in strip rolling
R_o, R_i, R_n	Outer, inner, and neutral radius, respectively, of a deforming ring
S	Sommerfeld number
t_0, t_f	Original and final thickness of the strip
T_0	Thickness of a deforming ring
v_0	Sliding velocity
W	Total normal load
$\dot{W}_f$	Friction power losses
$\dot{W}_i$	Internal power of deformation
$\dot{W}_s$	Shear or redundant power of deformation
α	Semicone angle of the die
α_1	Angle of inclination of the asperity (the wedge)
α, α_n, α_2	Angular positions, respectively, of: an arbitrary point; the neutral point; and the point of contact

$\dot{\gamma}$	Shear strain rate
ϵ	Thickness of the film of lubricant
η	Viscosity
μ	Coulomb's or Amonton's coefficient of friction
$\sigma_{\mathbf{0}}$	Flow strength
$\sigma_{\mathbf{s}}$	Shear stress in the liquid
$\sigma_{\mathbf{xb}}$	Extrusion pressure with its negative sign (that is, $\sigma_{xb} = -p$); also back tension
$\sigma_{\mathbf{xf}}$	Drawing stress or front tension
τ	Shear stress
$\Delta \boldsymbol{T}_{\mathbf{0}}$	Reduction in thickness

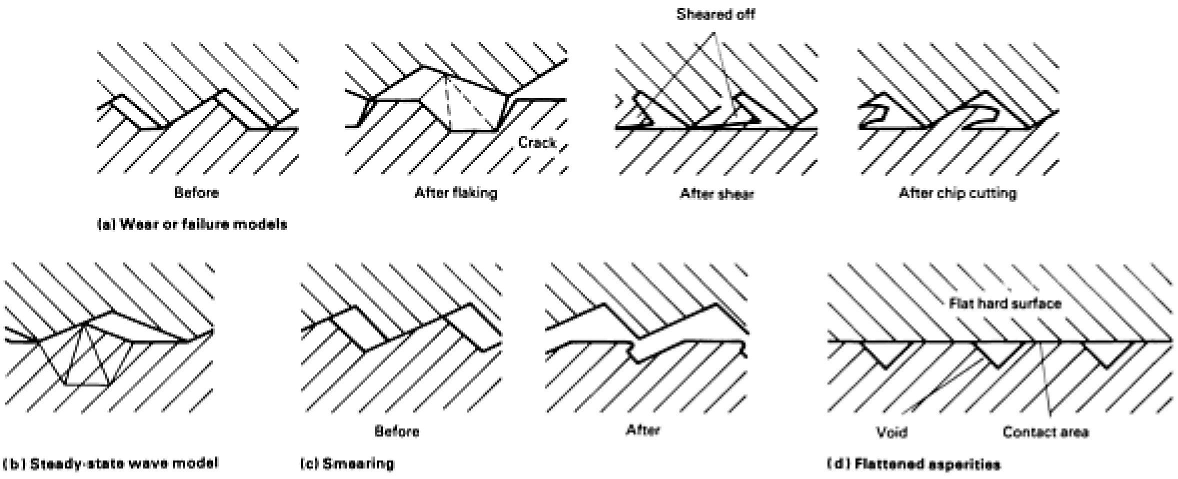

Fig. 3 Schematic of asperity deformation behavior

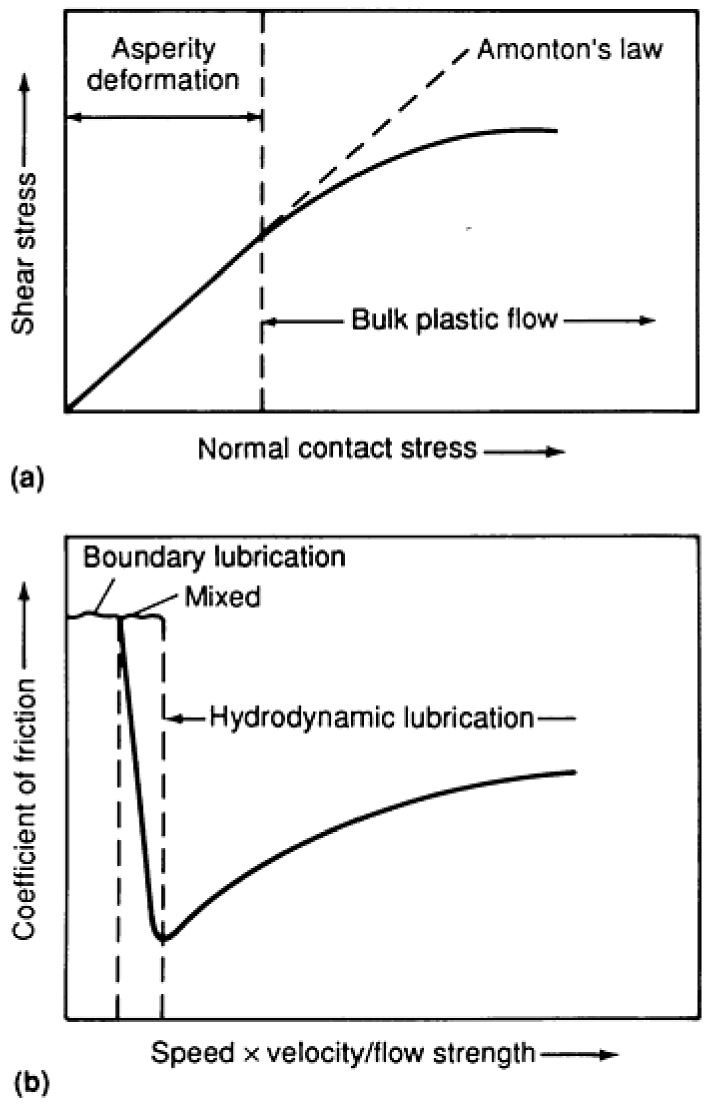

Fig. 4 Characterization of friction resistance as a function of (a) pressure, *p*, and (b) Sommerfeld number, *S*

Modeling of Friction

The difficulties in the determination of the friction value lie in the complexity of the phenomena (Fig. 4 and 5, and Appendix) and in the inability to accurately measure shear stresses. Therefore far-reaching approximations, as will be described presently, are used to describe friction behavior during metal forming. These approximations deal with apparent friction rather than with the fundamental phenomenon. One of the consequences of this approach is that friction must be measured separately for each forming process. Under presumably identical conditions of surface finish and lubrication, wire drawing will produce different friction values than strip rolling. As a result, when friction during rolling is to be determined, the rolling process must be simulated. The same holds true for the other metal-forming processes.

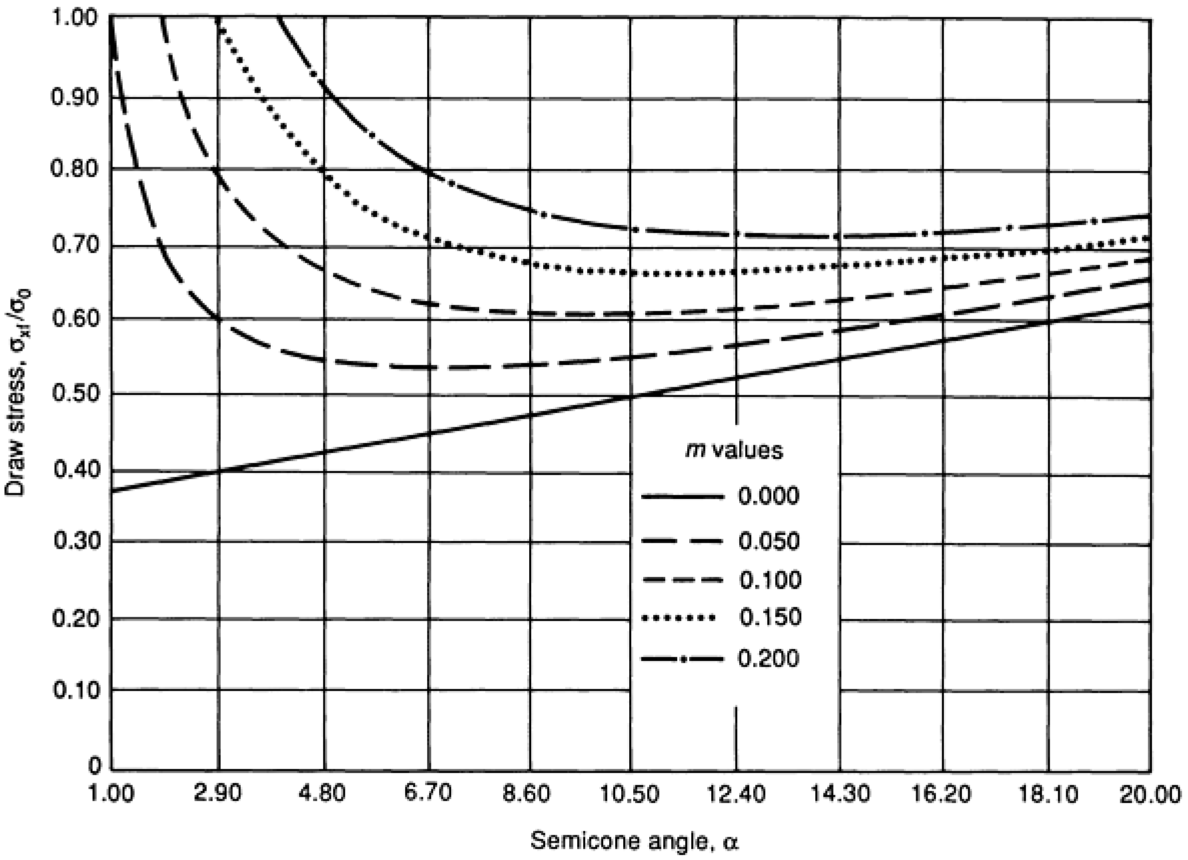

Fig. 5 Relative drawing stress as a function of semicone angle and friction factor (*m*). See also Eq 4.

Standard practice in the study of metal forming is to assume that the resistance to sliding along the interface between the tool and the workpiece is uniform along the entire contact surface. The most common simplifying assumptions made with regard to friction stress (τ) between the workpiece and the tool involve Coulomb friction, constant friction, and hydrodynamic-, hydrostatic-, and thick-film lubrication.

For Coulomb friction, it is assumed that the shear stress (τ) is proportional to the pressure (p) between workpiece and the die. It follows then that:

$$\tau = \mu p \qquad \textbf{(Eq 1)}$$

where the proportionality factor (μ) is called the Coulomb coefficient of friction.

For constant friction, it is assumed that the shear stress is proportional to the flow strength of the workpiece material, and

$$\tau = m\sigma_0/\sqrt{3} \qquad \textbf{(Eq 2)}$$

where the proportionality factor (m) is called the shear (or friction) factor, with $0 \leq m \leq 1$. The factors (μ) and (m) are assumed constant for a given die, workpiece, and lubricant.

When a lubricant film separates the workpiece from contact with the die, hydrodynamic or hydrostatic film lubrication prevails together with its special laws of shear within the lubricating medium. Sometimes high-viscosity lubricants adhere to the workpiece, resulting in thick-film separation of the workpiece from the tool. Film lubrication may also separate the workpiece from the die on the entry side to a smaller or larger extent. At the extreme, the entire workpiece is separated

from the die by this lubricant film. Under such conditions, the parameters μ or *m* are replaced by the viscosity of the lubricant (η), where stress in the liquid (σ_s) is expressed as

$$\tau = \sigma_s = \eta\dot{\gamma} \qquad \textbf{(Eq 3)}$$

where $\dot{\gamma}$ is the shear strain rate within the lubricant.

In the section of this article on "Measurement of Friction," the determination of friction is described for forging, wire drawing, and strip rolling. For each of these processes, the apparent friction is determined experimentally through the application of analytical solutions. The experimental data is treated by the mathematical expression of the relation between the parameters that were measured and the sought friction. In each technique a minimal use of instrumentation is required. All these assumptions for the characteristics of friction--namely Coulomb's/Amonton's coefficient (μ), constant factor (*m*), and film lubrication (η)--are treated. An iterative procedure can also be implemented when friction and pressure depend on each other, are solved simultaneously, and their distributions along the contact surface are treated as variables. Bay (Ref 2) gives such a treatment for the extrusion process.

Modeling of Flow through Conical Converging Dies

In the process of wire drawing, a wire is pulled through a converging die where its size is reduced from R_0 to R_f (Fig. 1). Passing through the die, the wire rubs against the conical and cylindrical surfaces of the die and encounters friction resistance. The effect of friction on the drawing force and drawing stress during the fabrication of wire through conical converging dies is discussed in Ref 3, 4, 5, 6, 7, 8, 9, 10, 11. The characteristics of the die and the flow patterns in Fig. 1 are common to wire drawing, open-die extrusion, and hydrostatic extrusion. A typical solution presented in Ref 12 expresses the relative drawing stress (σ_{xf}/σ_0) as a function of the input parameters, including the constant friction factor (*m*), as follows:

$$\frac{\sigma_{xf}}{\sigma_0} = \frac{\sigma_{xb}}{\sigma_0} + \dot{W}_i + \dot{W}_s + \dot{W}_f \qquad \textbf{(Eq 4)}$$

where σ_{xf} and σ_{xb} are the front and back tensions, respectively, and where

$$\dot{W}_i = 2\,f(\alpha)\,\ln\frac{R_0}{R_f}$$

is the contribution of the internal deformations,

$$\dot{W}_s = \frac{2}{\sqrt{3}}\left(\frac{\alpha}{\sin^2\alpha} - \cot\alpha\right)$$

is the shear or redundant power term,

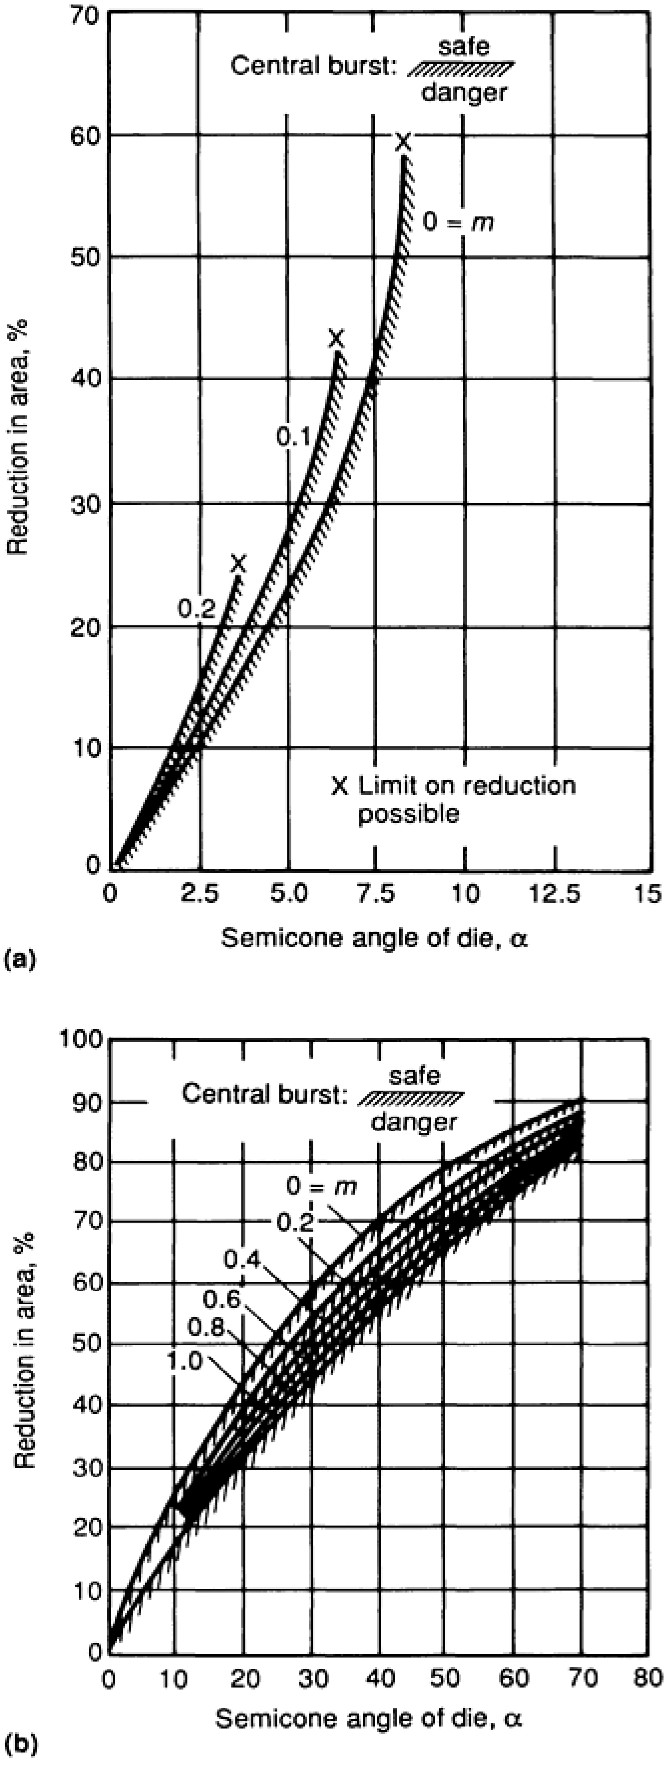
$$\dot{W}_f = \frac{2}{\sqrt{3}}\,m(\cot\alpha)\ln\frac{R_0}{R_f}$$

is the friction term along the conical surface of the die, α is the semicone angle of the die, and

$$f(\alpha) = \frac{1}{\sin^2 \alpha} \left\{ 1 - \cos \alpha \sqrt{\left(1 - \frac{11}{12} \sin^2 \alpha\right)} + \frac{1}{\sqrt{(11 \cdot 12)}} \ln \frac{1 + \sqrt{11/12}}{\sqrt{11/12} \cos \alpha + \sqrt{(1 - (11/12) \sin^2 \alpha)}} \right\}$$

The characteristics of Eq 4 are presented in Fig. 5, where the semicone angle of the die (α) is the abscissa and the relative drawing stress the ordinate. Each curve in Fig. 5 demonstrates a minimum at some optimal angle. For angles smaller than the optimal angle, friction losses ($\dot{W}_f$) are excessive. Friction losses drop with increasing die angles, but redundant power losses increase with increasing die angle. Beyond the optimal angle, excessive distortion occurs with increasing die angles, and the drawing stress increases. The optimal die angle that minimizes the drawing stress is increasing with the increase in reduction and friction. With higher friction it is advisable to use larger die angles.

More expressions have been derived for the determination of process limitations due to tearing, dead zone formation, and shaving (Ref 12). When the phenomenon of central burst is analyzed, one finds that increasing friction deters central burst during extrusion, but promotes it during drawing (Fig. 6).



(a)

(b)

Fig. 6 Criteria for central burst in (a) drawing and (b) extrusion

Hydrodynamic Lubrication. The analysis of hydrodynamic lubrication by Hillier (Ref 4) offers a simple and applicable treatment. This treatment, with a slight modification to account for variations in the thickness of the lubrication film, is presented in Ref 12. The historical development and the state of the art in the application of hydrodynamic lubrication to wire drawing are described in Ref 5 and 6.

In early studies of the equipment design for analysis of hydrodynamic lubrication (Ref 7, 8), a long tube with a narrow gap between the tube and the wire was firmly attached at the entrance side of the die (Fig. 7). The lubrication adhered to the wire and was dragged into the clearance between the tube and wire. At about 3 m/s (600 ft/min), the pressure that built up at the approach to the die reached 70 to 275 MPa (10 to 40 ksi), and the liquid formed a film between the wire and the die (Ref 7).

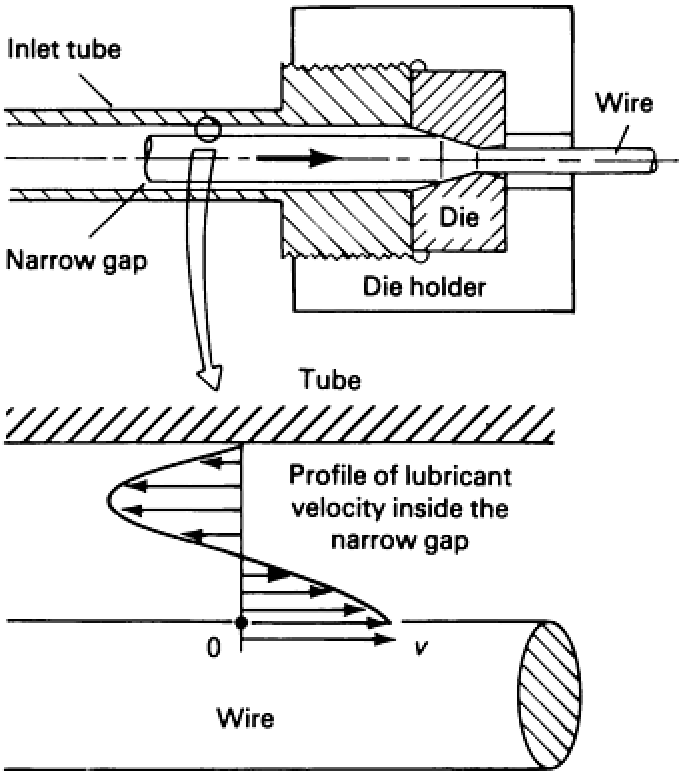


Fig. 7 Schematic of inlet tube for hydrodynamic lubrication

A method whereby the wire passes through a pressurized chamber (Fig. 8) has been studied by several investigators (Ref 9, 10, 11). Using this technique, the lubricating liquid is supplied to the chamber at high pressure by external means (Ref 13). The hydrodynamic effect does not depend entirely on the speed, viscosity, or chamber/tube length. With higher pressure in the chamber, hydrodynamic lubrication can be accomplished with lower velocities and lower fluid viscosities.

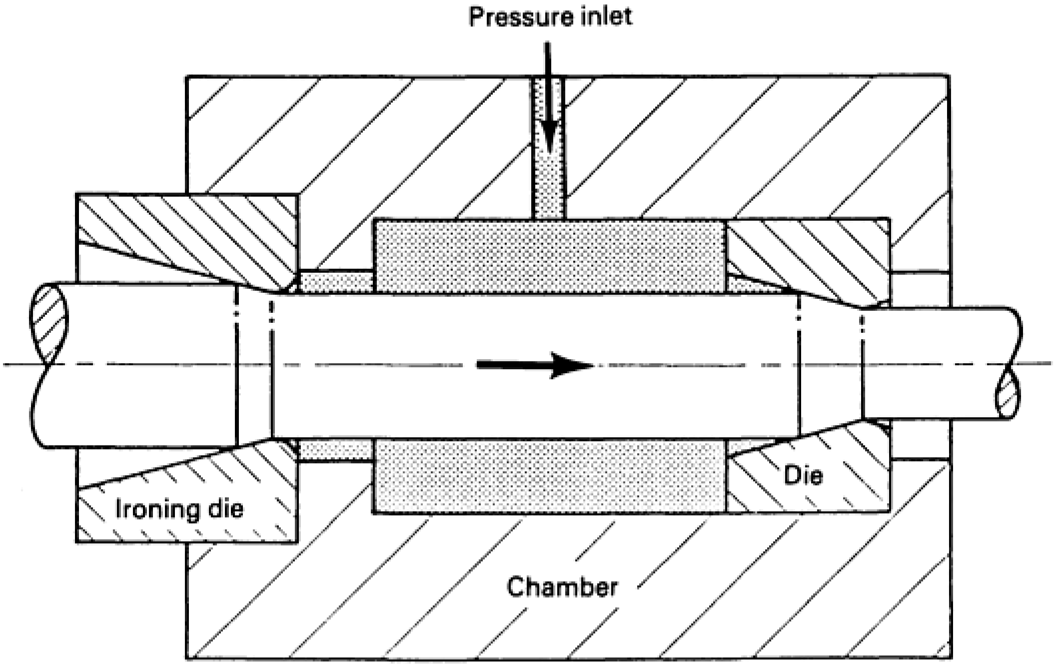

Fig. 8 Schematic of wire drawing through a pressurized chamber

The introduction of hydrodynamic lubrication through a pressure box is shown in Fig. 9. The pressure chamber is inserted into the soap bin of a conventional wire-drawing bull block. The bin preceding the entrance die to the chamber is filled with powdered soap. The wire running through the powder supply drags powder into the chamber through the narrow gap between the incoming wire and the approach die.

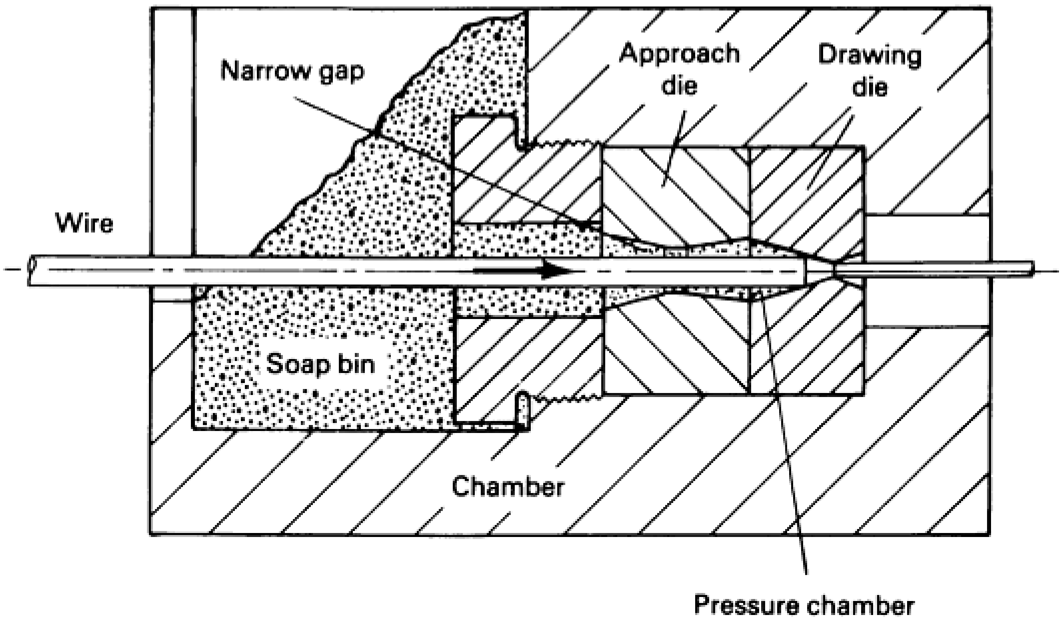

Fig. 9 Set-up for hydrodynamic lubrication with dry soap

When the wire is pulled through the soap, some soap is dragged into the chamber. In the small clearance gap, the soap powder shears, heats because of this shear, and then melts. Liquid lubricating soap then enters the pressure chamber. The faster the wire is drawn, the higher are the temperatures and pressures introduced in the chamber causing hydrodynamic

lubrication. A chemical bond between the wire and the molten soap is also produced. As soon as the wire exits the die, its temperature drops and the soap freezes and forms a layer on the wire. There is now a layer of lubricant performing the duties of hydrodynamic lubrication, that is, keeping full separation between the deforming wire and the next five or six dies. The pressures produced in these chambers, without any external or auxiliary agent, are in excess of 275 MPa (40 ksi).

One difficulty associated with the use of a powdered-soap bin is in maintaining steady drag of powder into the chamber. Inconsistencies in the particle size and dryness of the powder vary the effectiveness of its adhesion to the wire and the quantity of powder dragged. At the extreme, a hollow channel in the powder surrounds the incoming wire and no soap is dragged in. Greater uniformity of the powder and constant agitation (directly or through the box) may improve the performance. Proper surface preparation also may be called for. A recent development utilizes the conventional powder spray system with electrostatically charged particles.

With phosphating, the most popular method, a predetermined layer of a spongy phosphate coating is applied to the surface of the wire electrolytically. This sponge can absorb and retain a large volume of lubrication liquid. Even without the lubricant, the phosphate sponge provides an effective separation between the die and the workpiece, thereby minimizing friction and wear.

The average shear stress and the thickness of the lubricant (Eq 9.19 of Ref 12) are:

$$\frac{\bar{\tau}}{\sigma_0} = 2\,\frac{(\cos^2\alpha/\sin\alpha)\,(1 - R_f/R_0) + L/R_f}{(1/\sin\alpha)\,[(R_0/R_f)^2 - 1] + L/R_f} \times \frac{\left[\dfrac{2v_f}{R_f\sigma_0}\right] f(\alpha)}{[(\cot\alpha\,\cos^2\alpha)/3]\left[1 - \left(\dfrac{R_f}{B_0}\right)^3\right] + \dfrac{L}{R_f}} \qquad \textbf{(Eq 5a)}$$

and

$$\frac{\epsilon}{R_f} = \sqrt{\left(\frac{\eta v_f}{R_f\sigma_0}\right)\frac{1}{f(\alpha)}\left\{\frac{\dfrac{\cot\alpha\,\cos^2\alpha}{3}}{\left[1 - \left(\dfrac{R_f}{R_0}\right)^3\right] + \dfrac{L}{R_f}}\right\}} \qquad \textbf{(Eq 5b)}$$

When the dimensionless factor $\eta v_f/(R_f\sigma_0)$ (called the Sommerfeld number) increases from zero, both the relative average shear stress (τ/σ_0) and the relative thickness of the lubricant (ϵ/R_f) increase. For small values of the Sommerfeld number, the expected thickness of the lubricant is lower than the surface roughness of the material and the die, and hydrodynamic lubrication does not prevail. Therefore, for small values of $\eta v_f/(R_f\sigma_0)$, the actual friction is much higher than that predicted by Eq 5a and 5b (see the Appendix to this article for additional information).

On portions of the apparent contact area, there is actually clearance between the workpiece and the die (Fig. 10). When lubrication is provided, some lubricant is dragged between the two surfaces by the moving workpiece. As the value of $\eta v_f/(R_f\sigma_0)$ increases, more of the voids between the surfaces are filled with lubricant. In addition, more of the pressure load on the workpiece is transmitted through the lubricant, and less load acts to smooth the asperities on th workpiece. Subsequently there is less actual metal-to-metal contact and friction drops. At a sufficiently high value of $\eta v_f/(R_f\sigma_0)$ or beyond this critical value, enough lubricant is dragged into the interface to cause complete separation of the two bodies. No metal-to-metal contact occurs, and full hydrodynamic lubrication with low friction exists. A further increase in $\eta v_f/(R_f\sigma_0)$ will cause a monotonic increase in the friction value and in the thickness of the lubrication layer.

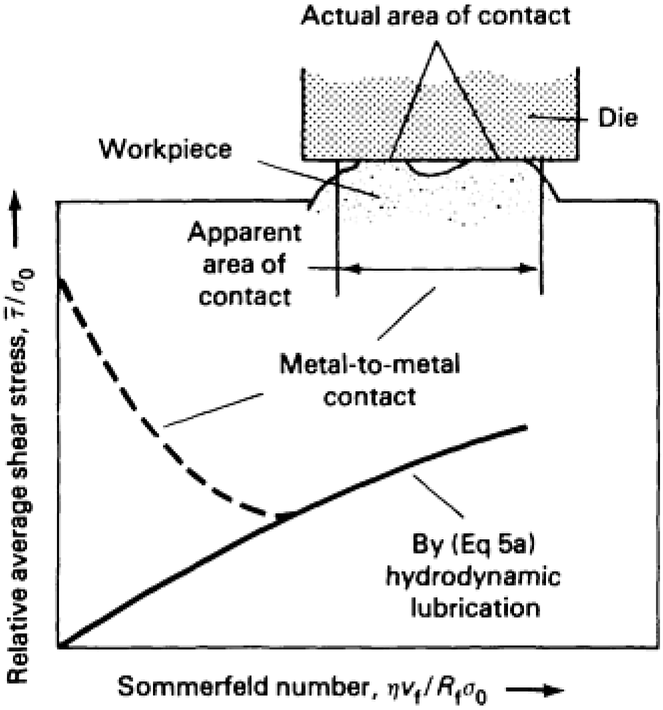

Fig. 10 Effect of Sommerfeld number on relative shear stress, friction, and lubrication characteristics

The onset of hydrodynamic lubrication is distinctly observable. Nevertheless, even when hydrodynamic lubrication prevails, a few occasional high spots on the workpiece will contact the die.

If one assumes an arbitrary value for the film thickness $(\epsilon/R_f)_{cr}$ at the exit as the critical onset value at which hydrodynamic lubrication commences, then by Eq 5aand 5b, the critical Sommerfeld number for the onset of hydrodynamic lubrication is:

$$S_{cr} = \left[\frac{\eta v_f}{\sigma_0 R_f}\right]_{cr} = \frac{f(\alpha)\,(\epsilon/R_f)^2_{cr}}{\frac{\cot\alpha\,\cos^2\alpha}{3}\,[1-(R_f/R_0)^3] + L/R_f} \quad \text{(Eq 6)}$$

from which the critical speed is readily determined. The critical Sommerfeld number decreases with an increase in the bearing length (L/R_f) or with a decrease in the die angle (α) or in the critical film thickness $(\epsilon/R_f)_{cr}$.

More detailed information on the phenomenon of hydrodynamic lubrication during flow through converging dies can be found in Ref 14.

Modeling of Strip Rolling

The following description of rolling is given in Ref 14:

> The main purpose of strip rolling, where the width of the strip is much greater than its thickness, is to reduce the latter. In the following discussions, both rolls have the same radius R_O and surface conditions, are equally powered, and run at the same velocity. They transfer energy to the strip through the friction between the two bodies [Fig. 11]. Under regular conditions, the

strip moves slower than the roll at the entrance and faster than the roll at the exit, with a neutral point in between at which both speeds are equal. The friction force acting between the entrance and the neutral point advances the strip between the rolls, while the friction acting on the exit side from the neutral point opposes the rolling action.

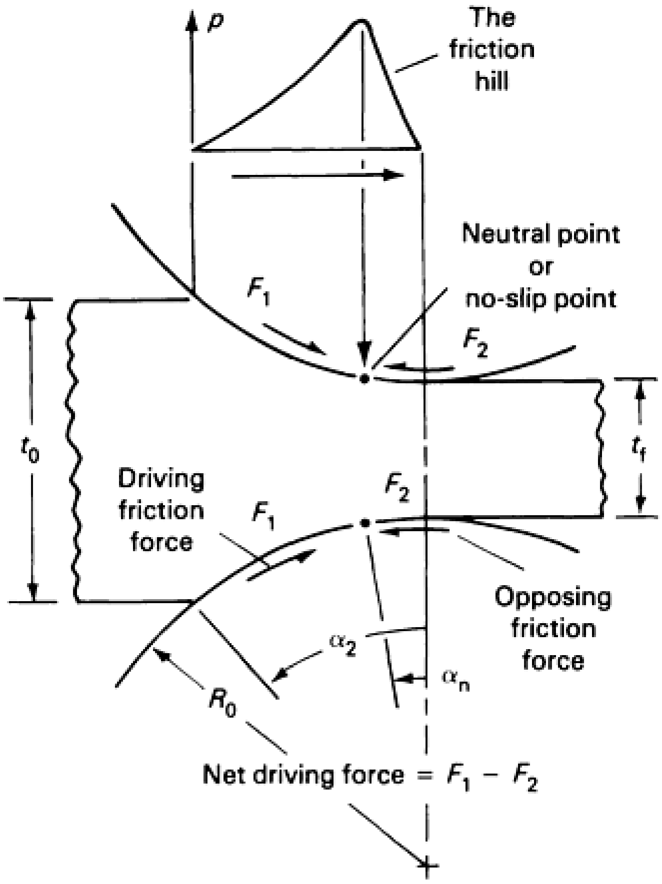

Fig. 11 Positive and negative friction directions during strip rolling

As reduction increases, the position of the neutral point approaches the exit. When the maximum possible reduction is attempted, the neutral point reaches the exit. This situation is very unstable. Any slight increase in reduction or drop in friction will cause the strip to stop moving and the rolls to start skidding over the strip. The distribution of the pressure between the rolls and the strip is described by the "friction hill" in Fig. 11. The peak of the friction hill occurs at the neutral point.

Hydrodynamic Lubrication. Lubricant is applied at the entrance side of each pair of rolls (stand). At the entrance side, the layers of lubricant that are in contact with the rolls or with the strip adhere to their respective metal surfaces and move inward toward the exit. An inlet entry zone, which is shaped as a wedge, also forms. The outer layers of this wedge move inward and a return flow of lubricant (in the form of an eddy current) occurs between the surface layers (Fig. 12a). At low rolling speeds, the entry zone wedge is negligibly small. With increasing rolling speeds (or increasing liquid viscosity or increasing values of the Sommerfeld number) the wedge increases both in thickness and depth. The Sommerfeld number is:

$$S = \frac{\text{Viscosity} \cdot \text{Strip exit velocity}}{\sigma_0 \cdot t_f} \quad \textbf{(Eq 7)}$$

With increasing values of *S*, the point where metal-to-metal contact between the strip and the rolls is established moves further toward the exit.

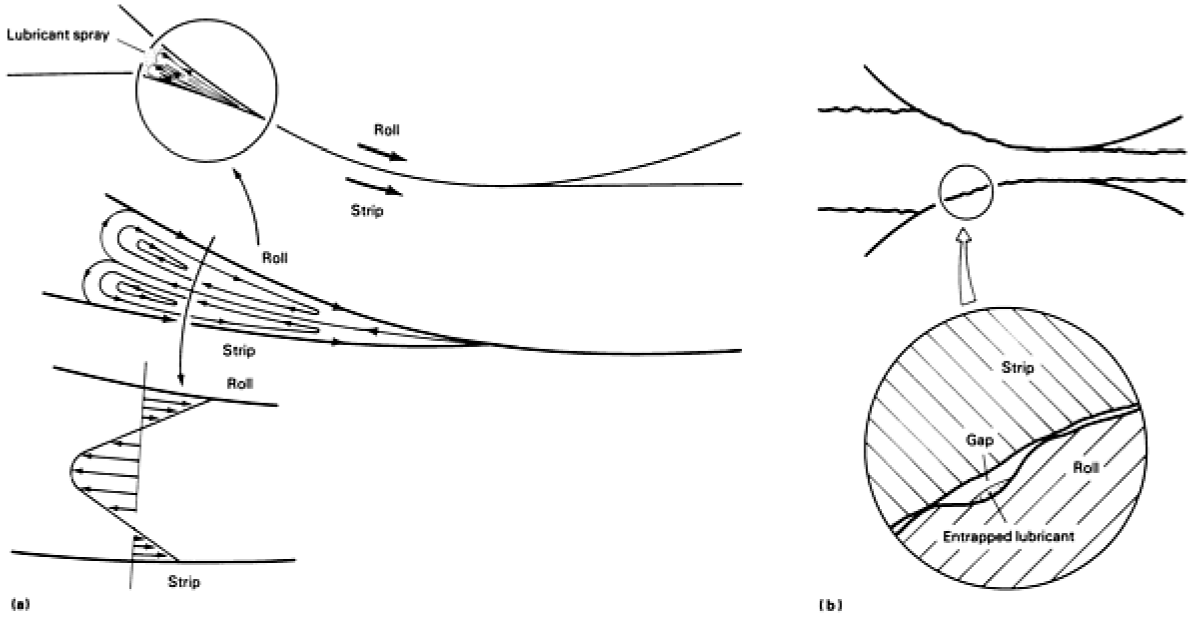

Fig. 12 The lubrication entry zone (a) and surface irregularities (b) associated with strip rolling

The surfaces of both rolls and strip are not perfectly smooth surfaces in that they contain irregularities in the form of peaks (or crests) and valleys (cavities) (Fig. 12b). Some lubricant passes from the entrance to exit side through the labyrinth of channels created by these irregularities. As the strip is deformed, the crests are flattened and the entrapped lubricant is pressurized in the diminishing volume of the cavities. At slow rolling speeds, the excess lubricant in the diminishing cavity space is squeezed to flow back into the entry zone. At higher rolling speed, the escape of excess fluid from the diminishing gap of the labyrinth between the rolls and the strip is relatively slower. The entrapped lubricant is then pressurized and causes partial separation between the rolls and the strip. At low speed, pressure is transmitted from the rolls to the strip through metal-to-metal contact. At higher speeds, more of the pressure is transmitted through the entry zone and through the entrapped lubricant. As the pressure transmitted through metal-to-metal contact is reduced with higher speeds, the friction is decreased. Eventually, at high speeds, no metal-to-metal contact exists.

When conditions for complete hydrodynamic lubrication are reached (Fig. 13), friction is at its minimum value. Therefore, with increased speeds, high shear rates are created in the liquid where the shears stress is proportional to the shear strain rate to the second power, and friction rises at a mild rate. Friction values are much lower when hydrodynamic lubrication prevails than when metal-to-metal contact is prevalent.

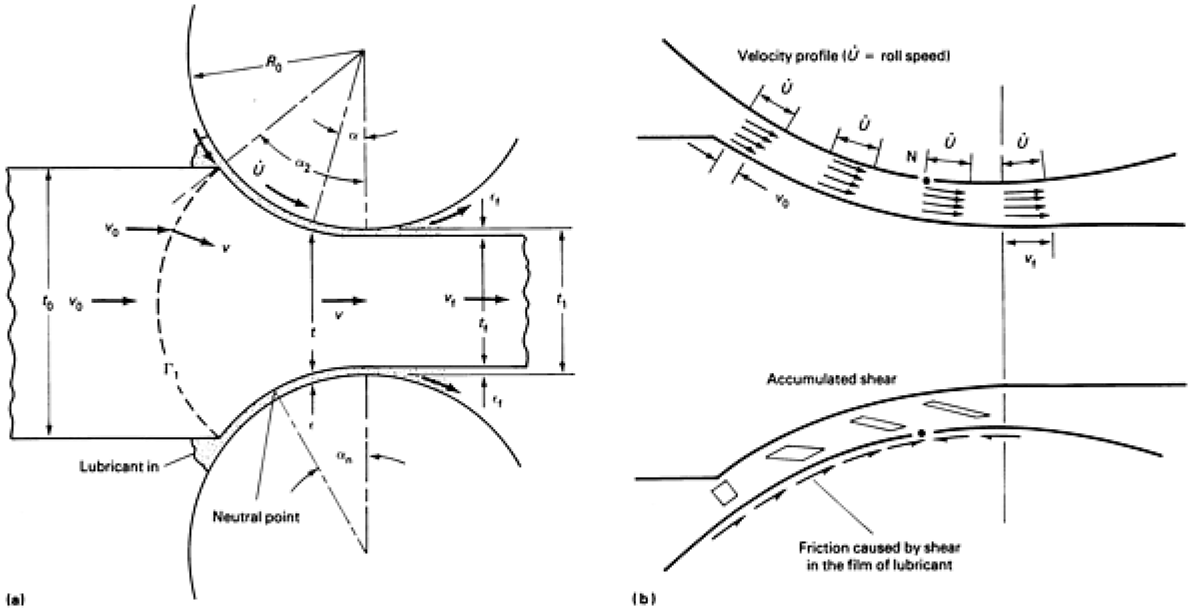

Fig. 13 Hydrodynamic lubrication during strip rolling. (a) Overall schematic. (b) Shear in the lubricant film

With increasing speed the friction hill effect is also reduced, and roll separation force and roll flattening become less pronounced. With reduced roll separation force, the elastic stretching of the mill as well as roll bending and roll flattening are reduced, causing the gap between the rolls to decrease. With the increasing thickness of the lubricant film and reduced mill flexing, the thickness of the emerging strip reduces. The actual gap between the rolls is larger than the thickness of the strip by twice the film thickness. Because friction drag decreases with increasing rolling speed, the neutral point approaches the exit and forward slip is reduced.

Two critical points may now be reached. The first is skidding due to insufficient friction drag while the second is the establishment of hydrodynamic lubrication. If the strip is thin enough, hydrodynamic lubrication is reached first and skidding will not develop. When speed continues to increase after hydrodynamic film lubrication is established, friction drag and forward slip, which have already reached their respective minimum points, begin to increase (see lines 1 to 4 in Fig. 14). For increasing values of strip thickness (lines 2, 3, and 4 in Fig. 14), the forward slip decreases and the critical value of roll speed at which the neutral angle and forward slip reach a minimum is increased. The values of the neutral angle and forward slip at which hydrodynamic lubrication begins increase with increasing thickness values.

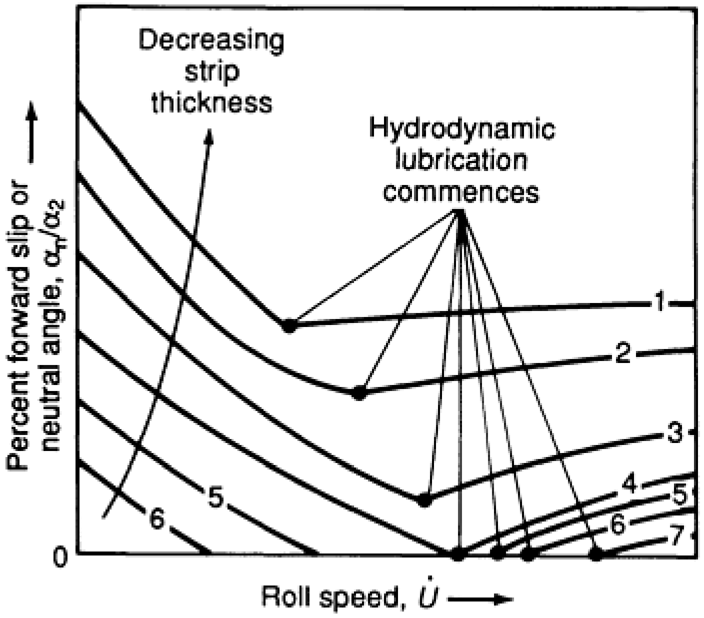

Fig. 14 Forward slip and position of the neutral point versus rolling velocity. See text for explanation of numbered curves.

At a critically high strip-thickness value, hydrodynamic lubrication commences when forward slip and the value of the neutral angle are zero (line 4 in Fig. 14). When the thickness of the strip is above the stated critical value, for lines 5 to 7, friction drops to below the minimum required for rolling before hydrodynamic lubrication can be established. Skidding then commences at the critical roll speed. It can be observed that at higher values of speed, referred to here as the minimum required speed, rolling with hydrodynamic lubrication may be reestablished. It should also be noted that the minimum required speed can be reduced by the use of lubricants of higher viscosity.

The following variations in the friction hill are expected with increasing speed:

- The peak of the friction hill gets lower and, together with the neutral point, shifts closer to the exit
- The entry zone expands and the corner of the liquid wedge moves further away from the entrance and closer to the exit. The meaningful slope of the friction hill on the entrance side starts at the area around the tip of the entry zone
- The roll separation force gets lower
- Roll bending/flattening and mill stretching are reduced
- Strip thickness is reduced
- For relatively thick strip (or low dry-friction value, m_o), a critical roll speed of the first kind may be reached. When this occurs, friction becomes so low (below the critical value required) that the neutral point is at the exit and skidding will commence (lines 5 and 6). At the moment that skidding begins, the strip stops
- For relatively thin strip another critical speed (the critical speed of the second kind) can be reached, even before skidding commences. When this occurs, the point of the entry zone will reach the exit and hydrodynamic lubrication will commence. A further increase in speed will cause a thicker lubricating film to separate the rolls from the strip and make the rolling more stable (see lines 1, 2, and 3 in Fig. 14)
- For relatively thick strip, even when a critical speed of the first kind commences first, a further increase in speed may ultimately produce a critical speed of the second kind and reestablish hydrodynamic lubrication (see lines 4 to 7 in Fig. 14)

Changes in the entry zone, the friction hill, the neutral point, and strip thickness as a function of speed for thick and thin strip are shown schematically in Fig. 15.

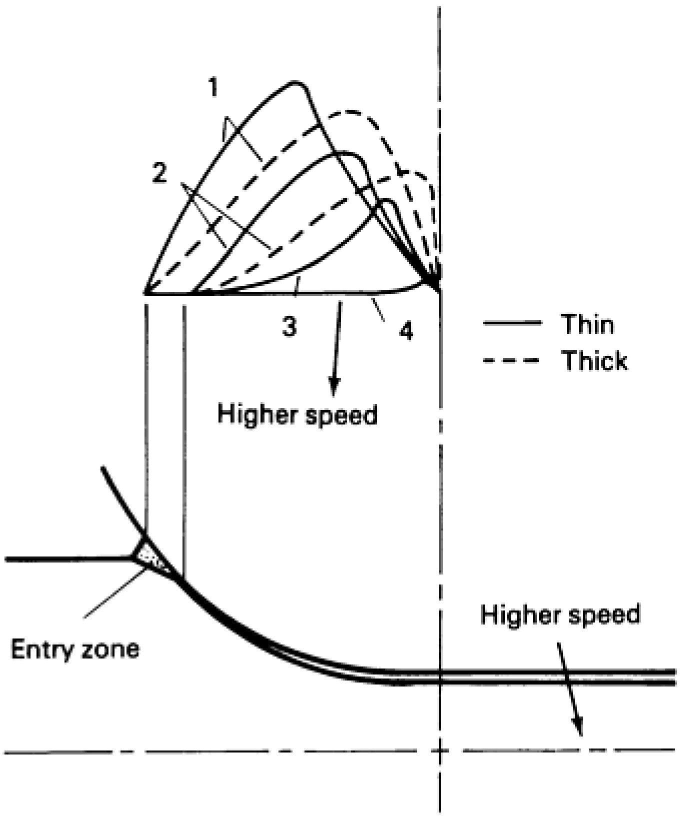

Fig. 15 Variations in the "friction hill" versus speed. The parameters *m, R_O*, σ_{xb}, σ_{xf}, and percent reduction are constant.

Measurement of Friction

Ring Forging. Figure 16 shows the deformation characteristics of two identical rings reduced in height incrementally by the same amount (ΔT_0). One ring is lubricated well and is pressed with low friction, while the unlubricated ring is pressed with high friction. The characteristic behavior is drastically different in the two cases. In the low-friction operation, the inner radius (R_i) of the ring increases in size, while in the high-friction operation, the inner radius of the ring decreases in size.

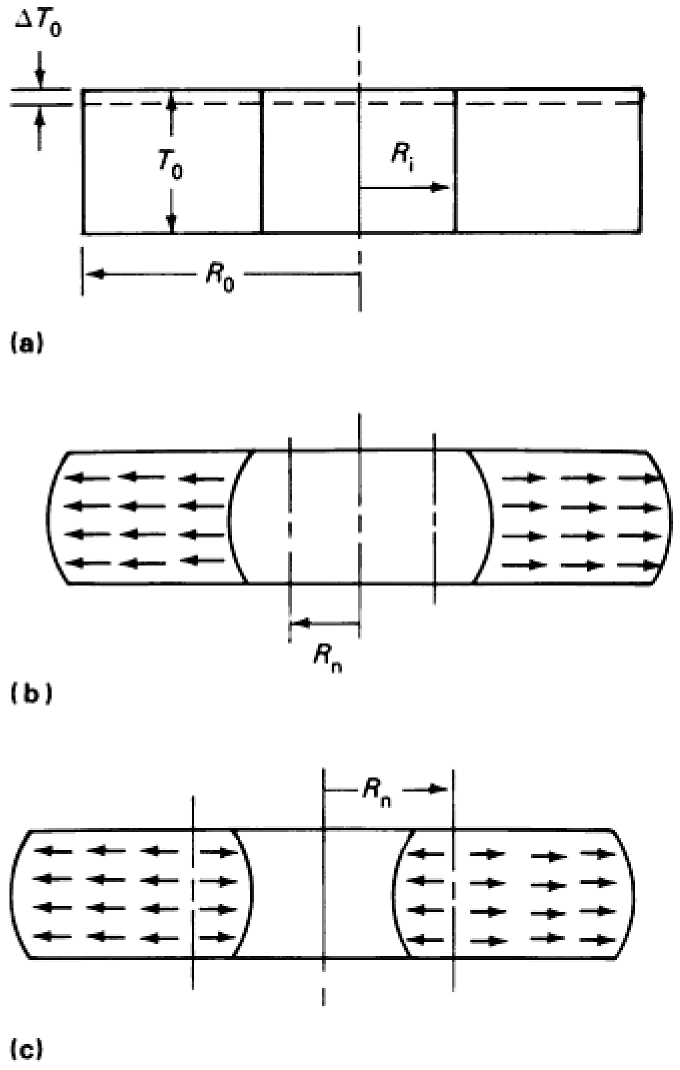

Fig. 16 Deformation behavior during ring forging. (a) Original ring. (b) After deformation with low friction. (c) After deformation with high friction

The bulge direction changes accordingly, minimizing relative sliding of the workpiece over the platens. The outer radius (R_o) expands in both cases.

In describing the flow pattern, consider an imaginary cylinder of radius $R = R_n$, where R_n is the neutral radius. In the high-friction ring, all points with radius $R > R_n$ move outward and their radial positions increase while all points with radial position $R < R_n$ are moving inward. Points on the radius $R = R_n$ are stationary, and hence this radius is called the neutral radius. In the high-friction ring of Fig. 16, the neutral radius resides in the ring itself, so that the neutral radius is larger than the inner radius ($R_n > R_i$). On the low-friction ring, the neutral radius is smaller than the inner radius. Therefore, all points on the low-friction ring are in a radial position $R > R_n$. The increase in outer radius for higher friction is smaller than that for low friction.

When $R_n \leq R_i$, the position of the neutral radius (R_n) can be determined as follows (Ref 15):

$$\left(\frac{R_n}{R_o}\right)^2 = \frac{\sqrt{3}}{2}\,\frac{1-(R_i/R_o)^4\,x^2}{\sqrt{x(x-1)\,[1-(R_i/R_o)^4 x]}}$$

where **(Eq 8a)**

$$x = \left\{\frac{R_o}{R_i}\exp\left[-m\,\frac{R_o}{T}\left(1-\frac{R_i}{R_o}\right)\right]\right\}^2$$

When $R_i \le R_n \le R_o$ the position of the neutral radius is found by successive approximations from:

$$2m\,\frac{R_o}{T}\left(1+\frac{R_i}{R_o}-2\,\frac{R_n}{R_o}\right) + \ln\left|\left(\frac{R_i}{R_o}\right)^2 \frac{(R_n/R_o)^2+\sqrt{3+(R_n/R_o)^4}}{(R_n/R_o)^2+\sqrt{3\,(R_i/R_o)^4+(R_n/R_o)^4}}\right| = 0$$

(Eq 8b)

When a ring is forged and all the geometrical parameters, including the value of R_n, are determined experimentally, then the friction factor *m* is calculated, using Eq 8a and 8b. References 16, 17, 18, 19, 20, 21, 22, 23, 24, 25 provide additional information on ring test friction analysis, as follows:

Flow through Conical Converging Dies. Equation 4 and Fig. 5 show that during flow through conical converging dies, the forces required are dependent on the die cone angle. There always exists an optimal cone angle that requires the minimum force. With a cone angle smaller than the optimal cone angle, the drawing or extrusion force is high because the length of contact between the die and material is high, causing excessive friction losses. With a die of an angle larger than the optimal, the distortion is excessive, causing high forces.

When Eq 4 is differentiated with respect to α and the derivative is equated to zero, the resulting equations express implicitly the relation between the semicone angle of the die, which minimizes the drawing or extrusion stresses and the other variables.

Experimentally the optimal die angle can be determined by following the procedure offered by Wistreich (Ref 26). Several dies of identical exit diameter are used, each of different entry cone angle. Rods of identical material, treatment, diameter, surface condition, and lubrication are formed through the dies. The forming force (or pressure) is measured. A plot (Fig. 5) of the drawing or extrusion stress is obtained as a function of cone angle, assuming that reduction, friction, and flow stress are all constant. The point of minimum stress indicates on the abscissa the value of the optimal die angle (α_{opt}) for the experienced reduction and friction. When a second batch of rods of different initial diameter is drawn (or extruded), different values for the optimal die angle are obtained. The friction that prevails during each run of the experiment can be computed as follows:

$$m = 2\left\{\frac{1 - \alpha_{opt}\cot\alpha_{opt}}{\ln(R_0/R_f)} + \sqrt{3}(\sin\alpha_{opt}) \times \left[\sqrt{1 - \left(\frac{11}{12}\right)\sin^2\alpha_{opt}} - (\cos\alpha_{opt})f(\alpha_{opt})\right]\right\} \quad \textbf{(Eq 9)}$$

Strip Rolling. Avitzur (Ref 27, 28, 29) has developed an experimental procedure for the determination of the coefficient of friction during strip rolling. The expressions derived for these studies can be used to determine friction values when skidding commences.

With the assumption of a constant shear factor (see Eq 2 in this article), Eq 22 from Ref 29 reads:

$$m = \sqrt{\frac{t_f}{R_O}} \cdot \frac{\ln\left(\frac{t_0}{t_f}\right) + \frac{1}{4}\sqrt{\frac{t_f}{R_0}}\sqrt{\frac{t_0}{t_f} - 1} + \sigma}{\tan^{-1}\sqrt{\frac{t_0}{t_f} - 1}} \quad \textbf{(Eq 10)}$$

where

$$\sigma = \frac{\sigma_{xb} - \sigma_{xf}}{\frac{2}{\sqrt{3}}\sigma_0}$$

When skidding occurs, the following have to be measured: relative front $\sigma_{xf}/(2\sigma_0/\sqrt{3})$ and back $\sigma_{xb}/(2\sigma_0/\sqrt{3})$ tensions, roll radius (R_O), and incoming (t_0) and emerging (t_f) strip thicknesses. The value of friction is computed then by Eq 10. When no front or back tensions are applied, skidding can be induced only with small roll diameter. When $\sigma_{xf} = \sigma_{xb} = 0$, Eq 10 reduces to:

$$m = \sqrt{\frac{t_f}{R_O}}\,\frac{\ln(t_0/t_f) + (1/4)\sqrt{t_f/R_O}\sqrt{t_0/t_f - 1}}{\tan^{-1}\sqrt{t_0/t_f - 1}} \quad \textbf{(Eq 11)}$$

When $\sigma_{xf} = \sigma_{xb} = 0$, only the geometrical parameters t_0, t_f, and R_O have to be measured and a rolling mill with no instrumentation can be used for the evaluation of the coefficient of friction.

When $\sigma_{xf} = \sigma_{xb} = 0$ and skidding occurs, the following relation is proposed:

$$\alpha_2 = 2\mu \quad \textbf{(Eq 12)}$$

where α_2 is the contact angle. By replacing α_2 by strip thickness and roll radius, the following is written:

$$\mu = \left(\frac{1}{2}\right)\sqrt{t_f/R_O}.\sqrt{(t_o/t_f) - 1} \quad \textbf{(Eq 13)}$$

In a study detailed in Ref 27, strips of identical thickness were rolled with varying gaps between the rolls. The strip was pushed between the rolls to start the operation. If the full length of the strip passed the rolls, the gap was narrowed and

another strip fed in. This procedure went on until skidding started. When skidding started, the original and final thickness of that strip and the radius of the rolls were recorded. Another batch of strips with smaller original thickness, but the same annealed and surface conditions, was then rolled with the same lubricant. The previous procedure was repeated until skidding started. Several batches of various original strip thickness were tested. The friction values were computed using Eq 11 for each batch.

Appendix: The Wave Model

The model presented in Ref 30 has provided a quantitative description of Coulomb's (Ref 31) and Amonton's (Ref 32) characterizations of friction for moderate loads. This model is based on the "wave model" concept of the mobility of the asperities.

In his *History of Tribology* (Ref 33), Dowson explains the early recognition of the cause-and-effect relationships between surface irregularities and the resistance to sliding. Dowson summarizes Coulomb's ideas on the combined effects of the then-prevailing thoughts on cohesion and surface irregularities. Coulomb recognized that irregularities caused resistance to sliding, and sketched the opposing asperities as enmeshed fibers folding over and filling the voids previously occupied by opposing surfaces as sliding takes place. However, as Dowson points out, the energy dissipation was not then recognized because the science of thermodynamics had not yet been born. The theory of folding asperities would later be replaced by the concept of the mobile ridge.

Leslie observed that asperities on the harder surface (called "wedges" here) push on the opposing ridges of the softer surface. Unlike the popular theory of those days that a climbing motion occurred, ignoring the inevitable downhill companion motion, Leslie suggested that the softer ridge was pushed into and under the surface, producing a perpetual uprising ahead of the wedge of the harder surface and resulting in an endless climb (Ref 34). Evidence for the mobility can be seen in Fig. 17, which is reproduced from Ref 35. Simulations of plastic deformation of the asperities by the slip line and the upper bound techniques are presented in Ref 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49.

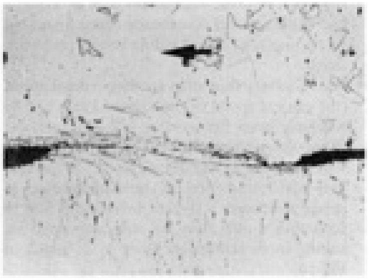

Fig. 17 Photomicrograph showing the mobility of asperities and the thin layer of deformations. Source: Ref 35

Presently, the model of the mobile ridge and the trapped lubricant on the interface between two sliding surfaces is examined quantitatively to provide the characteristics shown in Fig. 4(a) and of the Stribeck curve (Ref 50) shown in Fig. 4(b). To model the interaction between the asperities, the photomicrograph shown in Fig. 17 can be replaced by the illustration of wedge flow in Fig. 18. The tip of the wedge on the surface of the die indents into the surface of the workpiece, producing a ridge. Sliding between the two surfaces is made possible by the ridge being suppressed under the wedge when it passes under it. The material ahead of the contact is pushed upward, and the ridge experiences a wave motion. The lubricant trapped between the stationary wedge and the moving ridge is being forced to move with the solid that it contacts, and thus experiences an eddy flow. Figure 19 shows theengineering model for the flow depicted in Fig. 18. Here the deformation region of the ridge is described by three rigid triangles, each moving with respect to each other, through a sliding motion along their interfaces. In Ref 45, the triangles move in a linear motion, while in later studies (Ref 47), they move in the more general rigid-body motion (rotational motion).

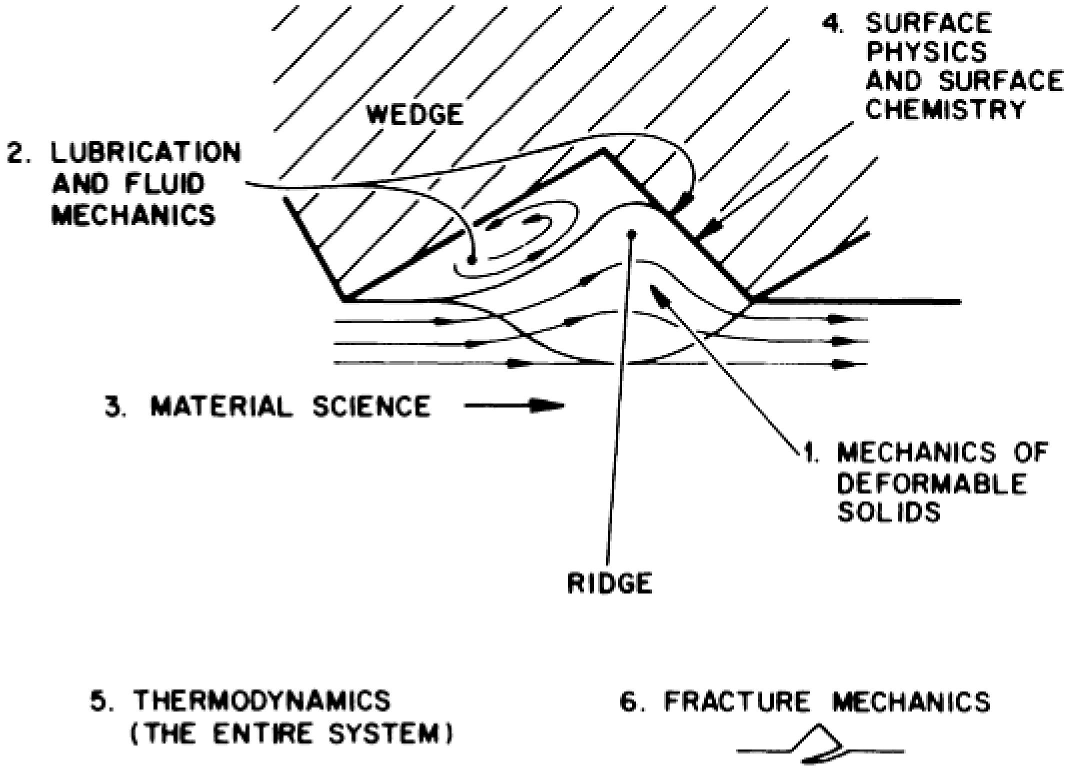

Fig. 18 Disciplines affecting wedge flow

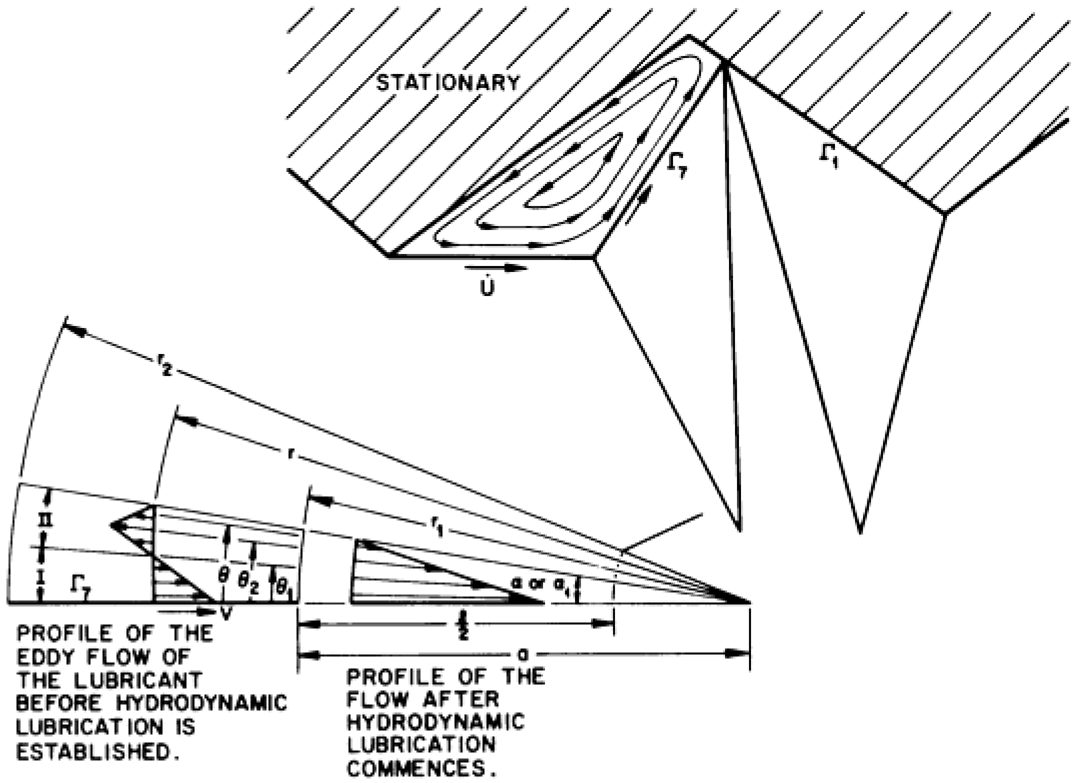

Fig. 19 Engineering model for wedge flow showing velocity field in the lubricant

The Characteristics of Friction

The model shown in Fig. 19 was used in Ref 44 and 45 to obtain friction characteristic by the upper-bound approach. The relationship between the friction force ($F/\sigma_0\ell$) and relative pressure ($p/\sigma_0\ell$) with different input parameters is given in Fig. 20 and 21. In Fig. 20, the characteristics of the global friction at the ordinate are described as a function of the local friction factor (m_0 as the input parameter, while the angle of the asperity (α_1) is constant at 5°. In Fig. 21, the angle of the asperity (α_1) is the parameter, while the local friction is constant at m_0 = 0.2. Global friction increases first linearly with increasing pressure and then tapers off asymptotically to a constant value. Global friction also increases with increasing values of local friction and with increasing asperity inclination.

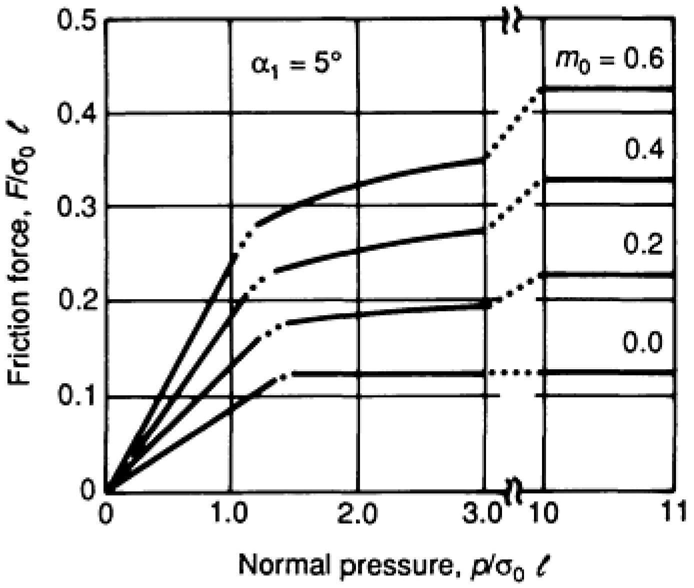

Fig. 20 The relation between the friction force and normal pressure with friction factor (m_0) as a parameter

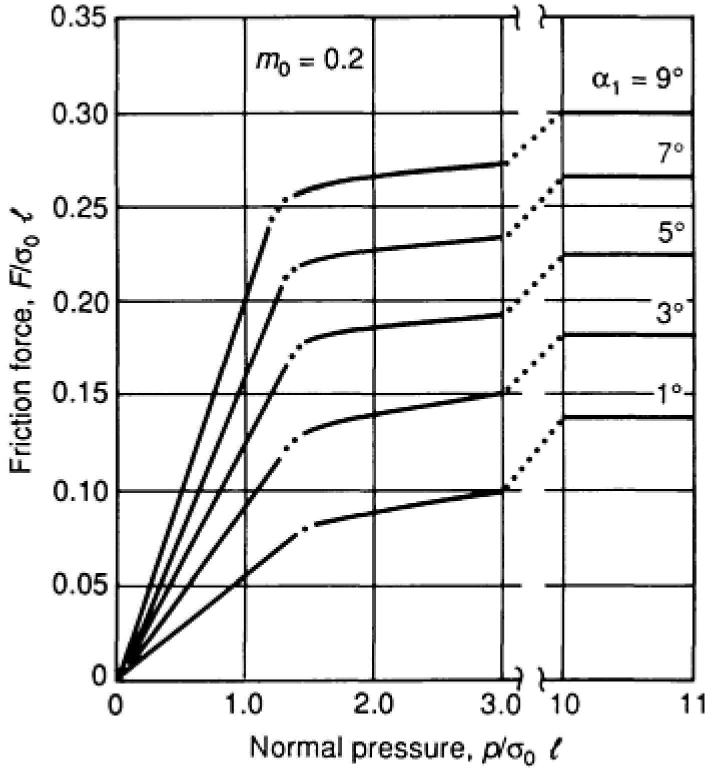

Fig. 21 The relation between the friction force and normal pressure with wedge angle (α_1) as a parameter

One observation worth nothing is that even when the local friction (m_0) is assumed to be zero, the global friction (m) is not zero. Resistance to sliding exists due to the deformation of the asperities at the surface. Another observation is that the global friction factor never reaches the value of $m = 1$. For high values of m_0 and/or of α_1, the wave model is replaced by the ridge shear failure model shown in Fig. 3(a).

The range of the resulting changes in the power consumed through the mobility of the ridge, and through shear losses in the trapped lubricant between the asperities due to the eddy flow, is wider than shown in Fig. 4(b) as demonstrated in Ref 51, 52, 53, 54. This complexity is complexity is evident from the calculated value of the global friction factor (m) as presented in Ref 51, and Fig. 22 and 23. In Fig. 22, the abscissa is the Sommerfeld number (S), where the dimensionless Sommerfeld number combines the velocity of sliding (v_0), the viscosity of the lubricant (η), the strength of the material (σ_0), and the length of the asperity (ℓ_0), in the form of $S = v_0\eta/(\sigma_0\ell_0)$. The ordinate is the global friction factor (m) and the parameter is the normal load (p) on the interface between the two sliding bodies. The local friction factor is $m_0 = 0.6$ and the inclination of the asperity is $\alpha_1 = 1$ °. For the lower load values ($p = 2$), the characteristic behavior shown in Fig. 4(b) is observed. The static friction factor value of m is highest when no sliding occurs. With increasing sliding speeds friction drops. Higher pressure values produce higher resistance to sliding. For higher pressures, the ridge is higher, and therefore the thickness of the film of the trapped lubricant is thinner. Furthermore, increases in the Sommerfeld number are not as effective in reducing the height of the ridge. Thus, for high pressures, the lubricant film remains thin even with increasing Sommerfeld number.

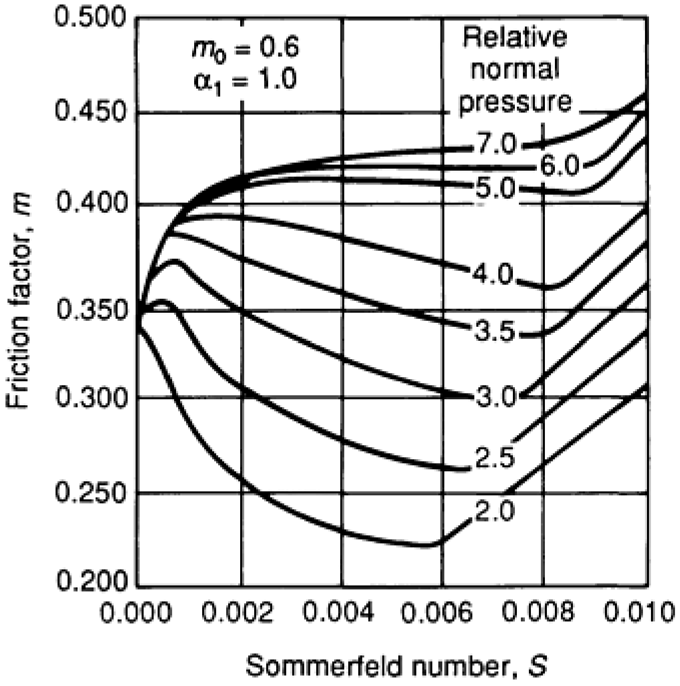

Fig. 22 Global friction versus Sommerfeld number at high pressure

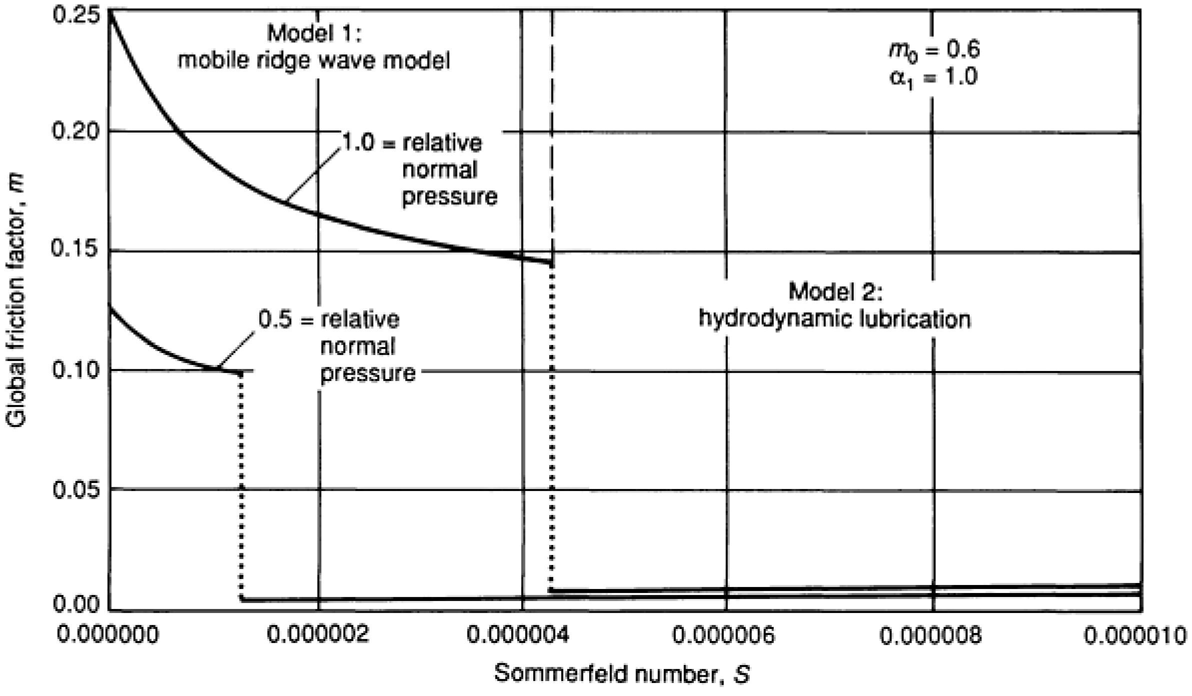

Fig. 23 Transition from model 1 (the mobile ridge) to model 2 (the hydrodynamic lubrication) friction mode

The two inserts in the lower left-hand corner of Fig. 19 display boundary lubrication (by model 1 with ridge mobility) and hydrodynamic lubrication (by model 2 with full film separation between the tool and the workpiece). The transition from model 1 (mobile ridge) to model 2 (hydrodynamic lubrication) is illustrated in Fig. 23. For small angles (α_1 = 0.1) and low pressure (p/σ_0 = 0.5), a gradual decrease in the global friction value (*m*) with increasing Sommerfeld number (*S*) is observed. When the critical value of the Sommerfeld number is reached and hydrodynamic lubrication commences, the friction drops abruptly to $\leq$2% of the static value.

The drastic friction drop presented by the wave model has also been observed in other treatments of the onset of hydrodynamic lubrication during wire drawing and rolling (Ref 12). However, in the present study, it is worth noting that the abrupt drop in friction when hydrodynamic lubrication commences is expected only if all asperities are identical. Asperities come in all sizes and shapes, and the critical Sommerfeld number for each occurs at a different value. Thus, the actual decrease in *m* is gradual. The increase in *m* with further increase in *S* is very slight.

Additional information on the wave model, including comparisons of some of the studies/results described in this article, can be found in Ref 54, 55, 56.

Appendix: Static and Kinetic Friction Coefficients for Selected Materials

Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory

THE DEFINITIONS for static and kinetic friction coefficients are given in the Glossary of this Handbook. The friction coefficient between solids sliding, or about to slide, over one another under the influence of a nonzero normal force is a function of several factors whose relative contributions vary on a case-by-case basis:

- Composition of the materials
- Surface finish of each solid
- Nature of the surrounding environment
- Force holding the solids in contact (load)
- Velocity of relative motion
- Nature of the relative motion (for example, unidirectional, back and forth, steady, variable, and so on)
- Nature of the contact (conforming versus nonconforming surfaces)
- Temperature of the interfacial region
- Prior sliding history of the surfaces
- Characteristics of the machine and fixtures in which the materials are affixed

No single source has generated a comprehensive list of friction coefficients for materials under identical testing conditions; therefore, nearly all existing handbooks rely on compilations of data produced under a variety of testing conditions. Readers should be aware of this shortcoming and use the values only as very approximate guides, unless their applications are exactly the same as those methods used in generating the data.

The five tables of friction coefficient values in this Appendix contain both static and kinetic friction coefficients. They are arranged by material type as follows:

- Table 1: metals on metals
- Table 2: ceramics on various materials
- Table 3: polymers on various materials
- Table 4: coatings on various materials
- Table 5: miscellaneous materials

It should be emphasized that the data in the tables are for unlubricated solids at room temperature and in ambient air. The reference list provided with each table lists both the sources of the data for the table and a brief description of the testing conditions used to generate these data, if such information was available in the reference. If accurate friction information is required for a specific application, the use of carefully simulated conditions or instrumentation of the actual machine should be conducted in lieu of using tabulated values because even a small change in contact conditions (for example, sliding speed or relative humidity for some materials) can result in a marked change in the measured or apparent friction coefficient.

Introduction to Lubrication

Herbert S. Cheng, Northwestern University

LUBRICATION is introduced between two sliding solids by adding a gaseous, liquid, or solid lubricant at the sliding interface in order to reduce friction and wear, and to carry away heat and debris generated during the sliding process. Lubrication processes can take many different forms, depending on the gross geometry of the contacting bodies, the roughness and texture of the sliding surfaces, the contacting load, the pressure and temperature, the rolling and sliding speeds, the environmental conditions, the physical and chemical properties of the lubricant, the material composition, and the properties of the near-surface layer.

The two basic geometries for lubricated surfaces are conformal and counterformal (Fig. 1). Conformal surfaces usually appear in sliding journal and trust bearings, machine guideways, and seals. In conformal bearings, surfaces are usually separated by a thick oil or gas film generated hydrodynamically by the surface velocities or hydrostatically by an externally pressurized lubricant. These surfaces usually operate in the regime of thick-film hydrodynamic or hydrostatic lubrication. Lubrication performance--as measured by film thickness, pressure, and friction--can be predicted readily from analyses based on the Reynolds equation (Ref 1). The major lubricant properties of importance for conformal surfaces include viscosity and temperature-viscosity coefficient. Typical conformal bearings include engine main-shaft bearings; turbine; compressor, and pump bearings; and computer head/disk contacts.

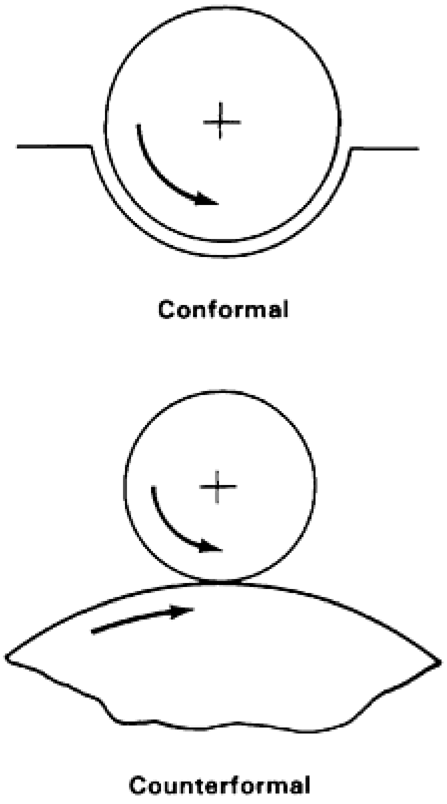

Fig. 1 Geometry of conformal and counterformal contacts

Lubrication of counterformal contacts takes place in an extremely small concentrated area known as the Hertzian conjunction. In these contacts, film thickness is very thin, of the same order of the surface roughness, and lubricant pressure is very high. Lubricant performance is affected strongly by the elastic deformation of the bearing surface. The lubricant film thickness and pressure and their distribution in the conjunction can be determined by elastohydrodynamic theories (Ref 2). Because of the extremely high pressure in the conjunction, the pressure-viscosity coefficient has a major

effect in generating the lubricant film at the inlet, and the temperature-viscosity coefficient has a strong influence on both temperature and friction for sliding contacts. These significant lubrication properties are discussed in more detail in the article "Liquid Lubricants" in this Section. Recent molecular-level studies indicate that the structure and properties of the first few molecular layers of a lubricant can be different from those of the bulk liquid.

Surface roughness and its lay orientation with respect to surface motion can have a significant influence on lubrication performance in the regime of mixed lubrication, where the load is shared between the lubricant pressure and the asperities. Roughness effects are particularly important in counterformal contacts because the majority of these contacts operate in mixed lubrication. Progressive wear failure and sudden scuffing failure are dependent on the lubrication process influenced by the micro-roughness geometry; they are also influenced by the contact temperatures in the conjunction. Detailed information about mixed lubrication can be found in the article "Lubrication Regimes" in this Section; contact temperature calculations are discussed in the article "Frictional Heating Calculations" in this Volume.

Thick-film lubrication deteriorates rapidly under combinations of extreme pressure, extreme temperature, low rolling speed, and high sliding speed. For these conditions, the lubricant film thickness is extremely small in comparison to the surface roughness, and the contacts operate in the regime of boundary lubrication. Straight mineral oils do not offer much relief from friction and wear. Additives must be relied upon to modify friction, reduce wear, and reduce oxidation of the lubricant. The functions of commonly used additives are explained in the article "Lubricant Additives and Their Functions" in this Section.

In extreme environmental conditions, such as elevated ambient temperatures above 500 °C (930 °F) or vacuum environments, conventional liquid lubricants often become less effective because of their tendency to rapidly oxidize or decompose at elevated temperatures and their tendency to vaporize or creep away from lubricated surfaces under high vacuum. The use of solid lubricants is often called for in these situations. Over the last four decades, the use of solid lubrication has grown steadily, largely due to sustaining efforts at the NASA Lewis Research Center and research supported by the U.S. Air Force. These efforts are discussed in the articles "Solid Lubricants" and "Lubricants for High-Vacuum Applications" in this Section.

Lubrication in counterformal contacts also is influenced by the ratio of the sliding velocity to the rolling velocity, otherwise known as the slide-to-roll ratio. The film thickness is generated primarily by the rolling velocity, which draws the lubricant into the conjunction. Sliding velocity has no effect on film generation unless the inlet viscosity is reduced significantly by the heat generated by sliding. The friction and contact temperature in the conjunction is influenced strongly by the sliding velocity. A lubricant in sliding contact usually behaves like a sheet of glassy solid sheared at the midlayer. Contacts that operate at a high slide-to-roll ratio generate a higher contact surface temperature in the conjunction and have a lower resistance to scuffing. This condition exists in gear teeth contacts at the beginning of the engagement between a pair of teeth; in cam follower/lobe contacts at the beginning and end of the lifting process; and in piston ring/cylinder bore contacts throughout the entire reciprocation cycle. For these conditions, additives should be used to reduce asperity friction and thereby prevent the excessive asperity temperature rise that leads to scuffing.

Contacts that operate at very low slide-to-roll ratios (that is, nearly pure rolling condition) generate much less heat in the conjunction, and can support a higher load without surface distress generated by sliding wear. This condition exists in gear teeth contacts at or near the pitch point and in all contacts between raceway/ball or raceway/roller contacts of rolling-element bearings. Surface or subsurface fatigue is the predominant mode of failure. Surface fatigue life improves greatly with a higher ratio of lubricant film to surface roughness. Elastohydrodynamic lubrication theories are directly useful for assessing fatigue life of these contacts. Film thickness formulas can be found in the article "Lubrication Regimens" in this Section and in the article "Friction, Lubrication, and Wear of Gears," which appears later in this Volume. The function and selection of lubricants for meeting the requirements of specific triboelements are discussed in the articles "Lubricants for Rolling Element Bearings" and "Internal Combustion Engine Lubricants" in this Section.

In metalworking processes, lubrication takes place at the interface between an elastic solid and a plastically deformed solid. Thick-film lubrication can be achieved but often is not because of the poor surface quality generated under these conditions. Mixed or boundary lubrication is usually specified for most metalworking processes in order to achieve the desirable friction that will enable control of the surface quality of the workpiece. In addition, the lubricant must also be a good coolant to carry away the heat generated by plastic deformation of the workpiece. Detailed coverage of the formulation and properties of modern metalworking lubricants can be found in the article "Metalworking Lubricants" in this Section.

Liquid Lubricants

Richard S. Fein, Fein Associates

Introduction

THE PRIMARY FUNCTION of liquid lubricants is to control friction, wear, and surface damage over the intended life of a system that contains machine elements, such as gears and bearings. Wear and surface damage occur under boundary or partial boundary lubrication conditions, but not under full hydrodynamic conditions. Secondary functions are to prevent corrosion and to scavenge heat, dirt, and wear debris. Lubricants can also transfer either force or energy, as occurs in hydraulic systems.

The choice of an appropriate lubricant depends on system needs and cost, as well as on health, safety, and environmental considerations. For a given system, minimizing the number of lubricants used generally simplifies maintenance and reduces the chances of applying the wrong lubricant. Inventory storage and handling are also reduced.

Machinery manufacturers help define system needs by recommending viscosity grades and the lubricant quality that is suitable for use with their equipment in various applications. In some cases, rather detailed specifications governing the oils to be used may be provided. With new equipment, the recommendations of manufacturers should be followed to ensure warranty protection. After the warranty period, the number of different lubricants can often be simplified (Ref 1), with the assistance of an experienced lubricant supplier.

This article describes types of base oils and the properties important to lubricant functioning; lubricant classifications; health, safety, and environmental considerations; and methods of lubricant application. Hydrocarbon-based oils, especially mineral oils, are emphasized because they are the most widely used. Additional details on most of these topics are provided in Ref 1, 2, 3, 4, 5.

Properties

Lubricant properties depend on the base oil (or blend of base oils) and on any additives that are used. Table 1 qualitatively indicates the important characteristics of a variety of base oils. Overall, mineral oils have good characteristics and are low in cost.

Table 1 Base oil characteristics

Property	Base oil type

Additives are chemicals that enhance the properties of an oil. They are added to base oils in concentrations that range from the order of tens of ppm to as much as 25%. Additives generally fall into three groups: polymers, polar compounds, and compounds containing active elements, such as sulfur and chlorine. They can also be classified by function, and are described as such in the article "Lubricant Additives and Their Functions" in this Volume. Some additives that offer advantages in one performance area may be detrimental in other areas, whereas others work best in combination. Additive use is justified by cost effectiveness.

The numerous lubricant properties that are important to end-use applications are listed in one of two categories in Table 2. Basic properties are physical or chemical characteristics that are essentially independent of the measurement method. Performance properties, on the other hand, do depend on the measurement method, because they are governed by interacting basic properties and test conditions. The most important properties, as well as those most often used for lubricant characterization, are described below, and typical values for selected properties are given in Table 3.

Note: Engine service classifications, such as SG/CD, are defined in Table 8.

Gravity and Density. Gravity is commonly used to identify a particular oil, that is, the density of an oil at 15.6 °C (60 °F) can be calculated by using the density of water as 0.99904 g/cm^3 at 15.6 °C (60 °F). Water has an American Petroleum Institute (API) gravity value of 10. As defined by ASTM D 287 (Ref 6), API gravity is:

$$\text{API gravity} = \frac{141.5}{\text{Specific gravity (15.6/15.6 °C)}} - 131.5 \qquad \textbf{(Eq 1)}$$

Thermal Expansion. Oil density decreases approximately linearly with increasing temperature over a considerable range. Table 4 gives the approximate thermal expansion coefficient for mineral oils (Ref 7).

Table 4 Approximate thermal expansion of mineral oils

Density, g/cm^3 at 15.6 °C (60 °F)	Expansion coefficient, 10^4/K
0.70	11.5
0.75	10.2
0.80	9.1
0.85	8.0
0.90	7.1
0.95	6.3
1.00	5.6
1.05	5.0

Note: Values determined using Roelands equation VIII-9 in Ref 7

Bulk Modulus. Oil density also increases with pressure, and the change in volume is often expressed as bulk modulus (Ref 8). This property, a measure of the resistance to oil compression, is important in the efficiency and dynamic responses of hydraulic and other pressurized-liquid systems.

Isothermal tangent bulk modulus and isentropic bulk modulus are defined thermodynamically, respectively, as $K_t = -V(\partial P/\partial V)_t$ and $K_s = -V(\partial P/\partial V)_s$, where the subscript t refers to a condition of constant temperature and the subscript s refers to entropy. However, the two secant bulk moduli are the ones usually used for engineering purposes.

The isothermal secant bulk modulus is:

$$B_t = \frac{V_0 P}{\Delta V} = \frac{\rho P}{\Delta \rho} \qquad \textbf{(Eq 2)}$$

where V_0 is the volume at atmospheric pressure; P is the gage pressure (0.1 MPa, or 1 atm, equals 0 gage pressure); ΔV is the volume decrease between 0.1 MPa and P; ρ is the density at P; and $\Delta\rho$ is the density increase between 0.1 MPa and P.

The isentropic secant bulk modulus, B_s, is related to the isothermal secant bulk modulus by the ratio of the specific heat at constant pressure, C_p, to that at constant volume, C_V, by the relationship:

$$B_s = \frac{C_P}{C_V}(B_t) \qquad \textbf{(Eq 3)}$$

Wright gives graphical correlations for determining the isothermal secant bulk modulus for mineral oils as a function of temperature and the atmospheric pressure density (Ref 8).

Color is used for lubricant identification purposes, except where staining or appearance are important. In ASTM D 1500, color is matched with standards ranging from the lightest to the darkest, that is, ASTM color 0.5 and 8.0, respectively.

Viscosity, the degree to which a fluid resists flow, is the most important property of a lubricant, and is covered fully in the article "Viscosity and Its Measurement" in this Volume. Viscosity relates directly to the ability of the lubricant to separate bearing surfaces, and often correlates with other performance characteristics.

Viscosity is expressed as being either dynamic (absolute) or kinematic. The latter, measured by ASTM D 445, is commonly utilized by lubricant suppliers and users. Kinematic viscosity is dynamic viscosity divided by density. The conversion factors between current and previously used viscosity units are provided in ASTM D 2161.

Viscosity-Temperature Relation. The viscosity of oils depends strongly on temperature, as shown in Fig. 1. The rate of change with temperature depends primarily on viscosity level, varying from about 0.5%/ °C for a 1 mm^2/s (1 cSt) oil to about 6-10%/ °C for 10^5 mm^2/s (10^5 cSt). The dependence of viscosity on temperature can be represented over a considerable range of temperatures by the ASTM D 341 viscosity-temperature (MacCoull-Walther) equation (Ref 6):

$$\log \log(\text{cSt} + 0.7) = A - B(\log T) \qquad \textbf{(Eq 4)}$$

where A and B are constants and T is absolute temperature in units of Kelvin. The constant 0.7 is valid for viscosities ranging from 2×10^7 down to 2 m^2/s (2×10^7 to 2 cSt); the constant increases as viscosity decreases below this latter value. Additional information regarding the ASTM equation is provided in Ref 9.

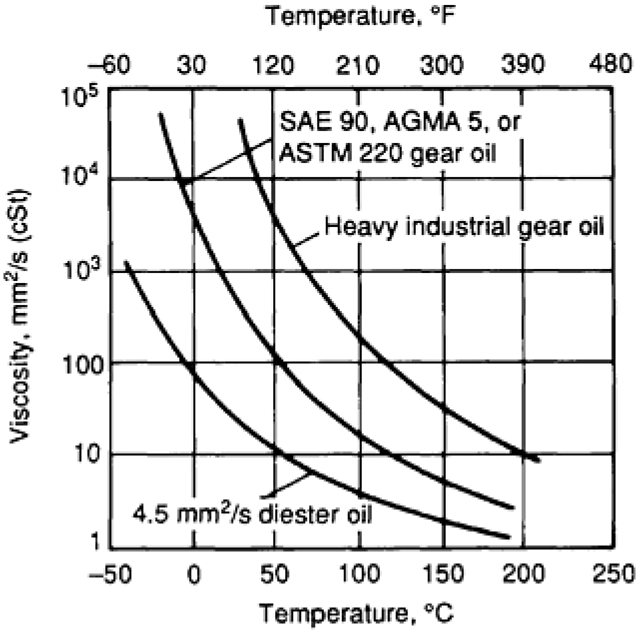

Fig. 1 Comparison of viscosities and temperature dependence

Viscosity index (VI) is an arbitrary method of expressing the viscosity-temperature sensitivity of lubricants, in which high numbers represent smaller changes in viscosity with temperature. Paraffinic oils have high VI numbers, whereas naphthenic oils have low VI numbers. The VI between 0 (the poorest oils in 1929) and 100 (the best in 1929) is given by ANSI/ASTM D 2270 as:

$$\text{VI} = 100\left(\frac{L - U}{L - H}\right) \qquad \textbf{(Eq 5)}$$

where L is the kinematic viscosity of a 0 VI reference oil at 40 °C (105 °F) that has the same kinematic viscosity at 100 °C (212 °F) as the unknown oil at 100 °C (212 °F); H is the kinematic viscosity of a 100 VI reference oil at 40 °C (105 °F) that has the same kinematic viscosity at 100 °C (212 °F) as the unknown oil at 100 °C (212 °F); and U is the kinematic viscosity of the unknown oil at 40 °C (105 °F).

ANSI/ASTM D 2270 tabulates reference oil viscosities and gives a formula for calculating VI numbers over 100.

Viscosity-Pressure Relations. Pressure increases viscosity, and the effects become appreciable for mineral oils at pressures above the order of 10 MPa (1.5 ksi). Classically, the Barus equation expressed the pressure effect

$$\eta_{t,P} = \eta_{t,0} \exp(\alpha P) \quad \textbf{(Eq 6)}$$

where P equals the gage pressure, $\eta_{t,P}$ equals the dynamic viscosity at temperature t and gage pressure P, $\eta_{t,0}$ equals the dynamic viscosity at temperature t and atmospheric pressure, and α equals the viscosity-pressure coefficient.

The Roelands equation is a much improved representation of viscosity change with pressure (Ref 7):

$$\log \eta_{t,P} + 1.200 = (\log \eta_{t,0} + 1.200)\left(1 + \frac{P}{C}\right)^Z \quad \textbf{(Eq 7)}$$

where C is a constant dependent on the units of gage pressure, P (C equals 196.1 MPa, or 28.4 ksi), and Z is a constant characteristic of the liquid under pressure.

For common nonaqueous lubricants, Z generally falls between about 0.5 and 0.8. For mineral oils and other hydrocarbons (including polymers), the following correlation quite accurately estimates Z from dynamic viscosities at 40 and 100 °C (105 and 212 °F) (Ref 7):

$$Z = 7.81\,(H_{40,0} - H_{100,0})^{1.5}\,F_{40,0} \quad \textbf{(Eq 8)}$$

where $F_{40,0}$ equals ($0.885 - 0.864 \times H_{40,0}$) and $H_{t,0}$ equals log [log($\eta_{t,0}$) + 1.200] at temperatures of t °C.

Elastohydrodynamic (EHD) Viscosity-Pressure Coefficient. Simplified hard (high-modulus) EHD equations commonly use the Barus-type α. For actual lubricants with pressure-dependent α, the appropriate value is:

$$\alpha_{EHD} = \left[\int_0^\infty \left(\frac{\eta_{t,0}}{\eta_{t,P}}\right) dP\right] \quad \textbf{(Eq 9)}$$

Figure 2 showns α_{EHD}, calculated with the Roelands equation, as a function of the atmospheric pressure viscosity $\eta_{t,0}$. The figure may be used to determine α_{EHD} for calculation purposes or, for more precise values, Table XIII-2 of Ref 7 can be used.

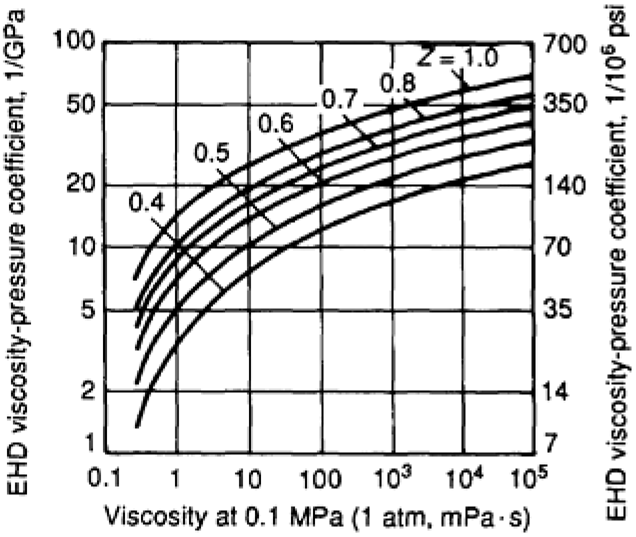

Fig. 2 Elastohydrodynamic viscosity-pressure coefficient. Source: Ref 7

Viscosity at atmospheric pressure and the EHD viscosity-pressure coefficient both strongly depend on lubricant temperature. Hence, for engineering purposes that use simplified EHD equations, it is convenient to express almost all of the lubricant contribution to film thickness in dimensionless terms as follows:

$$\text{Lubricant-speed parameter} = \frac{\alpha_{EHD}\,\eta_{t,0}\,U}{R_x} \quad \textbf{(Eq 10)}$$

where U is the mean surface velocity in the direction of motion and R_x is the effective radius in the direction of motion.

When the lubricant-speed parameter is used in place of the usual speed parameter used by theoreticians, the exponent of their materials parameter, $\alpha_{EHD}E'$ is greatly reduced (E' is the effective elastic modulus of the bearing materials). Hence, effects on the materials parameter by common lubricants only slightly affect calculated film thicknesses. The lubricant portion of the lubricant-speed parameter, $\alpha_{EHD}\eta_{t,0}$, is sometimes called the lubricant parameter.

At the high pressures encountered within the load-carrying zone in hard EHD, lubricants can act as plastic solids with a shear strength. The shear strength increases linearly with pressure according to:

$$\tau_{t,P} = \tau_{t,0} + \beta_t P \quad \textbf{(Eq 11)}$$

where β_t is the pressure coefficient of shear strength at temperature *t;* $\tau_{t,0}$ is the shear strength constant at temperature *t* and 0 gage pressure; and $\tau_{t,P}$ is the shear strength at temperature *t* and gage pressure *P*.

Low-Temperature Flow Properties. At low temperatures, oils become too viscous to pour from a container. Mineral oils also may not pour, because they precipitate crystals of wax at low temperature. Pour point is defined by the ASTM D 97 test.

In addition, the viscosity (that is, the shear stress per unit of shear rate) at low temperatures is commonly not independent of shear rate or stress nor of temperature and shear history, as it is for a "Newtonian" fluid. Therefore, kinematic viscosity (or dynamic viscosity derived from kinematic) determined at low shear rate is no longer a good predictor of how well a lubricant will flow in sumps, pump inlets, oil passageways, and the like. Consequently, a series of tests is used to measure lubricant flow characteristics under conditions that more closely simulate the application shear stresses and shear rates. These methods are:

- ASTM D 2983, Brookfield viscometer
- ASTM D 2602, cold cranking simulator
- ASTM D 4684, borderline pumping temperature of engine oil

Viscosity-Loss. Some lubricants, such as multigraded motor and gear oils, achieve their comparatively high viscosity at elevated temperature without excessive low-temperature viscosity by means of polymeric additives called viscosity index improvers (VIIs). VII oils are non-Newtonian in that the viscosity falls with increasing shear rate. If the shear rate is subsequently reduced after little shearing at high shear rates, then the viscosity returns to its original value and the difference between the low and high shear rate values is termed "temporary viscosity loss." If the oil is sheared extensively at high rates, then mechanical breaking of polymer chains occurs and the viscosity does not return to its original low shear rate level. The loss of low shear rate viscosity is termed "permanent viscosity loss." The temporary viscosity loss of lubricants that have experienced permanent loss is smaller than the temporary loss of a new lubricant.

Temporary viscosity losses typically range between 5 and 30% at the high temperatures of bearings in modern automotive engines (for example, 150 °C, or 300 °F) and shear rates are typically 10^6/s. Permanent viscosity losses also commonly fall in the 5 to 30% range.

A high-temperature, high-shear-rate viscosity of new and sheared oils that correlates with engine performance is measured using the ASTM D 4624 capillary viscometer, the ASTM D 4683 tapered bearing simulator, and the ASTM D 4741 rotational tapered plug tests. Permanent viscosity loss is measured by one or both of the ASTM D 3945 methods for shear stability of polymer-containing fluids using a diesel injector nozzle.

Ash is the mass percent of the oil that remains after combustion. It is used mostly for identification purposes in new oils, but in some cases correlates with deposit and wear performance in engines. Ash is typically measured using the ASTM D 482 method. For unused oils with metal-containing additives, sulfated ash (ASTM D 874) indicates the concentration of the known additive.

Volatility, the tendency to evaporate, is important in terms of fire safety in lubricant handling and use, lubricant consumption under high-temperature and vacuum conditions, and lubricant contamination of the environment. Fire safety is indicated by flash and fire points, which also are sometimes used for oil identification. The flash and fire points are usually determined by the ASTM D 92 Cleveland open cup procedure.

The boiling point range of a lubricant up to 538 °C (1000 °F) is determined by the ASTM D 2887 method using temperature-programmed gas chromatography. The evaporation tendency of lubricants is measured by the ASTM D 2715 procedure, although ASTM D 972 is the most common evaporation test used for motor oils.

Acidity and alkalinity indicate the extent of oxidation of a lubricant and its ability to neutralize acids from exterior sources such as combustion gases. The acidity of lubricants is measured by the amount of potassium hydroxide required for neutralization (mg KOH/g). Basicity is measured in the same units, which is the equivalent of the amount of acid required for neutralization.

Color-indicator methods ASTM D 974 or D 3339 are suitably applied to oils containing acids or bases whose ionization constants in water are greater than 10^{-9}. They are not suitable for many additive oils, especially those containing alkaline detergents, dispersants, or metal-containing inhibitors. For these additive oils, the potentiometric method, ASTM D 664, can be used to determine the total acid number (TAN), strong acid number, total base number (TBN), and strong base number. ASTM D 2896 measures the reserve alkalinity as the TBN, using the potentiometric perchloric acid method.

Stability is discussed below in terms of oxidative and thermal characteristics.

Oxidative stability is the resistance to reaction with oxygen, a natural lubricant "aging" process. Oxidation is undesirable because it increases lubricant viscosity, corrosivity, and deposit-forming tendencies. Oxidation is a sensitive function of time and temperature, oxygen availability, and the presence of water and catalyst metals. It is also sensitive to the mixing and recycling of volatile oxidation products. Oxidation-inhibiting additives can substantially increase the useful life of lubricants, whereas some additives used for other purposes (such as some extreme-pressure additives) can degrade life (Ref 3, 4).

Commonly used test methods are ASTM D 943, D 2272, D 2893, and D 4742. Many proprietary tests are also used. Table 5 shows approximate oxidation-limited temperature ranges as a function of time at temperature for mineral oils with and without oxidation-inhibiting additives.

Table 5 Approximate temperature exposure limits for mineral oils

Exposure time, h	Oxidation				Thermal range	
	Not inhibited		**Inhibited**			
	°C	**°F**	**°C**	**°F**	**°C**	**°F**
1	150-170	300-340	180-193	356-380	410-435	770-815
5	130-152	266-306	163-177	325-350	392-415	738-780
10	122-144	251-290	155-170	310-338	384-407	723-765
50	102-125	216-257	138-153	280-307	365-387	689-729
100	94-118	201-244	130-147	266-297	358-379	676-714
500	74-99	165-210	113-130	235-266	339-359	642-678
1000	66-91	151-196	105-123	221-253	331-351	628-664
5000	46-73	115-163	88-107	190-225	313-331	595-628
10,000	38-65	100-150	80-100	176-212	305-323	581-613

Thermal stability is the resistance of oils to chemical breakdown in the absence of oxygen or water. It can cause carbonaceous or gummy deposits. Thermally induced breakdown is a sensitive function of time at temperature, which, for hydrocarbons, cannot be effectively inhibited. Additives that are used for other purposes in lubricants often are less thermally stable than the base oil. Table 5 also shows the approximate thermally limited temperature ranges for mineral oils.

Carbon residue, which remains after evaporation and pyrolysis, indicates the tendency for coke formation upon the thermal decomposition of ashless oils. In the United States, it is commonly measured by the ASTM D 524 Ramsbottom method. It can also be measured by the ASTM D 187 Conradson method.

Corrosivity is the tendency of a lubricant and its contaminants to chemically react with ferrous and nonferrous metals. Corrosion damages bearings and other structural elements and accelerates lubricant oxidation by catalysis. It is measured in performance tests, including many standard bench oxidation tests. Consequently, oxidation and (nonrust) corrosion properties of a lubricant are commonly considered together. Corrosion can be reduced by additives that inhibit the oxidation process, form protective films on surfaces, or deactivate the catalytic properties of dissolved metals.

Rust consists of hydrated iron oxides and results from aqueous corrosion of ferrous metals. It can damage bearings and interfere with the motion of close-clearance parts, such as hydraulic valves. It also sometimes can breach containment systems and weaken parts. Rust is important because lubricants contain dissolved water and may contain liquid water. In addition, lubricant-wetted parts often are exposed to humid air.

Rust is controlled by using additives that form protective barriers on ferrous surfaces and by reducing the water content of lubricants. ASTM D 665 and D 3603 are commonly used to measure lubricant rust prevention properties.

Detergency and dispersancy are properties that involve the suspension of oil-insoluble materials, in the case of the former, and prevention of sludge and varnish formation, in the case of the latter. The insoluble materials can be oxidation and corrosion products; reaction products of gas-phase materials, such as those that blow by piston rings; or other materials that leak into the lubricant. Both detergency and dispersancy are provided to lubricants by means of additive molecules that consist of insoluble-material-attracting polar groups and oil-attracting groups.

Detergents are oil-soluble salts of organic acids. The base is usually metallic, and typically contains calcium or magnesium. Detergents often contain an excess of alkaline inorganic salts (that is, they are "overbased") that serve to neutralize acids in either blow-by combustion gases or formed by lubricant oxidation. Dispersants are ashless organic compounds that prevent flocculation and coagulation of colloidal particles. The performance of these additives is typically evaluated by a variety of proprietary tests.

Foaming and air release are important properties because machine elements mix air into lubricants. Bubbles that are stable can:

- Reduce heat transfer
- Interfere with lubricant flow
- Cause lubricant to be expelled through vents
- Accelerate oxidation, because of heat generated during compression
- Produce spongy hydraulic-system performance

Foaming is controlled by very low concentrations of antifoam additives. Additives often adversely affect air release. Foaming is measured by ASTM D 892 and other performance-type procedures.

Filterability is the ability to remove particulate matter from lubricants by passing them through porous media. Particles of contaminants cause abrasive wear and may form deposits that interfere with lubricant flow or the motion between parts. Filterability is affected by base oil type and viscosity, additives used for other purposes, and operating conditions. It is determined by a variety of performance tests.

Lubricant Classification

A lubricant can be classified by its viscosity, the type of performance tests it can pass, the type of mechanism for which it is intended, and the industry in which it is used. Lubricants are also classified as automotive, aviation, marine, or industrial lubricants. A particular lubricant generally fits a number of these classifications.

Described below are the most common lubricant categories. Specialized industrial classes, such as paper machine oils, are not included, but can be found in Ref 1, 2, and 3.

Viscosity Grades. Table 6 shows approximate kinematic viscosity levels at 40 °C (105 °F) for several grading systems. The International Organization for Standardization (ISO) viscosity grades (ASTM D 2422) are the nominal kinematic viscosities in mm^2/s at 40 °C (105 °F). They cover the widest viscosity range in increments of about 1.5-fold. The American Gear Manufacturers Association (AGMA) grades are also identified.

Table 6 Comparison of viscosity classifications

ISO viscosity grade, mm^2/s	AGMA number	Approximately equivalent SAE class	
		Engine oil	**Gear oil**

1000	8A	. . .	250

The Society of Automotive Engineers (SAE) grades have viscosity limits set at 100 °C (212 °F), whereas those with W suffixes also have low-temperature requirements. Table 7 shows these limitations for the SAE engine oil classifications (Ref 10). For engine oils, the W requirements enable the starting of engines at cold temperatures and the pumping of enough oil at these temperatures to prevent engine damage.

Table 7 SAE engine oil viscosity classification (J300)

SAE viscosity grade	Viscosity, Pa · s	Borderline pumping temperature (max.)		Stable pour point (max.)		Viscosity, at 100 °C (212 °F), mm^2/s	
		°C	**°F**	**°C**	**°F**	**Min**	**Max.**

(a) At -30 °C (-22 °F).

(b) At -25 °C (-13 °F).

(c) At -20 °C (-4 °F).

(d) At -15 °C (5 °F).

(e) At -10 °C (14 °F).

(f) At -5 °C (23 °F)

Cross-graded, or multigrade, oils meet the limits of both designated grades (that is, an SAE 10W-30 oil meets the SAE 10W and SAE 30 requirements). Cross grading with mineral-based oils is achieved by using polymeric viscosity-index-improving additives. It also can be achieved by using synthetic-based oils. Outside of the United States, minimum high-temperature, high-shear (HTHS) viscosity (at 150 °C, or 300 °F, and 10^6/s shear rate) is generally specified for the SAE cross grades to protect against wear. Both U.S. and Japanese automobile manufacturers specify a minimum HTHS viscosity for all grades (Ref 11).

Engine oils meet different levels of performance requirements of the American Petroleum Institute (API); the Comité Des Constructeure D'Automobiles Du Marché Commun (CCMC), which is now the Association des Constructeurs Europeens D'Automobiles (ACEA) in Europe; the U.S. military in the United States and Europe; and U.S., European, and Japanese engine builders.

Some premium products meet most of the major requirements of all of these groups. High-quality products generally contain detergent, dispersant, wear inhibitor, friction modifier, oxidation inhibitor, corrosion inhibitor, rust inhibitor, pour depressant, and foam inhibitor additives.

Table 8 gives the current API classifications (arrived at through participation of API, ASTM, and SAE) for gasoline engines, some light-duty diesel engines (S categories), and diesel engines (C categories). There is also an energy-conserving classification. Table 9 shows the engine tests required for the most severe API classifications. Some low-cost oils in the marketplace only meet obsolete classifications, such as SA and SB, which correspond, respectively, to straight mineral oils and oils with modest oxidation and corrosion inhibition (which also can inhibit wear).

Table 8 API engine service classifications

S categories	
SE	Satisfies 1972 U.S. warranty conditions for gasoline engine lubricants. Improved protection against oxidation, high-temperature deposits, rust, and corrosion
SF	Satisfies 1980 U.S. warranty conditions for gasoline engine lubricants. Additives against high- and low-temperature deposits, wear, and corrosion. Improved oxidation stability and antiwear over SE
SG	Satisfies 1989 U.S. warranty requirements for gasoline engine lubricants and meets CC category requirements. Improved antiwear, cleanliness, and antithickening over SF
C categories	
CC	Lightly supercharged diesel engines and certain heavy-duty gasoline engines. Additives against high- and low-temperature deposits, rust, and corrosion
CD	Satisfies requirements of supercharged diesel engines, even with high-sulfur fuels. Additives against high-temperature deposits, wear, corrosion
CD-II	Severe-duty service of supercharged two-stroke engines. Satisfies CD requirements and a supercharged two-stroke multicylinder engine test
CE	Service typical of turbocharged or supercharged heavy-duty diesel engines manufactured since 1983 and operated under both low-speed, high-load and high-speed, high-load conditions
CF-4	Service in high-speed four-stroke-cycle diesel engines, particularly for on-highway heavy-duty truck operations. Exceeds CE requirements and designed to replace CE oils. May be used in place of CD and CC oils. Provides improved control of oil consumption and piston deposits

Table 9 Engine tests for API classification

Gasoline engines
CRC L-38 (CLR engine): Bearing corrosion, oxidation, shear stability
ASTM sequence IID (1977 Oldsmobile V-8 engine): Low temperature, rust, corrosion
ASTM sequence IIIE (1987 Buick V-6 engine): High temperature, wear, and oil thickening
ASTM sequence VE (Ford 4): Low temperature, sludge, varnish, and wear
ASTM sequence VI (1982 Buick V-6 engine): Fuel economy
Diesel engines
CRC L-38: Bearing corrosion, oxidation, shear stability
Caterpillar 1K: Piston deposits
Detroit diesel 6V-92TA (two-stroke engine): Piston deposits, ring and valve distress
Mack T-6: Ring wear, piston deposits, and oil consumption
Mack T-7: Diesel soot dispersion and viscosity increase control
Cummins NTC-400: Piston deposits, bore polishing, and camshaft roller pin wear

Two-cycle oils are used when the lubricant is supplied as a solution in the gasoline fuel or is directly injected in modern engines. Such two-cycle engines are common in boats, snowmobiles, chain saws, lawnmowers, and motorcycles. The oils prevent cylinder wall damage without producing spark plug fouling, surface ignition, or exhaust port plugging. They also provide good rust, corrosion, wear, ring sticking, and varnish protection.

The lubricants are available with diluents to facilitate mixing with gasoline at fuel-to-oil ratios that commonly range between 16 and 100. The engine manufacturer recommends the ratio to be used. Oils are certified by the National Marine Manufacturers Association (NMMA).

Railroad diesel oils are generally either SAE 40 grade or 20W-40 multigrade oils. Typically, they are of API CD quality, but are free of zinc to protect the silver bushings in railroad engines. They have relatively high TBNs to neutralize fuel sulfur acids.

Gas engine oils resist oxidation and nitro-oxidation and are used in engines that burn natural gas or liquified petroleum gas (LPG). They usually are low-ash dispersant-containing oils. However, higher-ash oils are used to neutralize sulfur acids when burning high-sulfur fuels.

Transmission and torque-converter fluids are intended to:

- Transmit power in torque converters and oil-wet clutch packs
- Lubricate the gears, pumps, and splines of transmissions

- Dissipate heat

They have excellent viscosity-temperature characteristics, oxidation resistance, wear prevention, well-controlled dynamic and static friction characteristics, and foam resistance. They also show good seal compatibility. Automatic transmission fluids (ATFs) are classified as Dexron II, Mercon, or Ford type F on the basis of auto manufacturer performance testing. The most common torque fluid classes are Allison C-3, Allison C-4, or Daimler-Benz 236.6.

Gear oil performance classifications range from straight mineral oils to oils compounded with a fatty oiliness additive (for worm gears) or with extreme-pressure (EP) additives (for hypoid gears). Table 10 shows the SAE J308b recommended practice, which covers the API classifications for automotive axles and manual transmissions (Ref 10).

Table 10 API system of lubricant service designations for automotive manual transmissions and axles

API-GL-1	Spiral bevel and worm gear axles and some transmissions under mild service
API-GL-2	Worm gear axles not satisfied by API-GL-1
API-GL-3	Manual transmissions and spiral-bevel axles under moderately severe service
API-GL-4	Hypoid gears in normal severe service without severe shock loading
API-GL-5	Hypoid gears in severest service, including shock loading

AGMA classifications for industrial gearing cover a similar range, with rust and oxidation (R&O), compounded, and EP types. The R&O type provides oxidation and corrosion inhibition and is used for lightly loaded spur and helical gears. The compounded type, with a few percent fatty additive, is for worm gears, whereas the EP type is for hypoid gears and heavily loaded and low-speed spur and helical gears.

Automotive gear oils often have higher EP performance and lower pour points than industrial gear oils. Industrial gear oils often have superior resistance to oxidation and rusting.

API-GL-5 lubricants commonly are qualified under U.S. military specification MIL-L-2105C and, sometimes, under MIL-L-2105D and Mack Truck GO-H. Some API-GL-5 lubricants also provide satisfactory limited-slip differential performance. AGMA EP-type lubricants often meet the U.S. Steel 224 requirement. Open gear lubricants typically contain tackiness additives and may be diluted with solvent for ease of application.

Multiuse lubricants for gears, hydraulic systems, and wet clutches and brakes are commonly used in tractors and other agricultural equipment. These typically meet the performance requirements of one or more manufacturers.

Hydraulic oils are primarily classified in terms of either normal or low flammability. Normal-flammability oils are hydrocarbon based, and range from noninhibited to R&O to antiwear oils. Some are VI improved and others have lubricity additives to prevent friction-induced vibration or noise (that is, stick-slip). Paraffinic mineral oils are most commonly used, but, when low pour points are needed, naphthenic oils are used. Sometimes, synthetic hydrocarbon oils can be used for their low pour point and wide liquid range.

Viscosities at operating temperature and at cold-start temperature are the most important properties (Ref 12). The oils usually are R&O inhibited and sometimes are pour-point depressed. Antiwear, antifoam, and detergent/dispersant additives may be used. Good water separability and filterability are also important properties. High bulk modulus and low gas solubility are desirable for high-pressure systems. Antiwear hydraulic oils protect vane, gear, and certain types of piston pumps.

Fire-resistant oils primarily are phosphoric acid esters. Fire-resistant water-miscible fluids include oil-in-water emulsions, water-in-oil emulsions, solutions of chemicals in water, and water solutions of viscosity-increasing polymeric additives (Ref 12). High-water-based fluids (>90% water) provide good heat transfer, are easily disposable, and the non-oil-containing types are nonflammable in situations where the water cannot be evaporated. However, they are temperature limited, may cause rusting, and require special equipment.

Turbine oils, when premium, have excellent oxidation resistance and water-separation properties. They also have good air separation and rust protection. They use highly refined base oils, mostly paraffinic, but some are naphthenic. Synthetic

hydrocarbon-based fluids are also available for applications requiring exceptional VI and broad liquid ranges. These oils are used for steam turbines, heavy-duty gas turbines, hydraulic systems, and air compressors. They typically satisfy a wide variety of original equipment manufacturer (OEM) and military specifications, as well as meet the AGMA R&O-type gear oil requirements.

Marine steam turbine oils with antiwear additives protect heavily loaded reduction gearing connected to the turbines. These lubricants, otherwise, are premium turbine oils. Phosphate ester lubricants are also used in heavy-duty gas turbines, where their fire resistance is needed.

Aircraft gas turbines are lubricated with synthetic oils that have excellent oxidation and thermal stability. Stationary gas turbines can be lubricated with synthetic or highly stable mineral turbine oils. The lubricants have excellent resistance to deposit formation; good protection against bearing and gear pitting fatigue, as well as corrosion; and good gear load-carrying capacity.

Engine manufacturer and government specifications define the aircraft gas turbine lubricants in three classes. They are often referred to as 3, 5, and 7.5 mm^2/s oils (viscosity at 100 °C, or 212 °F).

Compressor lubricants must be compatible with the gases being compressed, must lubricate, and, in some cases, must seal. The higher the pressure (and, thus, temperature), the greater the tendency of the lubricant to react with the compressed gas and to coke. Reduction in lubricant viscosity by solution of the compressed gas in the lubricant is also a possible compatibility concern (for example, hydrocarbon compression). For air compressors, fire and explosion in the pressurized space and deposit formation are the main concerns. For steam and other wet gas compression, lubricant displacement of water from lubricated surfaces is important.

Mineral compressor oils are usually formulated for other purposes. Premium R&O oils are used for most types of compressors, whereas motor oils are sometimes used for reciprocating trunk-type compressors. Antiwear hydraulic oils, motor oils, or automatic transmission fluids may be required for vane and rotary screw compressors. Cylinder oils used in cross-head compressors can be compounded for wet conditions. Synthetic hydrocarbon-based oils with excellent oxidation stability and good deposit resistance are increasingly used for high-speed, high-temperature compressors. Diester-based oils also are being utilized increasingly for rotary screw compressors.

Refrigerator oils must lubricate the compressor, be thermally stable at compression temperatures (to the order of 160 °C, or 320 °F), be compatible with the refrigerant, and flow at the lowest evaporator temperature (Ref 13). Mineral oil lubricants must be refined to remove the components that can precipitate or react with the refrigerant. Oil entrained in compressed gas is carried through the refrigerant system and must be returned from the evaporator. Thus, miscibility between the oil and refrigerant is important for lubrication and sealing performance. Environmentally safer refrigerants, such as R-134A, require synthetic oils, such as the polyglycol type for miscibility at operating temperatures.

A special test for refrigerator oils is the floc point at which a cooled solution of oil in refrigerant type 12 becomes cloudy, because of precipitate formation. To prevent ice precipitation in refrigerators, oils need to be very dry. The stability of refrigerator oils is typically determined by the amount of deposit formed from a mixture of oil and refrigerant after exposure to metals found in refrigerant systems at elevated temperature (for example, 175 °C, or 350 °F).

Circulation oils are used in systems where oil is circulated to many individual bearings in order to remove large quantities of heat and contaminants. Because good water and air separation, along with good oxidation and rust protection, are often required, R&O oils are most often used. In some applications, straight mineral oils may be satisfactory, whereas other applications may require antiwear protection.

Misting oils are used in mist and fog lubrication systems. They contain polymeric additives to control droplet size so that the oil coalesces on the lubricated part and does not escape as mist.

Health, Safety, and Environment

Lubricant manufacturers are required by law to provide a material safety data sheet (MSDS) for every lubricant in order to satisfy the hazard communication standard of the Occupational Safety and Health Administration (Ref 14). Lubricant suppliers can also furnish information on relevant environmental regulations and laws. However, it is the responsibility of the lubricant user to become familiar with the information and to comply with pertinent regulations. Lubricant manufacturers can provide telephone numbers for medical, safety, transportation, and other emergency assistance.

Toxicity is the ability, upon exposure to a substance, to harm human, animal, or plant life. For lubricants, the usual concern is the effects on humans. Generally, unused lubricants are not highly toxic when exposure occurs through the skin. However, more-toxic contaminants can be accumulated over a period of use. The most common short-term (acute) effect is contact dermatitis, which is a particular problem with cutting oils (which are not otherwise covered in this article). Long-term (chronic) effects, as evaluated by animal tests, indicate carcinogenicity for oils that have not been processed severely enough by solvent extraction or hydrogen treating.

Safety. A MSDS will list the toxic properties in terms of LD_{50}'s (the doses, in mass, of toxic substance per mass of animal that will be toxic to 50% of the animals tested). The prevention of toxic effects on humans requires the avoidance of lubricant contact, including breathing of vapor or mist. Oil-impervious clothing and boots are useful in some circumstances. Thorough washing should follow any personal contact.

The MSDS also lists properties such as flash and fire points. Explosion and fire avoidance measures should be considered whenever a lubricant either becomes hot enough to approach its flash point during normal use or can accidentally contact a flame or hot part, such as when an oil line breaks and sprays oil on an engine exhaust manifold. Flash and fire points can be substantially lowered by lubricant use that provides the opportunity to absorb volatile materials such as gasoline, diesel fuel, or solvents. When a lubricant must be used near or above its flash point, the lubricant/oxidant mixture must be kept either too lean or too rich to burn. It is good practice to read and understand the precautionary labels on a lubricant container, as well as the MSDS.

Environmental protection requires elimination of lubricant escape to air, water, or land. This entails careful storage and handling of both new and used lubricants, lubrication procedures, equipment maintenance (especially seals, gaskets, valves, and fittings), and disposal of used lubricants. It also entails avoidance of accidental release, measures that minimize the impact of a release that does occur, and plans to remediate any impact.

Lubricant disposal is costly and subject to evolving federal, state, and local regulations. Improper disposal is a potentially expensive future liability. Consequently, the minimization of used or leaked lubricant disposal is commonly cost effective (Ref 15). Used lubricant minimization involves engineering to reduce aging and other contamination of the oil, system maintenance, and periodic oil testing to determine used oil condition.

When analysis indicates that a lubricant is no longer suitable for service, it can often be reconditioned for further use, either on-site or off-site, by a contract recycler. Such recycling commonly involves water removal by gravity, centrifuge, coalescer, or vacuum evaporation, and fine-particle filtration. It also may involve clay treatment and possible additive refortification. Portable water removal and filtration units are often used at sites that have a number of lubricant systems.

Disposal is required for lubricants that can no longer be reconditioned. Over half of the used oil in the United States is utilized as fuel. It can be burned in industrial furnaces if contaminant concentrations do not exceed the limits for arsenic (<5 parts per million by mass, or ppmm), cadmium (<2 ppmm), chromium (<10 ppmm), lead (<100 ppmm), and total halogens (<4000 ppmm); if the flash point is at least 37.8 °C (100 °F) (Ref 16); and if it does not contain toxic substances. About one-third of the used oil is dumped and small percentages are rerefined, used for other industrial uses, or used for road oiling.

In view of the changing regulations and potential liabilities, good written records should document the source of the waste oil and its subsequent handling (storage, transportation, and disposal). An analysis of the used oil is desirable, and a retained sample also may prove useful in establishing that the oil was not contaminated. The generator of the used oil should contract with a waste oil hauler who carries adequate insurance and has a licensed treatment, storage, and disposal facility that complies with all federal and state regulations.

Methods of Lubricant Application

The lubricant application method plays a vital role in how the lubricant functions. The quantity of lubricant, its temperature, and its cleanliness are as important to bearing system performance as the selection of the proper lubricant.

Methods of providing lubricant to a bearing range from periodic manual application with a traditional oil squirt can to continuous automatic metering from a circulating oil system supplying an entire machine or group of machines (Ref 1, 2, 5). The appropriate method should supply the proper quantity of oil at a correct rate. Considerations that are involved in selection are whether the supply needs to be continuous, its adaptability to changed operating conditions, and the reliability of the method. Reliability considerations include the human factors and the effects of factors such as

temperature, sump level, and oil contamination on the quantity of oil delivered. In addition, the economics of the method and its convenience, safety, and environmental compatibility need to be considered.

Manual Application. The oil squirt can, a sprayer, or a brush is often satisfactory for machine elements used only occasionally, for low-speed lightly loaded bearings, or for inexpensive or rough machinery, such as wire rope, chains, or open gears. The oiling is intermitted and depends on periodic human action to supply the proper lubricant quality and quantity.

Drop oilers provide lubricant one drop at a time. Gravity-fed systems are common, and shut-off can be either manual or automatic. They are most economical to use when there are relatively few easily accessible lubrication points. Oiling is intermittent, and the oilers usually need to be manually resupplied periodically.

Splash lubrication is provided automatically and continuously to an enclosed mechanism by immersing the lower portion of a rotating or vertically reciprocating part in an oil sump.

Oil Carrier. The self-acting arrangements that can be used to carry oil from a reservoir to a bearing are described below.

Wick and Pad. A fibrous material carries oil by capillary action. Wicks can clog with an accumulation of oil contaminants. Pads of fibrous or otherwise open-pored materials that are filled with oil and are in contact with a bearing can also be used to apply lubricant. Accumulation of dirt, wear particles, and lubricant degradation products limit pad life.

Oil rings or chains are used for horizontal bearings with rotating shafts. They rest on the shaft and rotate with it, because of friction. The lower part dips into oil in a sump below the bearing and automatically drags oil by viscous forces as the oil-wet lower part rotates to the top of the shaft. The chain oiler has greater lubricant-carrying capacity than a ring oiler, but is limited to lower speeds by centrifugal action and churning drag.

An oil collar acts similarly to an oil ring, but is fixed to the shaft. It carries oil from the sump and the oil is displaced from the outer portions of the collar to the shaft by means of scrapers.

Pressurized Feed. Pumping lubricant directly to individual bearings provides positive oil feed to each. It is easily made automatic and is readily adaptable to recirculation of the supplied oil for filtration, temperature control, and other purposes. Usually, multiple bearings on a machine or mill are lubricated by the same oil-circulating system.

Pressurized feed circulating systems have the disadvantage of being initially expensive. However, their ability to provide dependable continuous flow of conditioned oil makes them attractive for applications involving heavy-duty expensive bearings.

Mist lubrication is provided by a mist of oil droplets in air that impinge on bearings. These once-through systems consist of an oil mist generator, plumbing, and droplet-sized reclassification nozzles. They can be designed to deliver oil automatically to many bearings spread over distances up to about 100 m (330 ft). Mist lubrication reduces energy losses that result from excess lubricant in bearings.

These systems commonly cost less initially than pressure-fed circulating systems. Although they are very dependable, the escape of stray mist into surrounding air can be an environmental problem, and deposition of oil degradation products can progressively clog mist fittings. Mist systems cannot remove an appreciable amount of heat from a bearing, compared with a pressure-fed circulating system.

Lubrication Regimes

Herbert S. Cheng, Northwestern University

Introduction

WHEN TWO SURFACES are in contact with each other, the load is carried by many high points, or asperities, on the surfaces. During sliding, the total tangential force required to shear these asperity junctions is usually high, causing unacceptable friction, wear, and surface damage. To reduce the frictional force and thus allow easier sliding, a lubricant is deliberately introduced to separate the asperities either totally or partially.

The use of liquid or gas lubricants is known as *fluid-film lubrication. Thick-film lubrication* refers to the total separation of asperities by a lubricant film thickness many times larger than the size of the lubricant molecules. If this condition exists only partially--that is, if part of the load is carried by the fluid pressure and the rest is borne by contacting asperities separated by a molecularly thin lubricant film--the term *thin-film lubrication* or sometimes *mixed lubrication* is used. In the most severe form of thin-film lubrication, the entire load is carried by asperities lubricated by surface films of molecularly thin liquids, gases, or solids; this condition is known as *boundary lubrication.* The exclusive use of solid lubricants is called *solid lubrication.*

The lubrication between two sliding surfaces can shift from one of the three regimes--thick-film, thin-film, or boundary lubrication--to another, depending on the load, speed, lubricant viscosity, contact geometry, and surface roughness of both surfaces. This dependence was first recognized in 1902 by Stribeck, who observed the variation of the sliding friction with a lubrication parameter $\eta N/p$, where η is the lubricant viscosity, N is the angular velocity of the cylindrical contact, and p is the average contact pressure. Figure 1 shows a typical Stribeck curve. At the right sides, where the friction increases slightly with the lubrication parameter, lubrication is in the thick-film regime; at the far left, where the friction is nearly constant, lubrication is in the boundary regime. In the middle, lubrication is in the mixed-mode, or thin-film regime. The boundaries of these regimes would move to the right if the surfaces became rougher and to the left if they became smoother. In addition to the variables η, N, and p, other parameters related to the study of lubrication regimes are defined in Table 1.

Table 1 Nomenclature for calculating regimes of lubrication

Symbol	Definition	Comments
G	Dimensionless material parameter	. . .
$G\infty$	Limiting shear modulus	. . .
h_0	Inlet film thickness	. . .
h_{min}	Minimum film thickness	. . .
h^*	Asperity film thickness or microelastohydrodynamic film thickness	Thickness of the oil film drawn into the asperity contact by microelastohydrodynamics; also referred to as the micro-EHL film thickness. First line of defense against sliding failure in mixed lubrication
$\bar{h}$	Average lubricant film thickness	Measure of the effectiveness of hydrodynamic lubrication. Depends on the speed, viscosity, pressure-viscosity exponents, contact radii, and the orientation of the roughness lays with respect to the entraining velocity. Theories in mixed lubrication are reasonably well developed (Ref 1, 2) to predict $\bar{h}$ as affected by the surface roughness height and lay orientation.
N	Angular velocity of cylindrical contact	. . .
p_i	Pocket pressure in hydrostatic bearing	. . .
p^*	Local asperity contact pressure	Represents the maximum contact pressure above the surrounding fluid pressure at each asperity contact. Its value depends on the height and the slope of asperities. Because the height and the slope are random functions, p^* is also a random function. The distribution of p^* controls the asperity shear stress and asperity contact temperature.
$\bar{p}$	Average (bulk) hydrodynamic pressure	From the elastohydrodynamic action, the lubricant pressure is generated within the Hertzian conjunction. For thick-film elastohydrodynamic lubrication, the distribution of pressure is a smooth function. However, for thin-film EHL, the pressure distribution is not smooth and contains fluctuations at the asperity contacts. $\bar{p}$ can be used as the average lubricant pressure, which varies from point to point within the Hertzian conjunction but ignores the local pressure fluctuations around the asperities. The average lubricant pressure in concentrated contacts can be predicted by lubrication analysis for rough surfaces (Ref 3).
$\bar{p}_a$	Average (bulk) asperity contact pressure	At the asperity contacts, the local pressure is intensified due to asperity deformation. These asperity contact pressures can be average out over a small area within the Hertzian conjunction to form a smooth function for the average contact pressure, $\bar{p}_a$. The average asperity contact pressure in concentrated lubricated contacts can be predicted from Patir and Cheng's analysis (Ref 3) based on the load and compliance relation developed by Greenwood and Tripp (Ref 4).
R	Radius of equivalent cylinder	. . .
$\bar{T}_s$	Average (bulk) surface temperature rise	Average surface temperature rise generated by the fluid shearing and the sliding asperities
T_s	Local asperity contact temperature rise	Indicates the temperature rise above the surrounding surface temperature at each sliding asperity. It is also a random function.
U	Dimensionless speed parameter	. . .
W	Dimensionless load parameter	. . .
γ	Pressure viscosity coefficient	. . .
η	Lubricant viscosity	. . .
η_0	Ambient viscosity of lubricant	. . .
θ	Angle of bite	. . .
Λ	Film thickness parameter	. . .
σ	Workpiece flow strength	. . .
τ_L	Limiting shear stress	. . .
τ^*	Local asperity contact shear stress	Represents the maximum shear stress at a sliding asperity above the surrounding fluid shear stress
$\bar{\tau}$	Average lubricant shear stress	Represents the average shear stress in shearing the thin lubricant film within the Hertzian conjunction

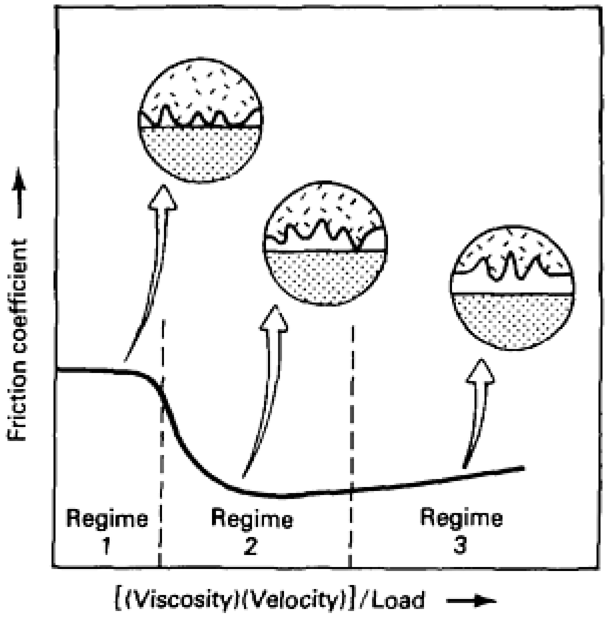

Fig. 1 Plot of friction coefficient, μ versus [(viscosity) (velocity)]/load, ($\eta_0 U$)/*P*, to show range of the three regimes of lubrication. Regime 1, boundary lubrication; regime 2, thin-film lubrication; regime 3, thick-film lubrication

Thick-Film Lubrication

A thick lubricant film can be generated by the tangential and normal relative motion between two surfaces. This mode is known as hydrodynamic lubrication. The effectiveness of such lubrication depends directly on relative speed and lubricant viscosity. For very slow contacts, a thick film is not likely to develop unless an externally pressurized lubricant is introduced into the lubricant film. This type of lubrication is known as hydrostatic lubrication.

For highly loaded contacts, elastic deformation of the surfaces can redistribute and broaden the contact area and lubricant pressure, thus greatly increasing the load capacity and lubricant film thickness compared with those generated by rigid contacts. Such thick-film lubrication resulting from the surface flattening effects of elastic deformation is known as elastohydrodynamic lubrication (EHL). In many metalforming operations, a thick lubricant film can also be formed at the interface between the rigid die surface and the plastically deformed surface of the workpiece. This mode of thick-film lubrication is often referred to as plastohydrodynamic lubrication (PHL).

Hydrodynamic Lubrication

When fluid lubricant is present between two rolling and/or sliding surfaces, a thick pressurized film can be generated by the surface velocities to reduce friction and wear. This mode of lubrication is commonly called hydrodynamic lubrication. Hydrodynamic film thickness can be formed by wedging the lubricant through a convergent gap with the tangential surface velocities, known as wedging film action, or by squeezing the lubricant out of the contact area with the relative normal velocity between the contacting surfaces, known as squeeze film action.

Wedging Film Action. In a converging hydrodynamic slider (Fig. 2), the thicker film at the inlet section can transport more lubricant than the thinner film at the exit section. Because the flow in an infinitely wide slider must be constant throughout the entire section, the lubricant pressure must rise at the inlet section to impede the flow and decrease at the exit section to enhance the flow, as shown in the pressure profile in Fig. 2. The pressure generated in such a converging gap represents the basic wedging film action in hydrodynamic lubrication.

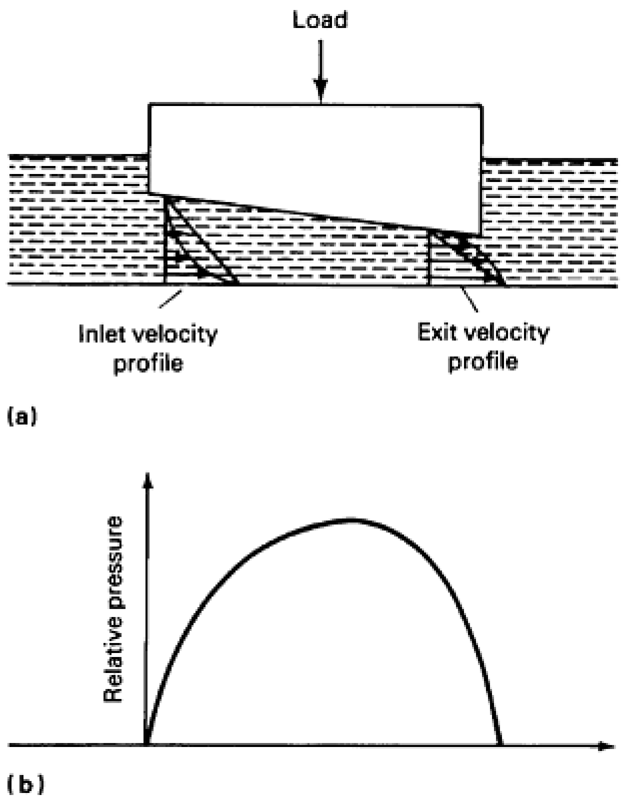

Fig. 2 Wedging film action in a hydrodynamic slider. (a) Velocity profiles at inlet and exit regions of wedge-shaped load. (b) Pressure distribution beneath wedge

Wedging film action takes place not only in flat sliders but also in curved sliders, between cylindrical surfaces such as journal bearings and lubricated rollers, and in spherical surfaces such as ball joints and ball bearings. In these cases, the gap profile may contain a divergent section in the exit section. Under such conditions, the pressure may terminate not at the end of the exit section but rather somewhere in the divergent section because of cavitation.

Squeeze Film Action. For a flat slider with a perfectly parallel gap, hydrodynamic pressure will not be generated by the wedging action. However, if the slider moves downward at a velocity normal to the surface, lubricant pressure will be generated by squeezing out the lubricant at both edges. For a parallel film, a parabolic pressure profile will be generated (Fig. 3).

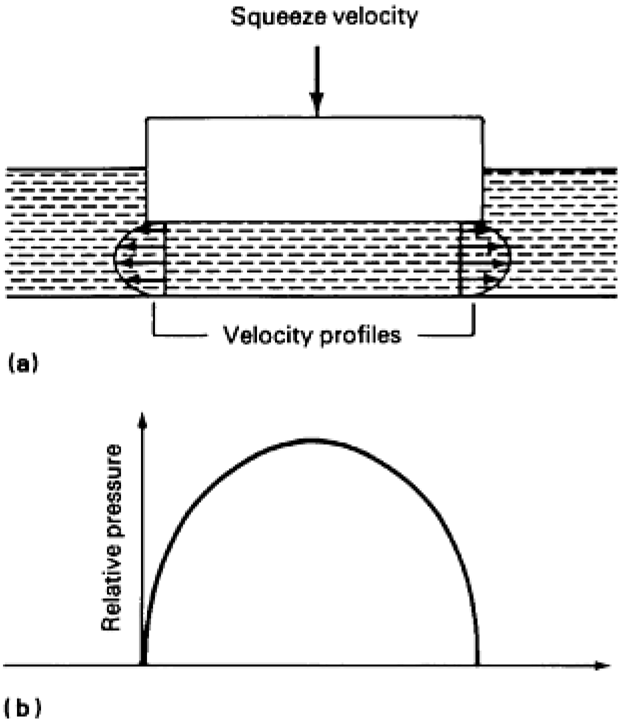

Fig. 3 Squeeze film action in a hydrodynamic slider. (a) Equal velocity profiles generated at each end of a flat slider that moves downward due to a squeeze velocity directed normal to the slider surface. (b) Pressure distribution beneath flat slider

For bearings operating under dynamic loads or reciprocating motion, squeeze film action can develop along with wedging action. The pressuregenerated by the squeeze action can become significant and often provides an effective damping component for stabilizing high-speed rotor-bearing systems.

Lubricant film thickness is important in hydrodynamic lubrication for designing against possible solid-to-solid contact. It is usually determined from solutions of the flow continuity equation, which calculates the lubricant pressure for a known film thickness. Charts and computer software are available for determining the lubricant film thickness for many common bearing geometrical configurations. Lubricant film thickness increases with the sum of the two surface velocities, lubricant viscosity, and bearing size, and decreases with load.

Figure 4 shows the Raimondi-Boyd design chart (Ref 5) for determining the minimum film thickness and eccentricity ratio for a 360° journal bearing. Design chart parameters are defined in Table 2. The effects of journal speed, viscosity, load, and the clearance-to-radius ratio are combined in a dimensionless Sommerfeld number, *S*. Charts for calculating minimum film thickness for other types of journal bearings can be found in Ref 5. The minimum film thicknesses for sliders used for thrust bearings can be calculated using methods outlined by Arnell *et al.* (Ref 6).

Table 2 Nomenclature for Raimondi-Boyd design chart in Fig. 4

Symbol	Definition
c	Radial clearance of bearing
d	Bearing diameter
f_{min}	Minimum friction force
h_0	Minimum film thickness: $h_0 = c(1 - \epsilon)$
l	Bearing length
N	Bearing speed (rev/s)
P	Load per unit projected bearing area
r	Bearing radius
S	Sommerfeld number: $S = \left(\frac{r}{c}\right)^2 \frac{\mu N}{P}$
W_{max}	Maximum load
ϵ	Eccentricity ratio: $\epsilon = [1 - (h_0/c)]$
μ	Effective lubricant viscosity

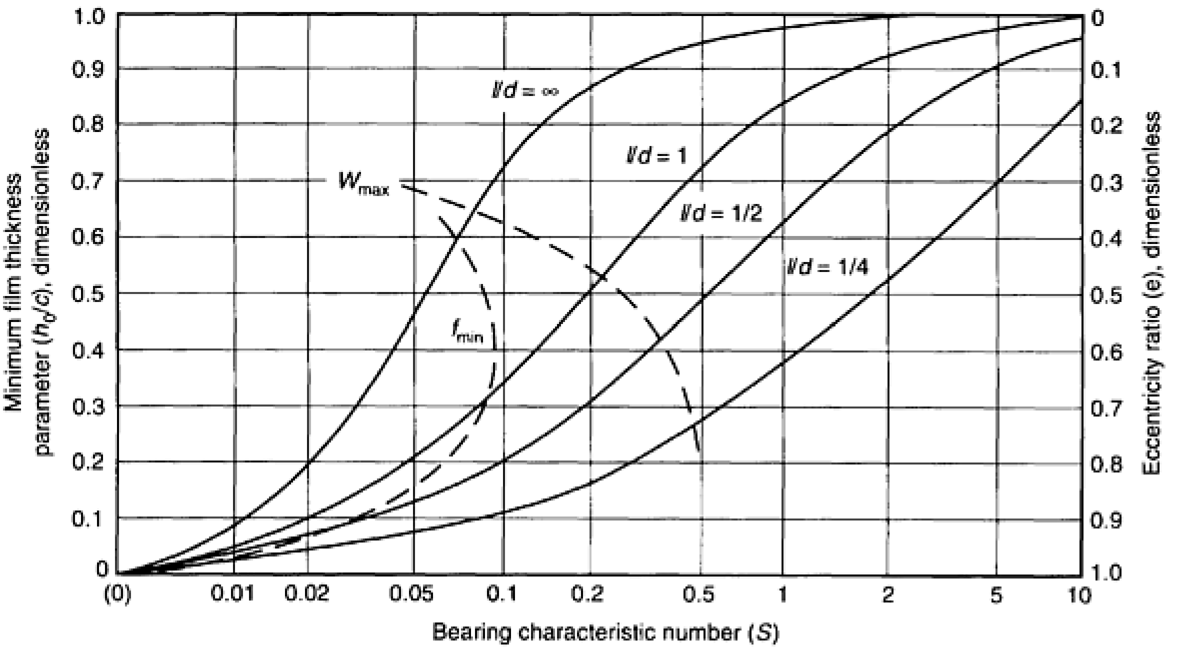

Fig. 4 Raimondi-Boyd design chart used to obtain the minimum film thickness and eccentricity ratio for a 360° hydrodynamic journal bearing. See Table 2 for definition of parameters.

Thermal Effects. Temperature significantly affects hydrodynamic lubrication by reducing lubricant viscosity and film thickness. For this reason, lubricants with a high thermal stability that yields a lower reduction in viscosity at elevated temperatures are generally preferred.

Determinations of lubricant film thickness that fully account for thermal effects require very complex analyses and lengthy computations. In most cases, hydrodynamic bearing lubrication designs including thermal effects can be based on an effective viscosity derived from a gross heat balance analysis and a film thickness calculated using isothermal analysis. These methods are described in Ref 5 and 6.

High-Speed Effects. For hydrodynamic bearings operating at high speeds, isothermal and gross heat balance analyses may not be sufficiently accurate for determining the regime of lubrication. Instead, a full thermal analysis for calculating the lubricant film thickness is usually required.

An increase in lubricant temperature reduces viscosity and yields a film thickness lower than that given by isothermal analysis. Because the reduction in viscosity is higher than the reduction in film thickness, friction normally decreases slightly when lubricant temperature is increased at high speeds.

In addition to the thermal effects, lubricant flow may become turbulent at high speeds because of the reduction in viscosity. The turbulence increases the flow resistance and the effective viscosity. This in turn generates a higher friction, a higher film temperature, and a slightly larger film thickness.

In many high-speed steam turbine compressor pumps, the fluid-film bearings operate in the regime where thermal and turbulence effects are both significant. To ensure that operation lies in the regime of full-film hydrodynamic lubrication, thermal hydrodynamic analysis using an effective turbulent viscosity, such as that contributed by Satar and Szeri (Ref 7) is often needed to determine an accurate film thickness.

Dynamic Loads. In many hydrodynamic bearings, the load is not steady. It changes because of variable external loading, such as the gas load during the firing cycle of a combustion engine or the unbalanced inertia forces of a high-speed rotor or reciprocating piston. In such cases, the lubricant film thickness is also unsteady and fluctuates periodically in response to the imposed periodic load. The ratio of the minimum film thickness to roughness in the fluctuating cycle calculated by transient film analysis indicates whether the bearing is operating in the full or partial hydrodynamic regime.

Transient film analysis includes both the wedging and squeeze film actions. The squeeze film action provides a cushion at the peak load and generally yields a larger minimum film thickness than the static analysis, which neglects the squeeze film action. Typical examples of dynamically loaded bearings include the main bearings and camshaft bearings in combustion engines and high-speed turbine bearings supporting dynamic loads caused by rotor unbalances.

Reciprocating Motion. In reciprocating sliders and oscillatory journal bearings, the cyclic sliding velocity also causes the film thickness to be cyclic, thus producing a squeeze film action. Typical examples include piston rings, piston skirts, and wrist pin bearings. In these cases, the minimum film thickness occurs at or near the top or bottom dead center of the reciprocating motion and can be determined by transient film analysis.

Hydrostatic Lubrication

If the surface velocities are insufficient to generate a thick film in hydrodynamic lubrication, hydrostatic lubrication, which uses an externally pressurized lubricant to generate a thick film, is often employed. Hydrostatic bearings are generally used in very low-speed applications such as machine tool guideways and radar antenna supporting bearings, in extremely low-friction devices such as instrument bearings, in cases of low-viscosity lubrication such as water and air bearings and in such applications as lifting a heavy rotor during startup and suppressing the rotor bearing instability in high-speed hybrid (that is, hydrodynamic and hydrostatic bearings).

Figure 5 shows the basic configuration of a hydrostatic bearings. The externally pressurized lubricant is first fed through a restrictor into a central pocket and then leaks through the bearing area to the outside. The pressure in the pocket (p_i), the film thickness across the bearing area (h), and the lubricant flow depend on the bearing load. For a heavy load, the pocket pressure approaches the supply pressure, yielding a very small flow and thin film thickness. For a light load, the pocket pressure becomes small, producing a high flow and a large gap.

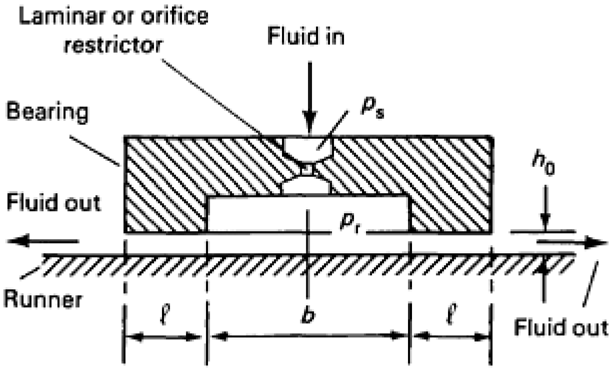

Fig. 5 Schematic showing key parameters that determine operation of a hydrostatic bearing. Nomenclature: p_s, supply pressure; p_r, recess pressure; h_0, film thickness; b, bearing pocket diameter; ℓ, bearing load thickness

Variations of load, flow, and stiffness with the lubricant film thickness of a hydrostatic bearing differ, depending on the types of restrictors used in the bearing. Figure 6 presents typical curves that show differences between the dimensionless loads, flows, and stiffnesses for orifice and laminar restrictors. Table 3 defines the terms used in Fig. 6. These curves can be used as a guide for selecting a restrictor geometry that will yield a film thickness satisfying the following requirements:

- The film must be sufficiently thick to avoid asperity contact
- Combined frictional and pumping loss must be low
- Leakage rate must be less than the maximum tolerable
- Stiffness must be high to prevent a large excursion of film thickness under fluctuating loading

Table 3 Nomenclature for hydrostatic bearings with orifice or capillary restrictor as plotted in Fig. 6

Symbol	Definition
b	Bearing pocket diameter
h	Film thickness across bearing area
h_0	Design lubricant film thickness
$\bar{h}$	Average lubricant film thickness: $\bar{h} = h/h_0$
L	Length of recess
p_r	Recess pressure
p_s	Supply pressure
$\bar{p}$	Average pressure
Q	Lubricant flow
$\bar{Q}$	Average lubricant flow: $\bar{Q} = Q\left(\frac{h_0^3 L p_s}{6 \mu \ell}\right)$
r	$r = p_r/p_s$
S	Stiffness
$\bar{S}$	Average stiffness: $\bar{S} = S\Big/\left[\frac{p_s L(b+\ell)}{h_0}\right]$
W	Load
$\bar{W}$	Average load: $W/[p_s L(b+\ell)]$
μ	Viscosity
ℓ	Bearing land thickness

Elastohydrodynamic Lubrication

When lubricant pressure causes elastic deformation of the surfaces that is on the same order as the lubricant film thickness, the influence of deformation on lubrication performance becomes a significant parameter. Contacts operating under this condition are in the regime of elastohydrodynamic lubrication.

A majority of lubricated contacts, such as rolling bearings and gear teeth, have surface deformation comparable to or exceeding the lubricant film thickness. Therefore, EHL is extremely important in determining friction and wear in many mechanical components. Characteristics of EHL in the thick-film regime are reasonably well understood and are reviewed in the following sections.

Film Thickness and Shape. In EHL, lubricant film thickness is the most important variable. It is formed by the wedging action at the inlet region between an elastically deformed Hertzian contact under a steady load. As in hydrodynamic lubrication, it increases with rolling speed, lubricant viscosity, and roller or ball size, and decreases with load. The influence of each of these effects varies, depending on contact pressure and modulus. For high-modulus

contacts, commonly known as hard EHL contacts, the film thickness also increases with the lubricant pressure-viscosity dependence. This effect is absent in low-modulus, or soft EHL, contacts. Examples of hard EHL contacts include metallic gears, rolling bearings, cams, and other Hertzian contacts. Examples of soft EHL contacts include all compliant bearings, elastomeric seals, and artificial hip and knee joints.

For hard EHL roller contacts, the film distribution as measured by interferometry (Ref 8) in the conjunction zone (Fig. 7) is largely uniform, with a small constriction at the exit of the conjunction. The minimum film thickness, h_{min}, for hard EHL contacts can be predicted using the Dowson and Higginson equation (Ref 9):

$$\frac{h_{min}}{R} = 2.65 \frac{G^{0.54}U^{0.7}}{W^{0.13}} \quad \textbf{(Eq 1)}$$

Equation 1 applies for moderate rolling speeds. For high-speed contacts, the loss of viscosity due to inlet heating will reduce the film thickness. This reduction can be determined by a thermal reduction factor based on numerical results obtained by Murch and Wilson (Ref 10).

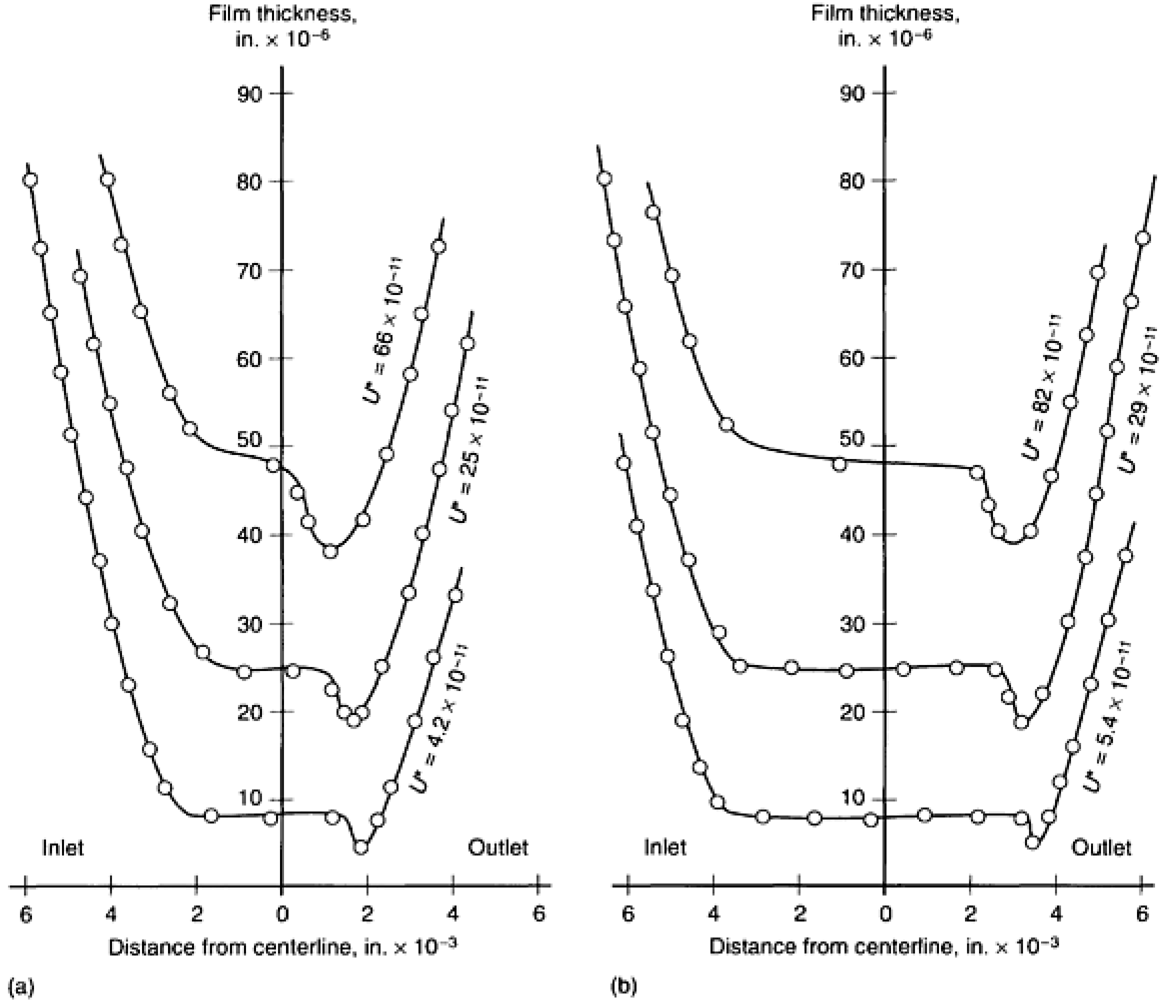

Fig. 7 Film profiles of EHL hard roller contacts at the midpoint of the conjunction zone in the direction of rolling for selected loads, *W*. (a) *W*, 750 N (168.5 lbf). (b) *W*, 1550 N (349 lbf). *U, a dimensionless speed diameter**

For elliptical conjunctions with the major axis oriented perpendicular to the rolling direction, the film thickness is still largely uniform over the conjunction zone. However, the uniform thickness is reduced slightly around the trailing edge, as shown in Fig. 8. The reduction along the two sides is greater than at the center. Empirical formulas for film thickness

based on extensive numerical analyses were developed by Hamrock and Dowson (Ref 11, 12, 13, 14) for the nominal and side minimum thicknesses.

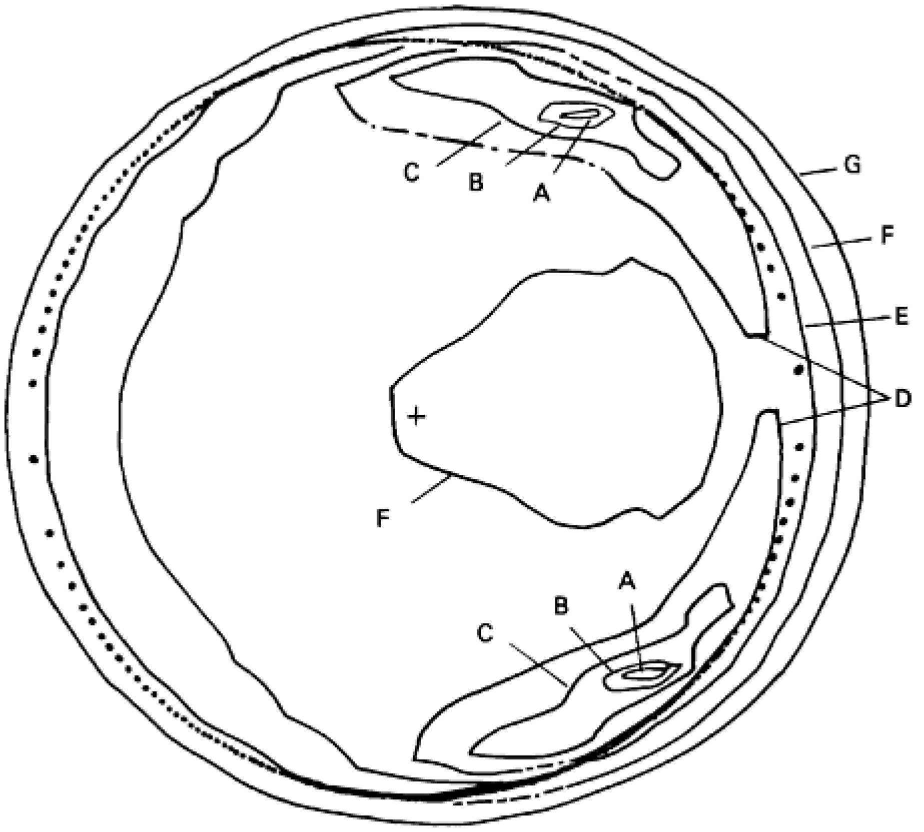

Fig. 8 Contour plot of film thickness, *h/R,* in a point contact. Contour legend: A, 4.0×10^{-6}; B, 4.2×10^{-6}; C, 4.6×10^{-6}; D, 5.2×10^{-6}; E, 6.0×10^{-6}; F, 7.4×10^{-6}; G, 9.0×10^{-6}. Test parameters: *U,* 0.1683×10^{-11}; *W,* 0.1106×10^{-6}; *G* 4.522×10^{3}

More recently, Chittenden *et al.* (Ref 15) extended Hamrock and Dowson's formulas to include the effect of an oblique angle between the entraining velocity and the minor axis of the contact ellipse. They contributed a set of comprehensive formulas for predicting the isothermal minimum and central film thicknesses for more general point contacts. Extensive experimental film measurements have been provided by Koye and Winer (Ref 16) for elliptical conjunctions with the major axis oriented along the rolling direction.

Pressure Distributions. The pressure profile in a line contact deviates slightly from the dry contact elliptical Hertzian profile. It contains a gradual buildup just before the conjunction and a secondary sharp pressure spike just before film termination, as shown in Fig. 9. The height of the pressure spike and its position depend on a nondimensional parameter, U/W^2. For the load level commonly used in hardened gears and rollers, pressure measurements at moderate speeds show no sign of pressure spikes or disturbances at the exit region (Ref 17). Calculated pressure profiles based on full EHL at high loads also show that the distribution is essentially Hertzian, with small inlet and exit disturbances.

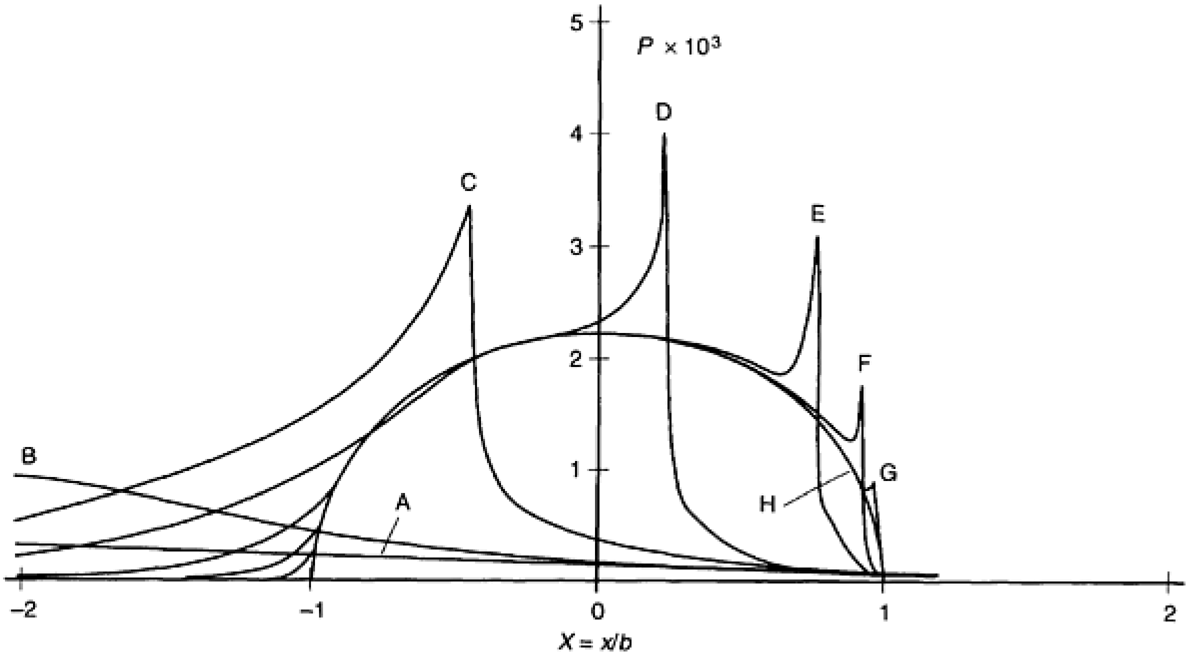

Fig. 9 Pressure distribution for a compressible lubricant at selected surface velocities, *U*. A, *U* = 10^{-8}; B, *U* = $10^{-8.5}$; C, *U* = 10^{-9}; D, *U* = 10^{-10}; E, *U* = 10^{-11}; F, *U* = 10^{-12}; G, *U* = 10^{-13}; H, (dry contact) *U* = 0. Test parameters: W, 3 × 10^{-5}; G, 5.0 × 10^{3}

Sliding Traction and Contact Temperature. In sliding EHL contacts, the tangential force in shearing the lubricant (traction) plays an important role in controlling the skidding of rolling bearings, in influencing fatigue life, and in governing the performance of traction drives. Early traction analyses (Ref 18, 19) and more recent traction models (Ref 20, 21) have revealed that the sliding traction coefficient varies with the sliding speed, as shown in Fig. 10. Traction increases linearly in the low-slip (low slide-to-roll ratio) region, reaches a maximum, and then decreases gradually with the sliding speed. The initial slope and the value of maximum traction depend on rolling speed, viscosity, and load, but the general trend is the same for all conditions. A study of lubricant rheology under high pressure and temperature successfully explained that the lubricant in the conjunction behaves like a viscoelastic substance in the low-slip region and that the viscoplastic behavior can be accurately predicted by a shear stress and shear rate relation containing three constants, all of which can be measured by independent experiments not related to EHL contacts.

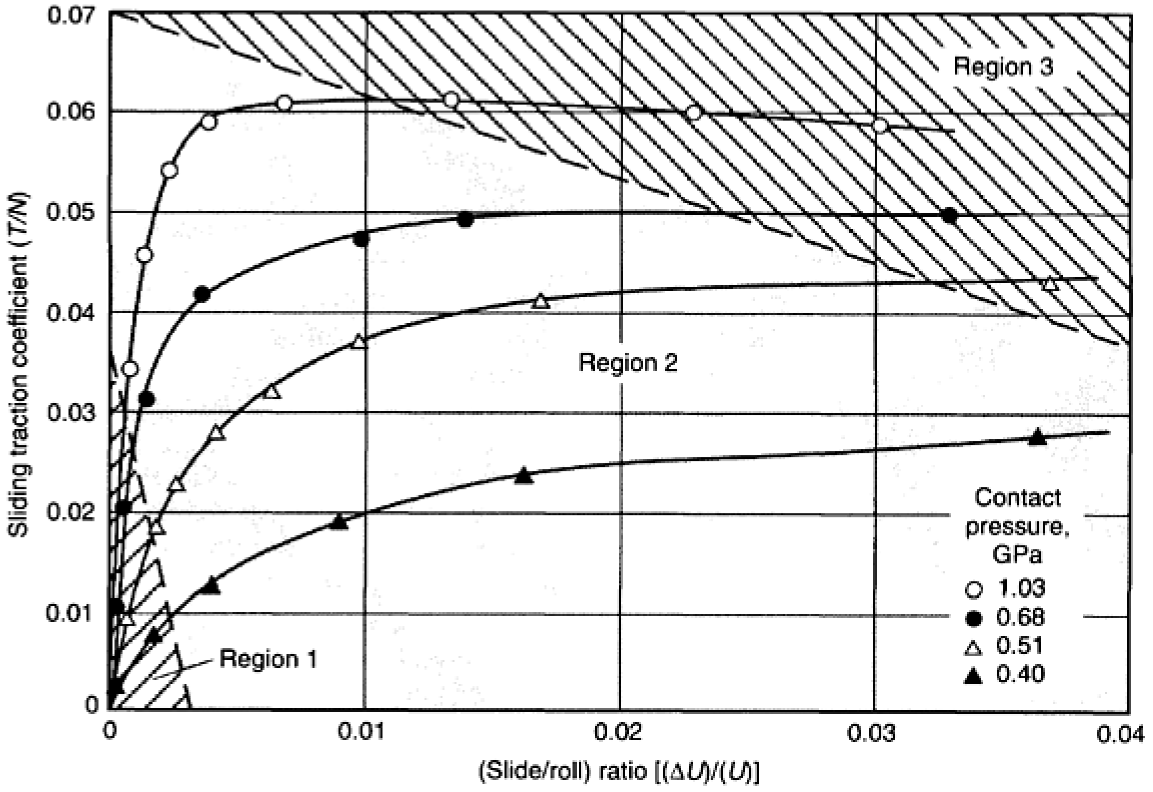

Fig. 10 Typical traction curves obtained at selected mean contact pressures when tested on a two-disk machine. Three distinct traction regions are represented: region 1, linear (that is, low-slip); region 2, nonlinear (isothermal); region 3, thermal. *T,* traction; *N,* normal load; Δ*U,* sliding velocity

The shear stress distribution and sliding traction in EHL contacts can be calculated by Gecim and Winer's model (Ref 22), which relates shear strain rate and shear stress by the equation:

$$\dot{\gamma} = \frac{\dot{\tau}}{G_\infty} + \frac{\tau_L}{\eta}\left[\tanh^{-1}\left(\frac{\tau}{\tau_L}\right)\right] \quad \textbf{(Eq 2)}$$

where the three rheological constants are the limiting shear modulus (G_∞), the limiting shear stress (τ_L), and the static equilibrium viscosity (η), all of which are functions of pressure and temperature and should be measured separately by independent experiments. These relations have been used in practice to determine the local shear stress in line or point contacts. A typical shear stress distribution along the center of an elliptical contact is shown in Fig. 11.

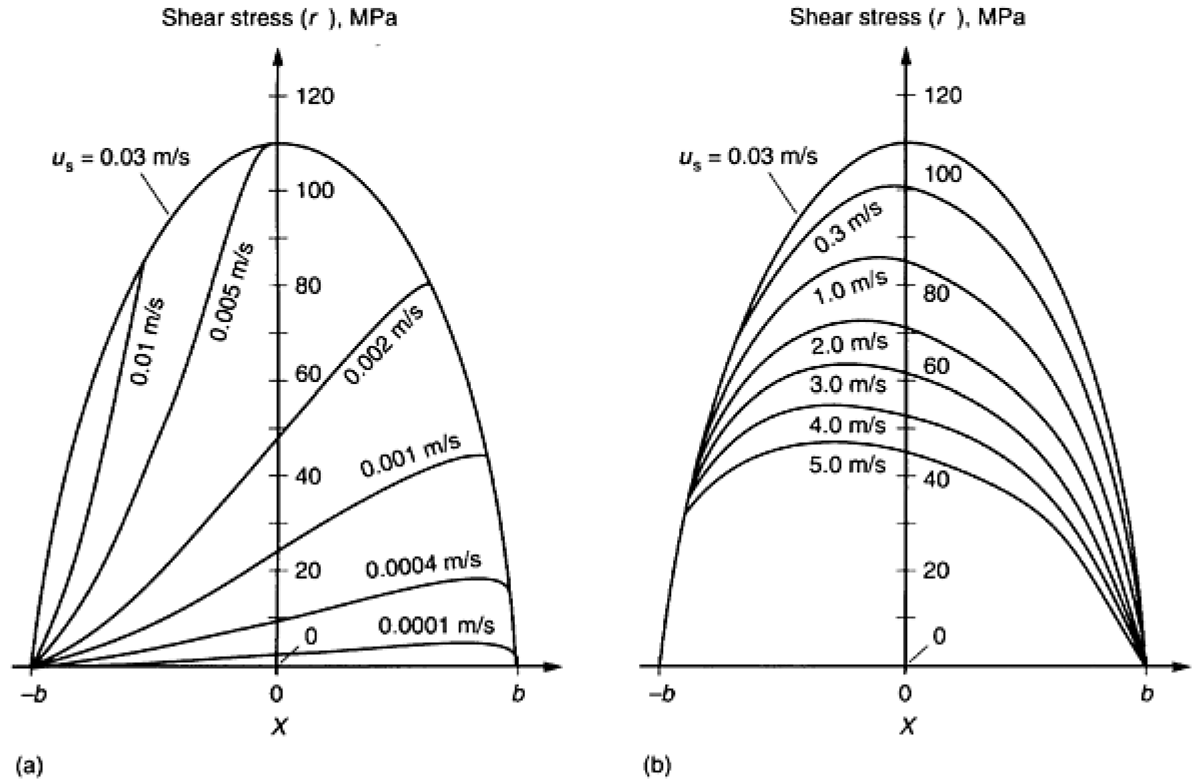

Fig. 11 Typical shear stress distribution along the center of an elliptical contact as a function of sliding condition. (a) Low sliding parameters (1 × 10^{-4} m/s $\leq u_s \leq$ 0.03 m/s). (b) High sliding parameters (0.03 m/s $\leq U_s \leq$ 5.0 m/s). u_s, sliding velocity

Surface temperature in sliding EHL contact is probably the most important variable controlling scuffing and related failures. A surface temperature measurement between a ball and a sapphire plate (Ref 23) confirmed that the Blok-Jaeger method for calculating the maximum surface contact temperature is quite reliable if an accurate sliding coefficient of friction is known. Once the shear stress distribution in full-film EHL has been determined, predicting a thermal map of the surface using Blok-Jaeger's approach is fairly simple. Figure 12 shows typical temperature maps for an elliptical contact with arbitrarily oriented rolling and sliding velocity vectors.

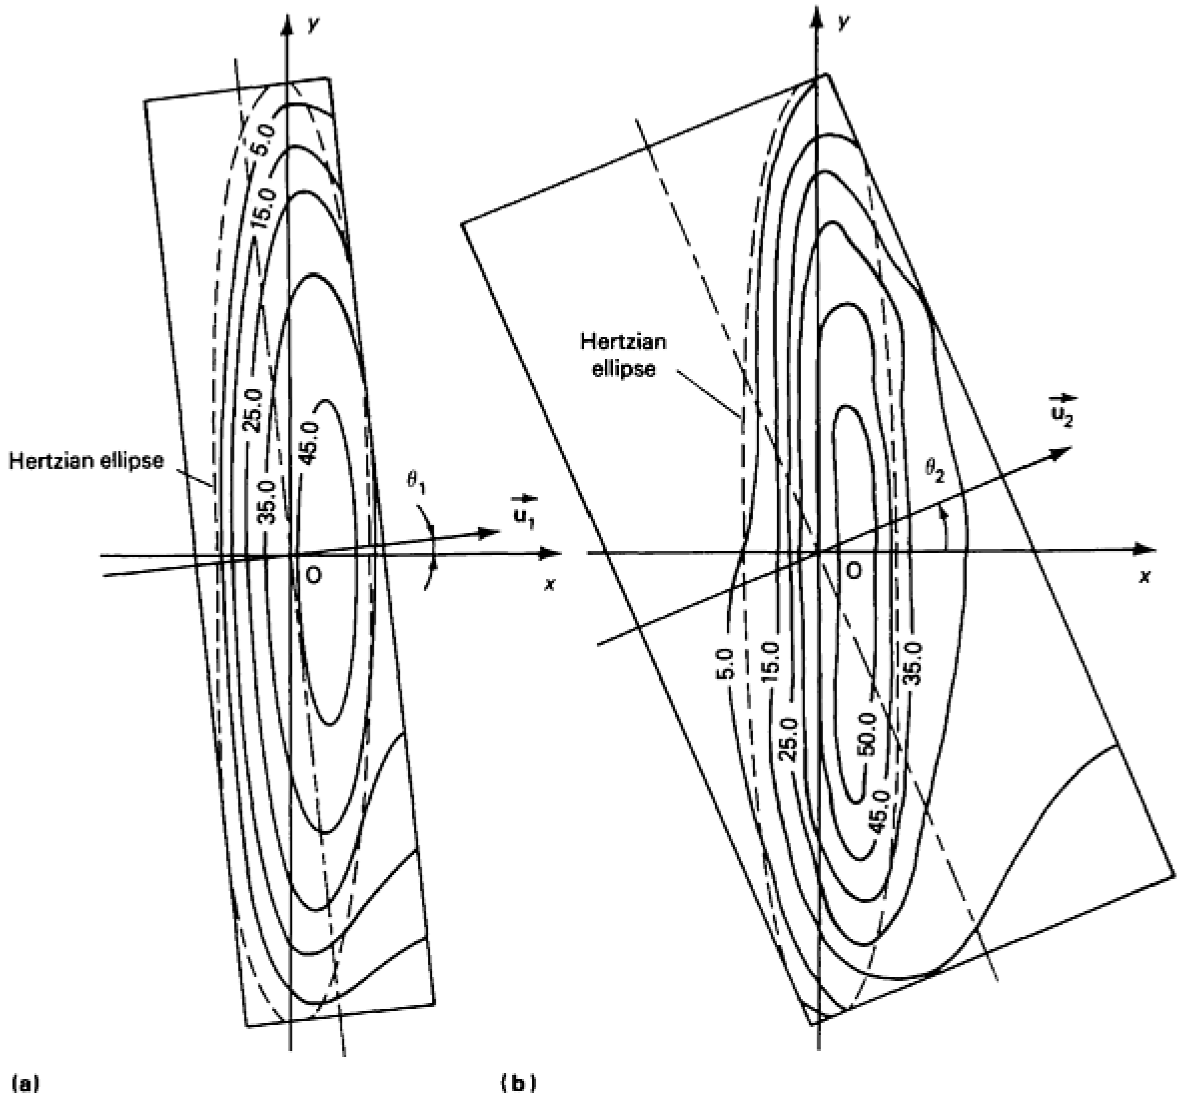

Fig. 12 Typical temperature (T, in °C) maps in an elliptical contact with arbitrarily oriented rolling (θ) and sliding vectors ($\overline{U}$). (a) T_1, θ_1, and U_1. (b) T_2, θ_2, and U_2 (where $T_2 > T_1$; $\theta_2 > \theta_1$; $U_2 > U_1$)

Plastohydrodynamic Lubrication

In metalworking processes, a thick lubricant film can be generated hydrodynamically between the workpiece and the roll or die to control friction and wear. The lubrication behavior between a rigid surface and a plastically deformed surface is known as plastohydrodynamic lubrication. Thick-film PHL occurs infrequently in metalworking lubrication; however, its behavior helps to understand mixed-film PHL, which is more common.

The lubricant film thickness is formed by wedging action just before the workpiece enters the plastically deformed working zone. The ratio of this inlet film thickness to the combined surface roughness of the die and workpiece determines the level of asperity contact at the inlet and throughout the work zone.

For metal rolling and extrusion, the inlet film thickness, h_0, can be calculated from Wilson and Walowit's simple formula (Ref 24), based on a linear wedge profile at the inlet region:

$$h_0 = \frac{6\eta_0\gamma U}{(\tan\theta)(1 - e^{-\gamma\sigma})} \quad \textbf{(Eq 3)}$$

where η_0 is the ambient viscosity of the lubricant, γ is the pressure viscosity coefficient, *U* is the entraining velocity of the surfaces at the inlet zone, θ is the angle of bite, and σ is the workpiece flow strength. The film thickness variation in the work zone depends on the increase in surface velocity caused by the reduction of the workpiece. Additional information is available in the article "Metalworking Lubricants" in this Volume.

Thin-Film Lubrication

Thin-film lubrication of concentrated contacts occupies the regime between thick-film elastohydrodynamic lubrication, where the entire load is supported by the lubricant pressure (regime 3 in Fig. 1), and boundary lubrication, where asperity contacts carry the entire load (regime 2 in Fig. 1). In thin-film lubrication (regime 2 in Fig. 1), the load is shared by the hydrodynamic (or fluid) pressure and the asperity contact pressure. For this reason, thin-film lubrication is sometimes referred to as mixed, partial hydrodynamic, or elastohydrodynamic lubrication.

The boundary between the thick-film and the thin-film regimes can be readily identified by a film parameter, Λ, the ratio of the average lubricant thickness to the composite surface roughness. For surfaces with a Gaussian height distribution, Λ = 3 separates the thick-film and thin-film regimes. The thin-film and boundary lubrication regimes are separated more conveniently by the load ratio, that is, the ratio of the load borne by the fluid pressure to that borne by the asperity contact pressure. The thin-film lubrication regime ends when this load ratio approaches zero. Because of the presence of asperity contacts in thin-film lubrication, the lubrication variables, including film thickness, pressure, shear stress, and surface temperatures, are no longer well-behaved, smooth functions, but instead contain local fluctuations caused by the asperity interactions. For this reason, average quantities--such as the average film, $\bar{h}$--are generally used to describe global or macroscopic variations, and random quantities--such as the asperity film thickness, h^*--are used to describe microscopic variations. Figure 13 illustrates the qualitative features of macrovariables and microvariables in thin-film lubrication.

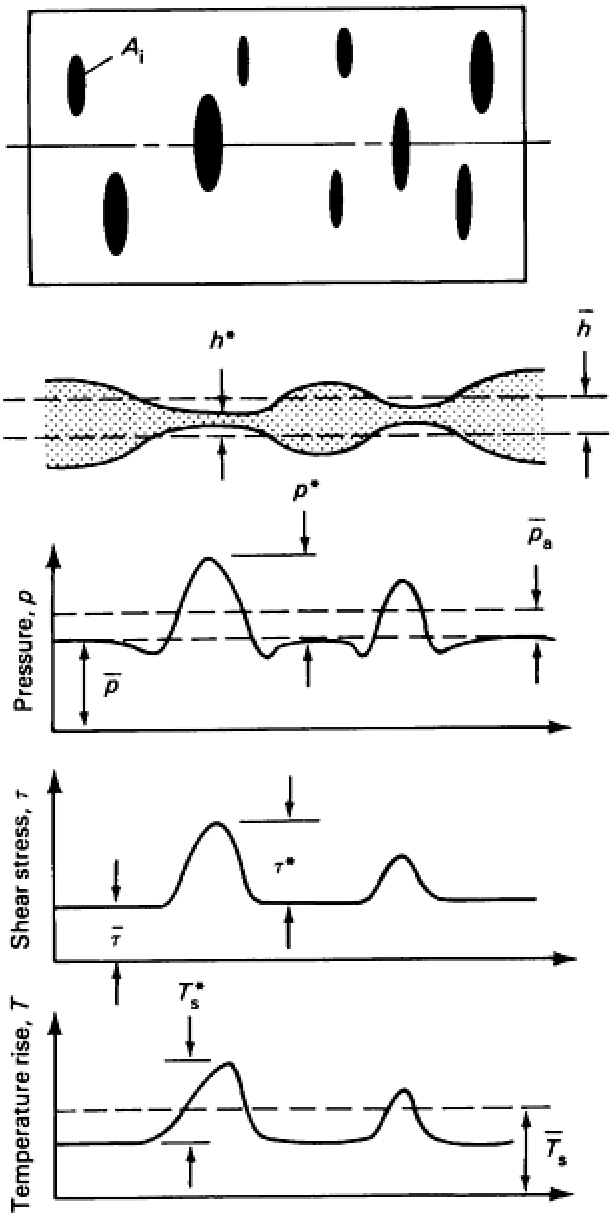

Fig. 13 Qualitative features of macrovariables ($\bar{h}$, $\bar{p}$, $\bar{p}_a$, $\bar{\tau}$, $\bar{T}_s$) and microvariables (h^*, p^*, τ^*, T^*_2) in thin-film lubrication as a function of asperity contacts, A_i

Modes of Asperity Lubrication

The tribological integrity of thin-film lubrication depends on how well the asperities are protected by various modes of lubrication. Figure 14 shows that sliding asperities are protected by three types of lubricating films:

- Micro-EHL and friction polymer films
- Physically adsorbed and other surface films
- Oxide film

Brief descriptions of the generation and breakdown of these films follow.

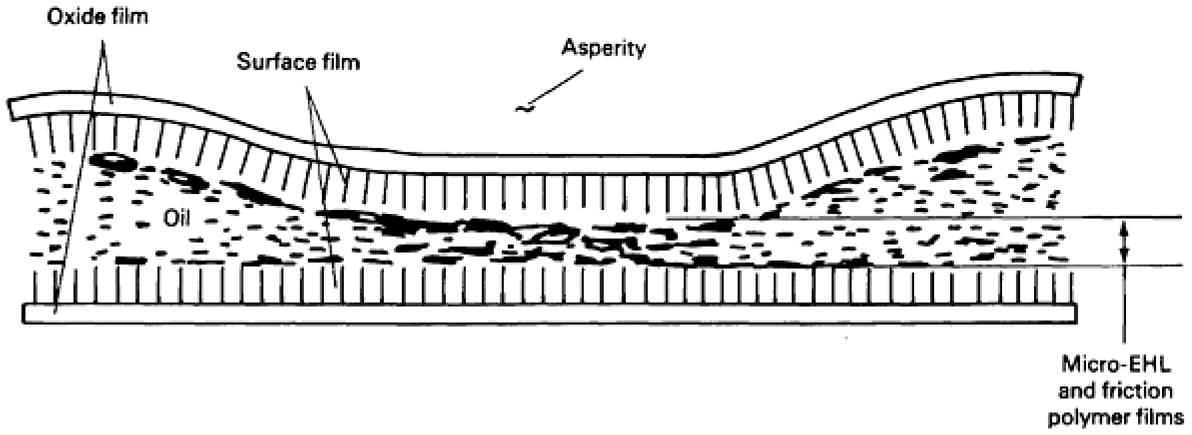

Fig. 14 Three-layer lubricating film that typically protects an asperity from friction and wear

Micro-EHL and Friction Polymer Films. A very thin film of oil can be developed at the asperities of an EHL contact by the normal approaching action of an asperity at the entrance region of the Hertzian conjunction, by the sliding action of the asperity within the conjunction, and by the collision between two sliding asperities. Such films are known as micro-EHL oil films and are the first line of defense against sliding failure. If the geometry of these contacts can be approximated as ellipsoidal tips, these thin oil films can be estimated using existing macro-EHL theories.

The thickness of a micro-EHL film is critically dependent on the lubricant viscosity around the asperity tips. If this viscosity is greatly enhanced by high lubricant pressure generated by the macro-EHL action, then an effective micro-EHL film can be generated: otherwise; the micro-EHL oil film will be too thin. For most mineral oils, the average lubricant pressure, $\overline{p}$, must reach approximately 300 to 500 MPa (45 to 75 ksi) to generate an effective micro-EHL film for protection against scuffing. More detailed descriptions of the breakdown of the macro-EHL action leading to scuffing can be found in Ref 25 and 26.

Another type of polymeric film can also be generated when the asperity temperature becomes excessive because of heating from the sliding friction. This type of film is known as frictionally induced polymeric film. In this process, the lubricant undergoes a primary oxidation and forms a product that, under further oxidation, can polymerize into high-molecular-weight polymers (Ref 27). The polymeric film offers additional protection, but continues to polymerize and finally becomes insoluble sludge and deposit, impeding lubrication.

Physically Adsorbed and Other Surface Films. Physical adsorption is the second line of defense against sliding failure in thin-film lubrication. In this process, a nanolayer or multilayer surface film is formed by adsorption of polar lubricant molecules onto the surface, providing an effective barrier against metal-to-metal contact. This process is reversible. At high temperatures, the adsorbed molecules return to the bulk fluid. When the temperature is lowered, the molecules again become adsorbed on the surface.

The effectiveness of the physically adsorbed surface film ceases when the asperity temperature, T^*_2, reaches a level at which desorption dominates the process. A large fraction of the surface will not be covered by the film, and sliding damage will ensue. For most mineral oils, the critical surface temperature at which half of the surface becomes desorbed is around 150 °C (300 °F). This critical surface temperature appears to depend on the ambient pressure around the sliding asperities (Ref 28). Figure 15 shows a sharp drop in the fractional adsorbate coverage as affected by the ambient lubricant pressure. The critical temperature for $\theta = 0.5$ (that is, half of the surface is uncovered by the surface film) shifts from 140 °C (285 °F) at atmospheric pressure to 250 °C (480 °F) at $\overline{p} = 10^7$ Pa (7×10^4 torr). These data are for poly-α-olefin oils. Similar behavior should also be exhibited by mineral oils. The breakdown of a physically adsorbed surface film generally occurs when the fractional coverage of the adsorbate drops below 0.5. To predict this condition, the asperity temperature, T^*_2, and the ambient lubricant pressure, $\overline{p}$, around the asperity, must be known.

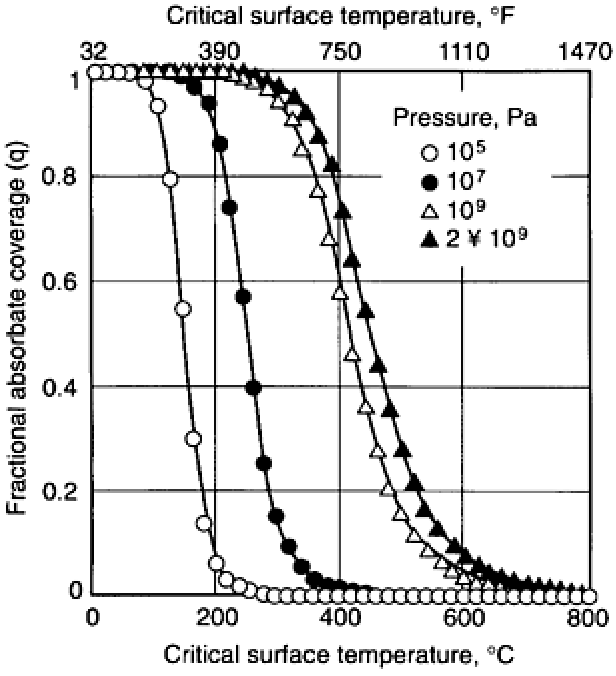

Fig. 15 Plot of fractional adsorbate coverage versus critical surface temperature as a function of lubricant pressure

In addition to adsorbed surface films, other types of surface films can be generated by chemisorption and chemical reaction of the surface with lubricant additives. These films will be discussed in the section "Boundary Lubrication" in this article.

Oxide Film. The last line of defense of the lubricated layers is the oxide film formed by oxidation of the surface with oxygen present in the atmosphere or dissolved in the lubricant. The breakdown mechanisms of oxide films by gradual depletion or by sudden transition from mild to severe wear are only partially understood. The critical conditions for transition from mild to severe wear appear to be associated with a critical speed rather than a critical load (Ref 29).

Boundary Lubrication

Boundary lubrication lies in the regime of extremely low $\Lambda$for cases of very low speed, low viscosity, and very high load. In this regime, the frictional coefficient is usually insensitive to speed, viscosity, or load. The load is totally supported by the asperity contacts. Friction and wear behavior is completely governed by any film that happens to be on the surface, either planned or unplanned. The frictional coefficient, μ, for ferrous surfaces lubricated by nonreactive oils is generally between 0.1 to 0.15. For asperities partially lubricated by surface films, μcan increase to 0.5--the frictional coefficient between most dry sliding iron oxides.

Three types of surface films are commonly known to be effective in boundary lubrication: physically adsorbed, chemically adsorbed, and chemically reacted surface films. Schematic diagrams of the molecular structure of each type of boundary film are shown in Fig. 16 (Ref 30).

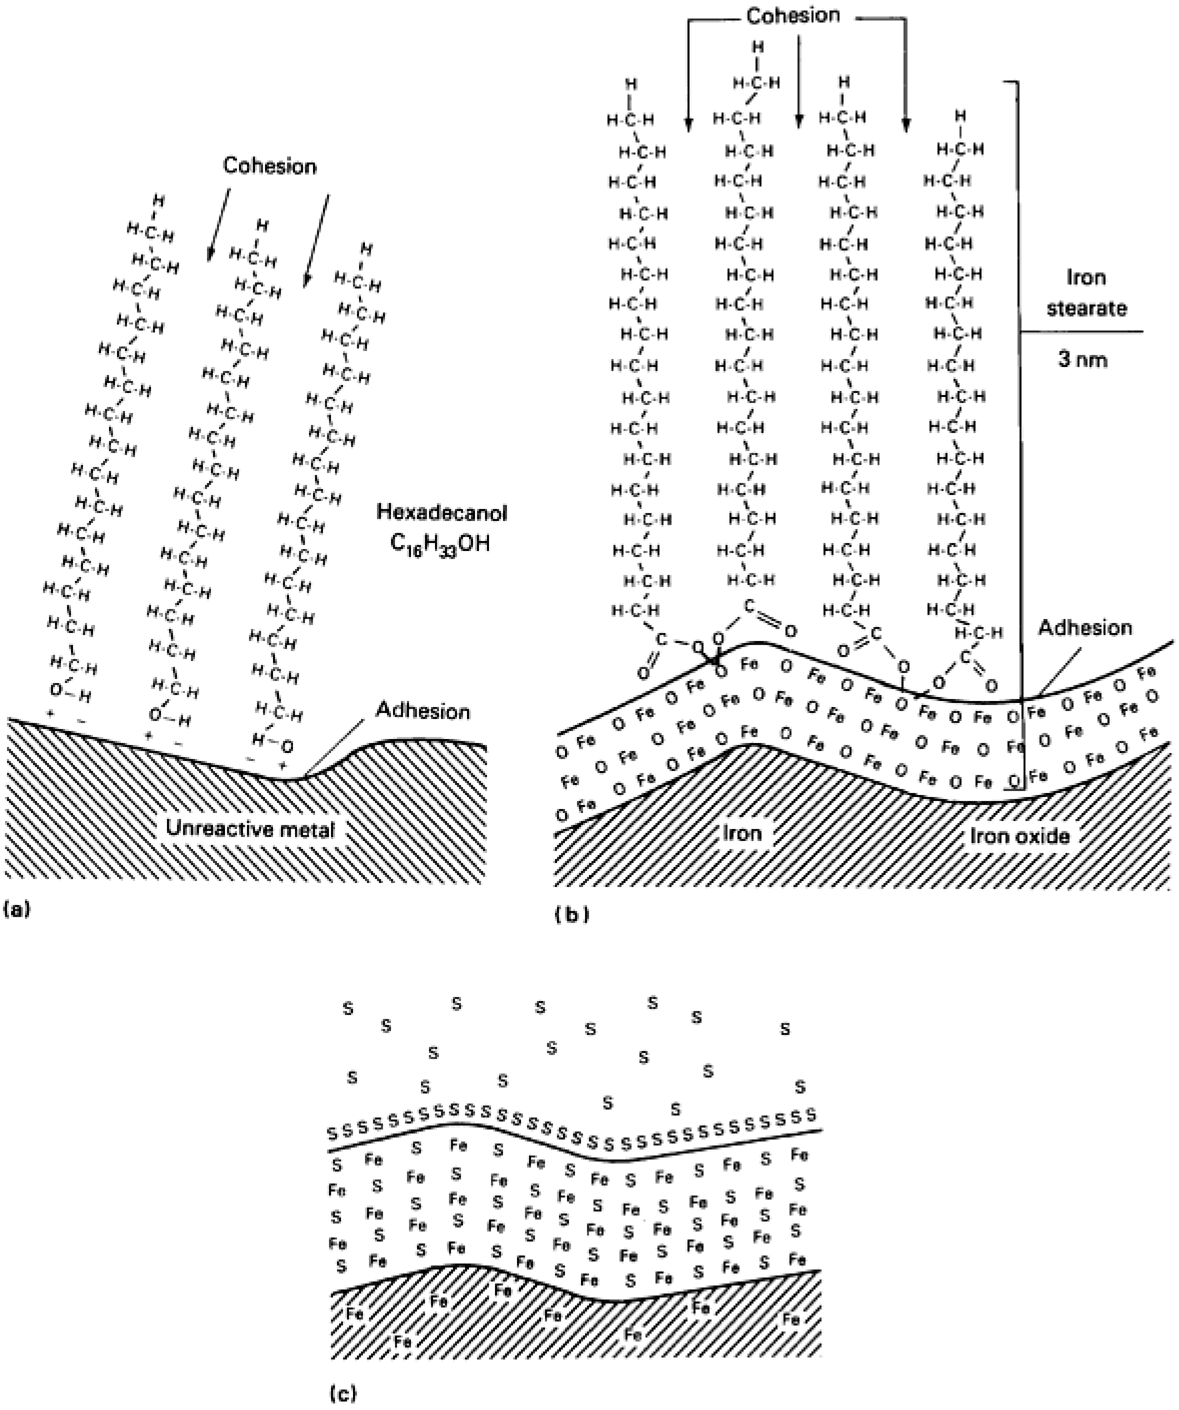

Fig. 16 Schematics showing three types of surface films present in boundary lubrication. (a) Physisorption with preferred orientation of three polar molecules of hexadecanol to a metal surface. (b) Chemisorption of stearic acid on an iron surface to form a monolayer of iron stearate, a soap. (c) Inorganic film formed by chemical reaction of sulfur with iron to form iron sulfide. Source: Ref 30

Adsorbed films are usually monomolecular and have thicknesses in the range of nanometers. Reactive films can be quite thick and are much more stable and durable than adsorbed films. They are enhanced by the additives in the base lubricants that form sulfides, chlorides, or phosphates with the solid surfaces, providing effective surface films for protection of sliding asperities under extreme conditions.

Lubricant Additives and Their Functions

Syed Q.A. Rizvi, The Lubrizol Corporation

Introduction

A LUBRICANT protects and prolongs the life of equipment by performing these important functions (Ref 1):

- Lubrication, because it reduces friction and wear by introducing a lubricating film between moving parts
- Cooling, because it helps dissipate heat away from the critical parts of the equipment
- Cleaning and suspending, because it facilitates the smooth operation of the equipment by removing and suspending deposits such as carbon, sludge, and varnish
- Protection, because it prevents metal damage that is due to oxidation and corrosion

Untreated, or nonformulated, lubricants (mineral-based oils and synthetic-based oils) do not possess the necessary properties to be effective in the demanding lubrication environments that exist today. To perform the above-mentioned functions properly, base fluids need the help of chemical additives. Additives improve the lubricating ability of the base oils by either enhancing the desirable properties already present or adding new properties. For this reason, additives are an integral part of modern formulated lubricants.

A formulated lubricant comprises a base fluid (Ref 2) and a performance package. The performance package contains a number of additives that help improve the lubricating ability of the base fluid. The quality and quantity of additives in the performance package depend on the quality of the base fluid and the intended use. In general, poor-quality base fluids need better additives, and possibly in larger amounts, than the base fluids of good quality. Likewise, applications that put more demand on the lubricant (engine oils and automotive gear oils) require superior additives than less-demanding applications, such as industrial lubricants and metalworking fluids.

Lubricants can be broadly classified as either engine or nonengine lubricants. Engine lubricants can be subcategorized, in terms of application, as:

- Gasoline engine oils

- Diesel engine oils (automotive, stationary, railroad, and marine)
- Natural gas engine oils
- Aviation engine oils
- Two-stroke cycle engine oils
- Alternate fuel engine oils

Nonengine lubricants are subcategorized as:

- Transmission fluids (automatic, manual, and power)
- Power steering fluids
- Shock absorber fluids
- Gear oils (automotive and industrial)
- Hydraulic fluids (tractor and industrial)
- Metalworking fluids
- Miscellaneous industrial oils
- Greases

Engine lubricants or oils are designed for use in internal combustion engines that operate on a wide variety of fuels. Major problems in these engines relate to the interaction of combustion products with the lubricant, which results in deposits and wear. The combustion products find their way into the crankcase as "blowby" and contaminate the lubricant. This causes the formation of a wide variety of oxygenated products through lubricant autoxidation. The interaction between the components of the blowby and these oxygenated products leads to the formation of harmful engine deposits which, if left unchecked, ultimately impair the operation of an engine (Ref 3, 4).

The performance of engine oils is judged on their ability to reduce friction, resist oxidation, minimize deposit formation, and prevent corrosion and wear. In the United States, the performance specifications for engine oils are established by the collaborative efforts of the Society of Automotive Engineers (SAE), the American Petroleum Institute (API), and the American Society for Testing and Materials (ASTM) (Ref 5). The API establishes the performance categories or service classifications and their descriptions for engine oils. The U.S. military and original equipment manufacturers (OEMs) have their own performance requirements, which can be over and above those of the API. Other countries have similar organizations that establish performance criteria and categories for lubricants used within their domains.

The SAE viscosity grades and API service classifications are the usual means used to define the performance of automotive engine lubricants (Ref 6, 7). The viscosity classification assures easy starting and lubrication at low temperatures, and adequate lubrication at high temperatures. The service classification assures the user that the lubricant meets the performance requirements of the equipment manufacturer.

Nonengine lubricants are used to lubricate equipment that operates in a noncombustion environment. Transmission fluids, hydraulic fluids, gear oils, and greases are used for mechanisms that transfer power from a power source, such as an engine, to parts that perform the actual work, such as wheels.

Transmission fluid performance requirements fluids are established by OEMs (Ref 8). The most important features of the transmission fluids are their frictional consistency (durability) and frictional compatibility with the transmission components. In automatic transmissions, such components include clutches and bands; manual transmissions and manual transaxles also include cone- or plate-type synchronizers. Unlike automatic transmissions, which use transmission fluids recommended by OEMs only, manual transmissions use a wide variety of fluids, including automatic transmission fluids, engine oils (5W-30), some gear lubricants, and specialty fluids. In addition to frictional properties, certain OEMs require that the transmission fluids used in their equipment must have improved shear stability, low-temperature fluidity, and other specific characteristics.

Power transmission fluids are designed for use in heavy-duty automatic transmissions and torque converters, which are commonly used in agriculture, transportation, and construction equipment. The viscosity and frictional properties of these fluids are critical to their performance. Both SAE and OEM performance specifications are used to describe these fluids (Ref 9).

Power steering fluid performance requirements are established by the OEMs. The quality is assessed on the basis of frictional properties, seal compatibility, oxidation resistance, and rust control. Some automatic transmission fluids closely meet these criteria and can be used in this application.

Shock absorber fluids require good frictional characteristics, oxidation resistance, wear protection, and seal compatibility. Compressibility and antifoaming characteristics are also desirable. The shock absorber producer and the OEMs jointly determine the performance criteria for these fluids.

Gear oils are formulated to provide both gears and axles with extreme-pressure protection against fatigue, scoring, and wear under boundary lubrication conditions (Ref 10).

Automotive gear oils are classified in a manner similar to engine oils; that is, through SAE viscosity grades (Ref 11), API service designations (Ref 12, 13), U.S. military specifications, and OEM performance requirements. However, the gear oil viscosity grading system is different from the engine oil viscosity grading system.

The service requirements of industrial gear oils are established by the American Gear Manufacturers Association (AGMA), the Society of Tribologists and Lubrication Engineers (STLE), and a variety of other organizations, such as U.S. Steel, Cincinnati Milacron, and Alcoa (Ref 14).

Hydraulic fluids are of two general types: those used to lubricate tractor hydraulics and those used to lubricate industrial hydraulic equipment.

Tractor hydraulic fluids combine hydraulic and transmission properties with extreme-pressure properties. Tractor hydraulic fluids differ widely in performance requirements because OEMs cannot agree on common specifications for a universal tractor hydraulic fluid. These fluids, in general, seek to provide extreme-pressure and wear protection, and to match the frictional requirements of the equipment. The quality of these fluids is assessed on the basis of their ability to meet individual OEM specifications, as well as these performance requirements: API GL-4 (for extreme pressure), Caterpillar TO-2/TO-4 (for friction), and Allison C-4 (for friction, oxidation, and wear).

Industrial hydraulic fluids comprise three categories: antiwear hydraulic fluids, fire-resistant fluids, and rust and oxidation-inhibited oils (R&O oils). The OEMs define the performance criteria for these lubricants. Each hydraulic pump manufacturer has its own performance requirements governing viscosity, antiwear properties, and ability to inhibit rust, oxidation, corrosion, foam, filter plugging, and demulsibility.

Metalworking fluids are used to facilitate the manufacture of metal parts. They do so by providing lubrication during workpiece formation, removing debris and heat, and aiding in the cutting, grinding, and shaping operations. Based on their functions, these fluids are classified as forming fluids, removal fluids, protecting fluids, and treating fluids. The specifications for these fluids are established by OEMs and the end users.

Miscellaneous industrial oils include turbine oils, slideway lubricants, rock drill oils, and the like. These lubricants are usually specified by the International Organization for Standardization (ISO) viscosity grades and U.S. military and (OEM) performance requirements.

Greases are classified by chemical composition and many other properties. They are commonly identified by the type of thickener used, by the National Lubricating Grease Institute (NLGI) consistency grades, and by NLGI service classifications (Ref 15).

Additives

Lubricant additives can be broadly categorized as being either chemically active or chemically inert. Chemically active additives, such as dispersants, detergents, antiwear and extreme-pressure (EP) agents, oxidation inhibitors, and rust and corrosion inhibitors, have the ability to interact chemically with metals (to form a protective film) and the polar oxidation and degradation products (to make them innocuous). Chemically inert additives, which improve the physical properties that are critical to the effective performance of the lubricant, include emulsifiers, demulsifiers, pour-point depressants, foam inhibitors, and viscosity improvers.

Most lubricant additives, except perhaps some viscosity improvers and pour-point depressants, consist of an oleophilic hydrocarbon group and a hetero atom (N,O,S, and P)-based polar functionality (Fig. 1). The hydrocarbon group is of

sufficient carbon length to impart the desired solubility characteristics to the additive. The additives that require greater solubility in oil (dispersants, detergents, and viscosity improvers) usually contain large hydrocarbon groups. Those that require either lower solubility or greater surface activity (foam inhibitors and EP agents) contain small hydrocarbon groups. A proper balance of polar and nonpolar characteristics is critical to the additive's performance.

Fig. 1 Typical additive molecule

The functional groups of chemically active and inert additives identified above, as well as friction modifiers and other additives, are described more fully below.

Dispersants

Dispersants are additives that are used to suspend oil-insoluble resinous oxidation products and particulate contaminants in the bulk oil. By doing so, they minimize sludge formation, particulate-related abrasive wear, viscosity increase, and oxidation-related deposit formation.

A dispersant molecule contains an oleophilic hydrocarbon moiety and a polar functional group. The polar group, usually oxygen- or nitrogen-based, attaches itself to the oxidation products and sludge particles, while the oleophilic hydrocarbon group keeps the particles suspended in oil (Ref 4). The hydrocarbon radical is either oligomeric or polymeric, and is usually aliphatic in nature. It contains from 70 to 200 or more carbon atoms to ensure good oil solubility, with a polybutenyl alkyl group being the most commonly used hydrocarbon group.

In some dispersants, the hydrocarbon moiety is derived from a high molecular weight polymer, such as olefin copolymer, polyacrylate, or styrene-ester polymer. Such dispersants can function as dispersants as well as viscosity improvers, and are appropriately called dispersant-viscosity improvers.

The chemical classes that are suitable for use as dispersants include alkenylsuccinimides, succinate esters, high molecular weight amines, Mannich bases, and phosphonic acid derivatives. Commercially, polybutenylsuccinic acid derivatives are the most commonly used dispersant types.

Both the succinimides and the succinate esters are prepared from polybutenylsuccinic anhydrides. Polyisobutylene (molecular weight between 440 and 5000) is reacted with maleic anhydride, either thermally or in the presence of chlorine, to yield the succinic anhydride. Further reaction of the succinic anhydride with amines (alkylenepolyamines and heterocyclic polyamines) results in the formation of succinimide dispersants. The reaction of the succinic anhydride with alcohols (especially polyhydric alcohols) results in the formation of succinate-ester dispersants. Figure 2 summarizes the syntheses of these dispersants.

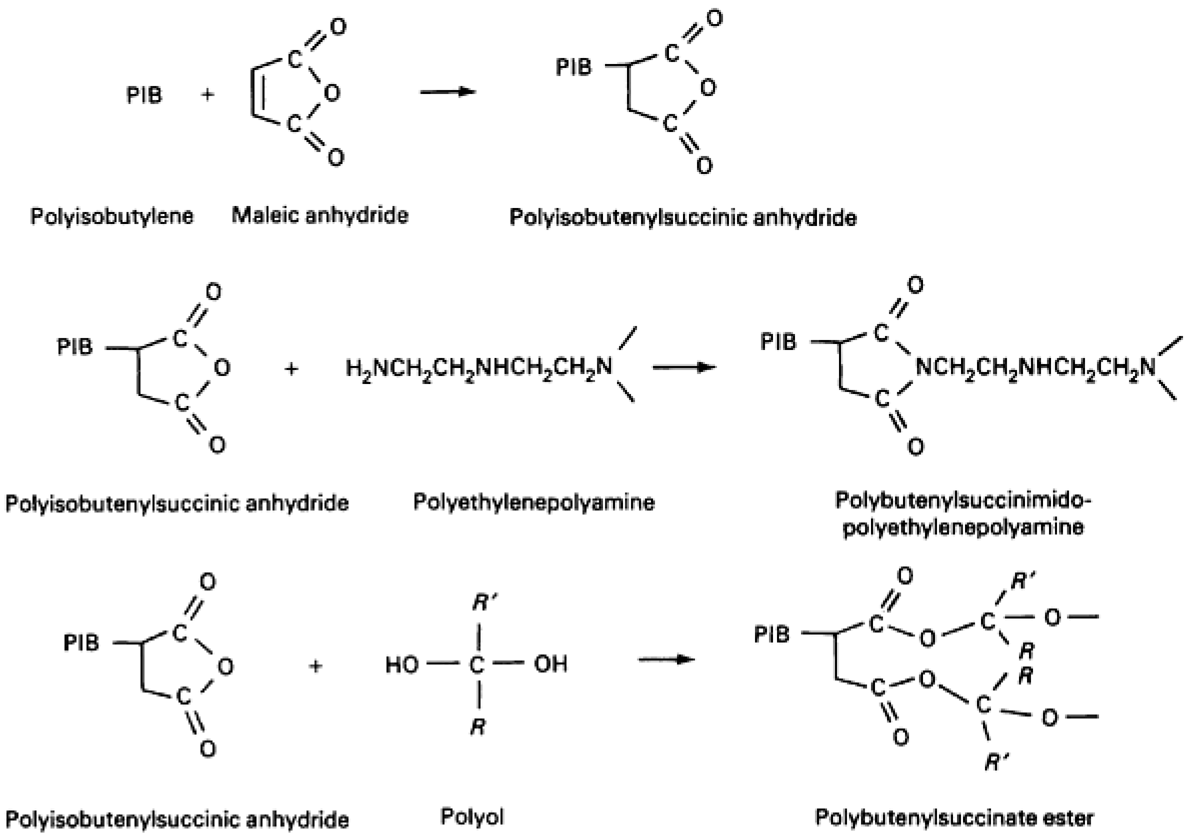

Fig. 2 Synthesis of alkenylsuccinic acid dispersants

Mannich dispersants are produced by the condensation of a high molecular weight alkylphenol (polybutenylphenol), an aldehyde, and alkyleneamines or alkylenepolyamines. Phosphonic acid ester dispersants are prepared by reacting phosphonic or thiophosphonic acids with either ethylene oxide or propylene oxide. The starting acids are obtained from the hydrolysis of the olefin-phosphorus pentasulfide adducts. The preparation of the Mannich products and the phosphonic esters is shown in Fig. 3.

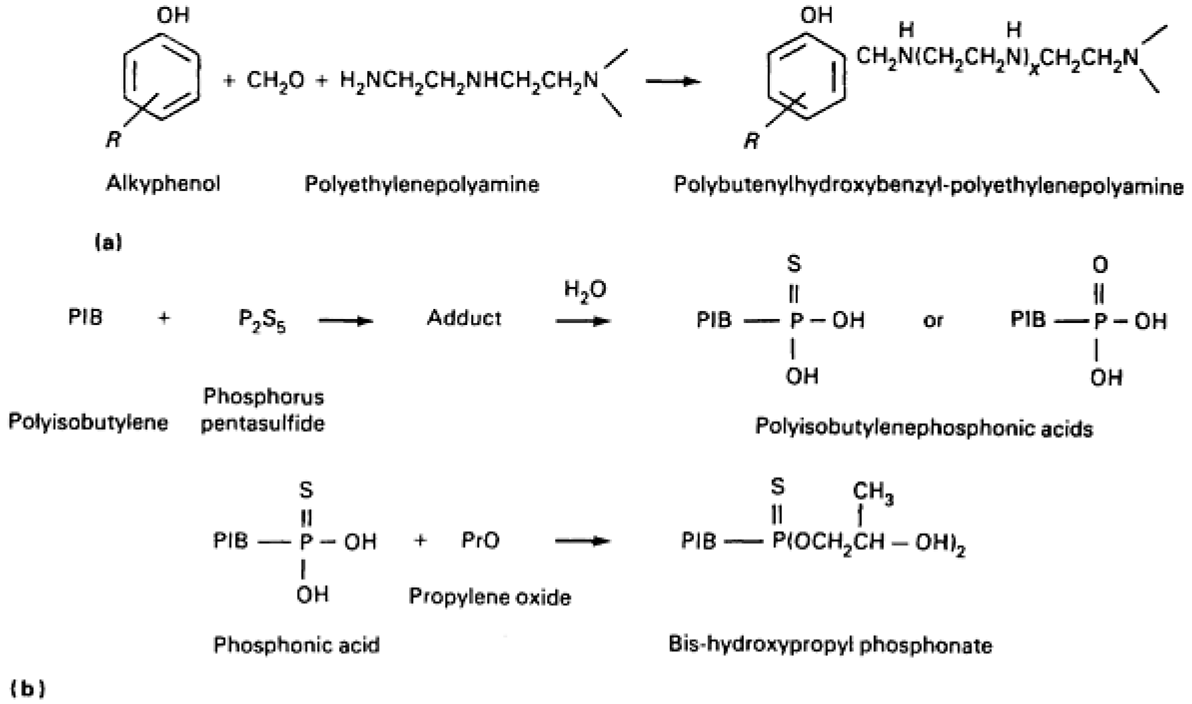

Fig. 3 Synthesis of dispersants (a) Mannich. (b) Phosphonic acid

The dispersants are primarily used in gasoline engine oils, diesel (heavy-duty and railroad) engine oils, natural gas engine oils, and aviation piston engine oils. Dispersants are also used in automatic transmission fluids and gear lubricants. The gasoline and heavy-duty diesel engine oils account for 75 to 80% of the total dispersant use.

Succinimide and succinate-ester (pentaerythritol esters of polyisobutenylsuccinic anhydride) types are used both in gasoline and diesel engine oils. High molecular weight amine and Mannich types are used in gasoline engine oils only. Succinimide dispersants also find use in automatic transmission fluids, power steering fluids, and, on a limited basis, in gear oils.

In gasoline and diesel engine oils, the effectiveness of a dispersant is assessed on the basis of its ability to disperse lamp black or used engine oil sludge in laboratory screen tests and its performance in various ASTM sequence dynamometer engine tests, as well as fleet testing.

Detergents

Detergents perform functions that are similar to those of dispersants. Additionally, detergents neutralize acidic combustion and oxidation products, and hence, control rust, corrosion, and resinous build-up in the engine.

Detergents are metal salts of organic acids. The quantity of metal can either equal or exceed the stoichiometric amount necessary for complete neutralization of the acid function. When the metal is present in a stoichiometric amount, the detergents are referred to as neutral; when excess metal is present, they are referred to as either basic or overbased.

Detergents are described chemically in terms of their soap content, the degree of overbasing, and the total base number (TBN), which is expressed as mg KOH/g of additive. The soap content refers to the amount of neutral salt and reflects cleaning ability, or detergency. The degree of overbasing describes the ratio of equivalents of metallic base to equivalents of acid substrate. The TBN of the detergent indicates its acid neutralizing ability.

Detergents, like dispersants, contain a surface-active polar group and an oleophilic hydrocarbon radical with an appropriate number of carbon atoms to ensure good oil solubility. Metal sulfonates, phenates, carboxylates, salicylates, and phosphonates are common examples of the polar groups that are present in detergent molecules.

Alkylbenzenesulfonic acids, alkylphenols, sulfur-coupled and methylene-coupled alkylphenols, carboxylic acids, and alkylphosphonic acids are the commonly used detergent substrates. The methods of their synthesis are shown in Fig. 4. Alkylbenzenesulfonic acids are obtained by sulfonating alkylbenzenes. The products obtained by sulfonating alkylaromatics from petroleum refining are referred to as natural sulfonates, and those obtained by sulfonating alkylaromatics from catalytic alkylation process are referred to as synthetic sulfonates. Alkylphenols are prepared from phenol and an olefin by using an acid catalyst. These alkylphenols can be further reacted with sulfur, sulfur dichloride, or formaldehyde to form sulfur-bridged and methylene-bridged alkylphenols. Alkylsalicylic acids are prepared through the use of Kolbe's process, which involves reacting an alkali metal phenate with carbon dioxide. Alkylphosphonic acids are the hydrolysis products of polyisobutylene-phosphorus pentasulfide adducts.

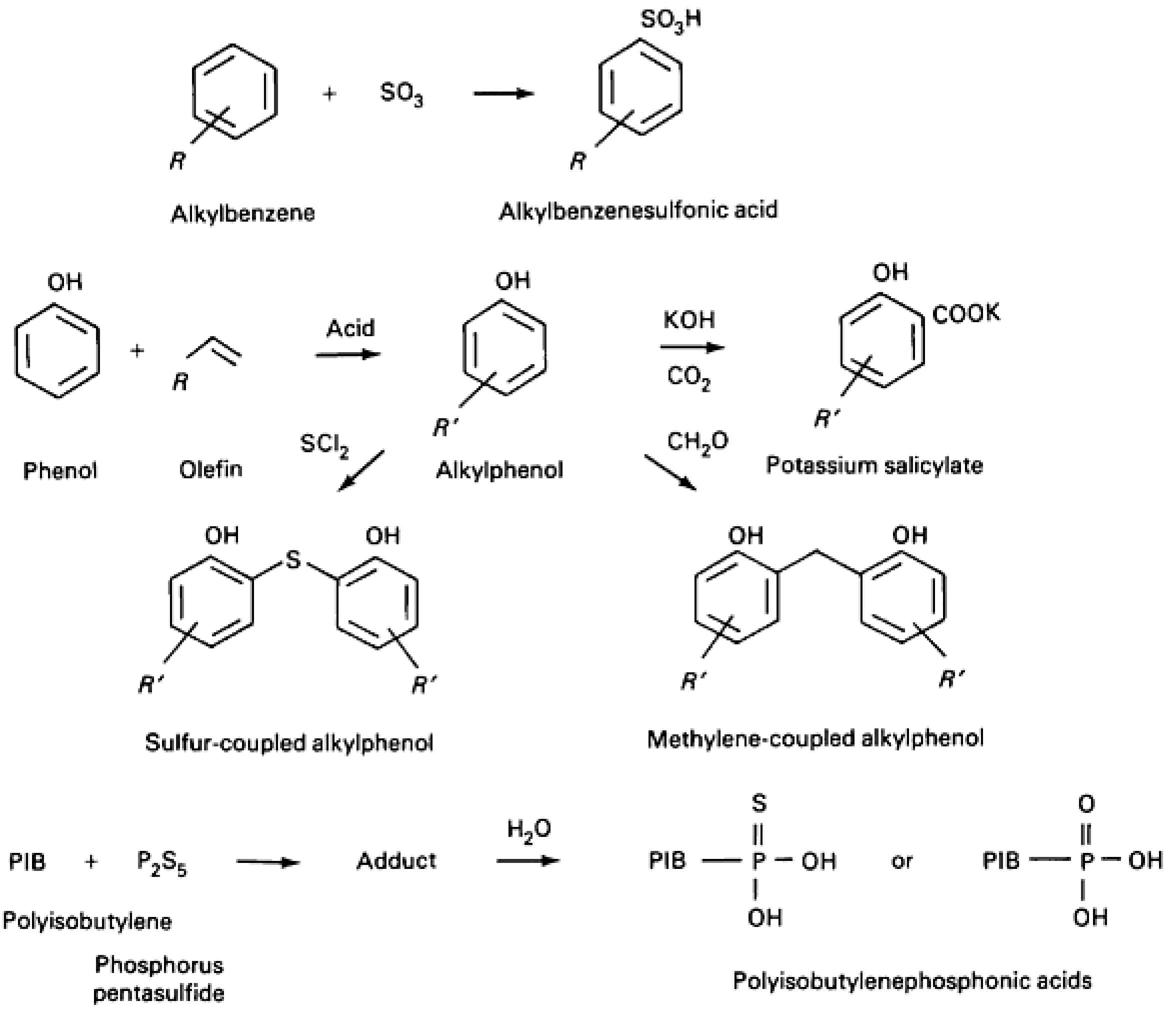

Fig. 4 Detergent substrates

The detergents are prepared by reacting an organic acid with an appropriate metal base in the presence of a polar promoter. A number of metals can be used to make detergents, but sodium, magnesium, calcium, and barium are the most common. Of these, calcium and magnesium are metals that are used most widely, with a clear preference for calcium because of its lower cost. Use of barium is being phased out because of toxicity concerns. The bases of choice are caustic (sodium hydroxide) for sodium detergents; lime (calcium hydroxide) for calcium detergents; magnesium oxide for magnesium detergents; and barium hydroxide for barium detergents. In basic detergents, which contain excess base, the base can be present as is or as metal carbonate. In practice, virtually all commercially available detergents are overbased to some extent. For example, commercial "neutral" sulfonates have a TBN of 30 or less. "Basic" detergents typically have a TBN that ranges from 200 to 500.

Sulfonate, salicylate, and carboxylate detergents are commercially available as calcium and magnesium salts. Phenate detergents are available as calcium salts, and phosphonate detergents are available as barium salts only. Basic calcium sulfonates constitute 65% of the total detergent market, followed by phenates at 31%.

The preparation of various detergent types is depicted in Fig. 5, whereas Fig. 6 shows the generalized structures for the neutral detergents. Basic detergents can be considered neutral detergents that contain the excess base in an associated form.

Substrate + Metal Oxide or Hydroxide (MO, $M(OH)_n$; Stoichiometric amount) $\longrightarrow$ Neutral Salt

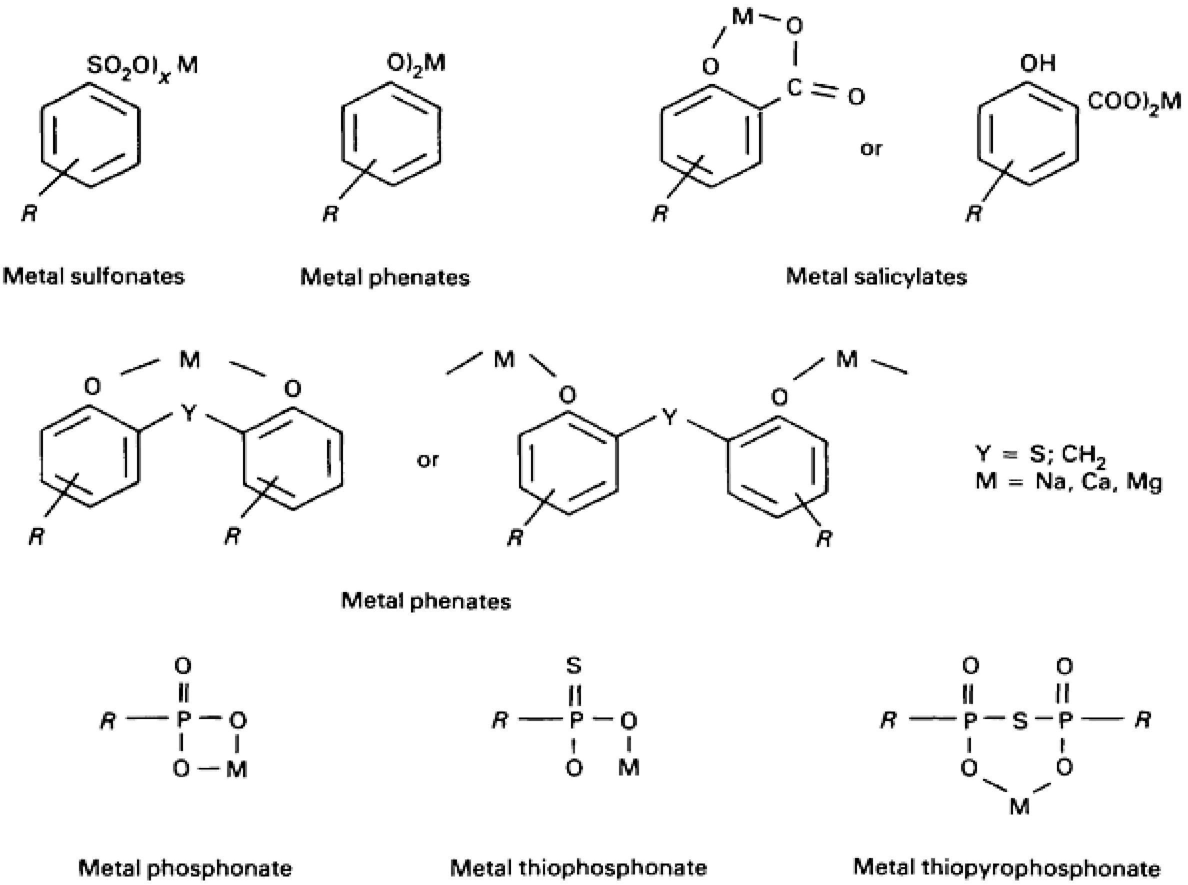

Fig. 6 Idealized structures for neutral detergents

Detergents are used in lubricants to keep oil-insoluble by-products of combustion and oil oxidation in suspension. Depending on the end use of the lubricant, insoluble by-products can be coke, acidic decomposition products, or deposit-forming resinous products (Ref 3, 4). Detergents control the buildup of these undesirable contaminants by keeping the equipment surfaces clean and by neutralizing the acidic products of lubricant oxidation and decomposition. They keep the equipment surfaces clean, both by forming a protective film on the metal surfaces through adsorption and by suspending the deposit-forming species in the bulk oil through association (Ref 16).

Detergents can act as oxidation inhibitors, depending on the nature of the functional group. For example, phenates, sulfurized phenates, and salicylates possess oxidation-inhibiting properties, presumably because of the presence of the phenolic functional group.

Detergents are primary used in crankcase lubricants. Gasoline and diesel engine oils account for over 75% of the total detergent consumption. Detergent treatment levels in engine lubricant formulations are fairly high; marine diesel engine lubricants contain the highest detergent concentrations. Marine engines use high-sulfur fuel, which leads to acidic combustion products (sulfuric acid) and, therefore, need the high base reserve in "basic" detergents for neutralization.

Detergency in diesel engine oils (for API quality) is evaluated using both single-cylinder engine tests (Caterpillar 1K/1H2) and multicylinder engine tests (NTC-400, Mack T-6). Some OEMs use their own specifications. Detergents have additional use in automatic transmission fluids and tractor hydraulic fluids. However, their use in these applications is not to control deposits, but to modify the frictional properties of the fluid.

Antiwear and Extreme-Pressure Agents

Wear is a phenomenon that occurs in all equipment that has moving parts. Three conditions that can lead to wear are surface-to-surface contact (frictional wear); surface contact with foreign matter (abrasive wear); and erosion by corrosive materials (corrosive wear). Abrasive wear can be prevented by installing an efficient filtration mechanism to remove the offending debris. Corrosive wear can be controlled by using additives that can neutralize the reactive species that attack the surface.

Under normal conditions of speed and load, two metal surfaces are effectively separated by a lubricant film, a condition known as hydrodynamic, or thick-film, lubrication. An increase in load or a decrease in speed promotes metal-to-metal contact. This causes a rise in temperature in the contact zone, which is due to frictional heat. The consequence is lubricant viscosity loss, which decreases the film-forming ability of the lubricant and the ability to minimize metal-to-metal contact. Under these conditions, the nature of lubrication changes from hydrodynamic to mixed-film to boundary, or thin-film, lubrication. Antiwear additives and EP agents offer protection under mixed-film and boundary conditions. (Ref 17).

Both antiwear and EP additives provide protection by a similar mechanism, except that the EP additives typically require higher activation temperatures and loading conditions than the antiwear additives. Simply stated, antiwear additives perform under mild conditions, and EP additives, under severe conditions. The severity of conditions is determined by the "load factor" experienced by the additive and the temperature at which the additive functions. Heavy loading requires EP agents and mild loading requires antiwear agents. Thus, it is important to consider both the load and the temperatures that the equipment is likely to experience before selecting antiwear and EP agents.

Antiwear agents are commonly used in engine oils, automatic transmission fluids, power steering fluids, and tractor hydraulic fluids. Extreme-pressure agents are used in gear oils, other power-transmitting fluids, shock absorber fluids, and metalworking fluids. In gasoline engine oils, the ASTM sequence IIIE and VE engine tests are used to determine the effectiveness of antiwear agents. In gear oils, the CRC L-37 and CRC L-42 axle tests are used to determine the performance of EP agents. The general effectiveness of these additives in metalworking fluids is determined by the use of Timken, four-ball, and Falex tests. Extreme-pressure additives are usually supplemented with antiwear additives to make the formulations effective at lower temperatures and milder loading conditions.

Most antiwear and extreme pressure agents contain sulfur, chlorine, phosphorus, boron, or combinations thereof. The classes of compounds that inhibit adhesive wear include alkyl and aryl disulfides and polysulfides, dithiocarbamates, chlorinated hydrocarbons, and phosphorus compounds (phosphites, phosphates, phosphonates, and dialkyl dithiophosphates).

Both antiwear and EP additives function by thermal decomposition and by forming products that react with the metal surface to form a solid protective layer. This solid metal film fills the surface asperities, thereby reducing friction and

preventing welding and surface wear. The metal film consists of iron halides, sulfides, or phosphates, depending on the antiwear and EP agents used. Friction modifiers differ from antiwear and EP agents in that they form the protective film through physical adsorption instead of chemical reaction.

Many effective extreme pressure and antiwear additives are corrosive to metals. Therefore, lubricants are typically formulated to optimize a balance between extreme-pressure and antiwear protection and corrosivity.

Antiwear Agents. Dithiophosphoric acid zinc salts are the most widely used antiwear agents. In addition to providing antiwear protection, zinc dialkyl dithiophosphates act as oxidation and corrosion inhibitors. They are primarily used in gasoline and diesel engine oils and in industrial lubricants.

Zinc dialkyl dithiophosphates or diaryl dithiophosphates are synthesized by reacting respective dithiophosphoric acids with zinc oxide (Fig. 7). The dithiophosphoric acids are product of the reaction of either an alcohol or a phenol with phosphorus pentasulfide.

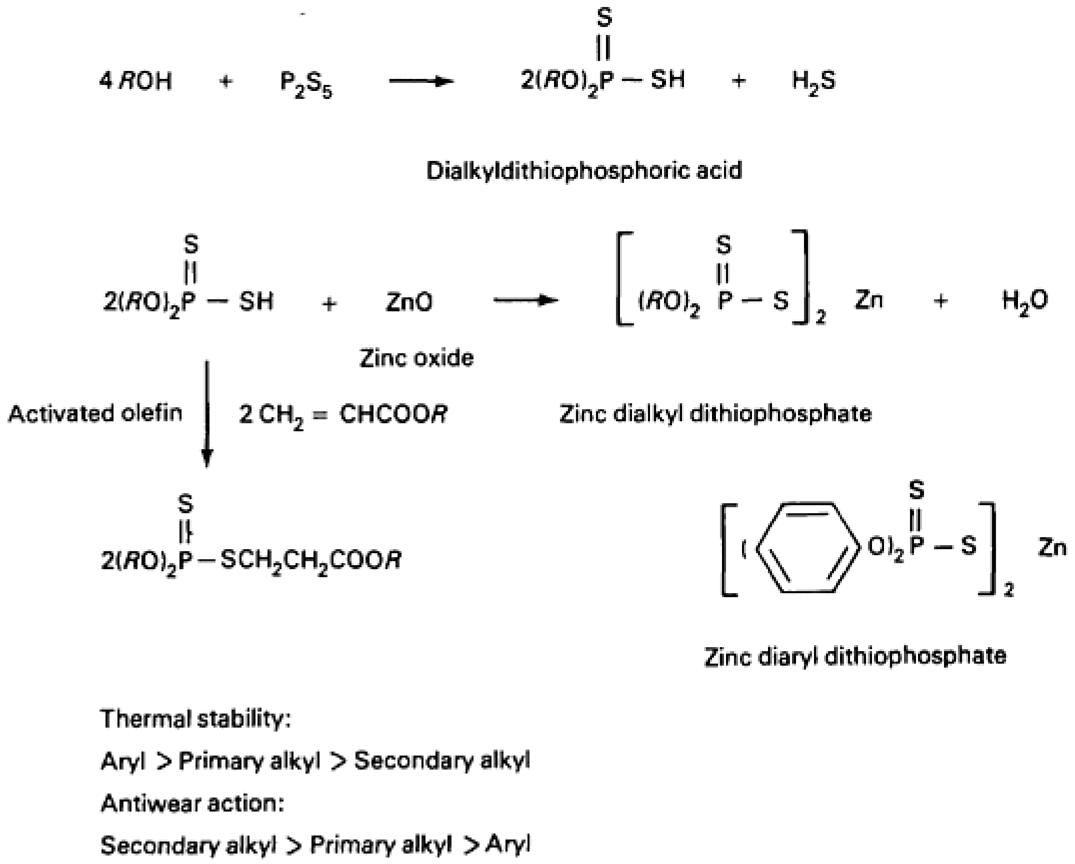

Fig. 7 Preparation of dithiophosphoric acid derivatives

The thermal and hydrolytic stability of these products depends on the nature of the organic group. The dialkyl dithiophosphates derived from primary alcohols are more thermally stable than those derived from secondary alcohols. They are extensively used in formulating gasoline and automotive diesel engine oils. Although the diaryl dithiophosphates are the most thermally stable of this family, they are hydrolytically the least stable. They are not very effective and therefore not often used as antiwear agents. Antiwear performance depends on the thermal stability of the dialkyl dithiophosphate, which in turn depends on whether the alcohol is primary or secondary. Dithiophosphate derivatives decompose (generally below 200 °C, or 390 °F) to form thiols, olefins, polymeric alkyl thiophosphates, and hydrogen sulfide (Ref 18, 19).

Antiseize additives are a separate class of antiwear additives that perform independently of temperature. They improve boundary lubrication by forming a protective film through deposition. Molybdenum disulfide and graphite are common examples that are generally used in greases, some industrial oils, and various break-in lubricants.

Extreme-Pressure Agents. Alkyl and aryl disulfides and polysulfides, dithiocarbamates, chlorinated hydrocarbons, dialkyl hydrogen phosphites, and salts of alkylphosphoric acids are common EP agents.

The polysulfides are synthesized from olefins by reacting with either sulfur or sulfur halides, followed by dehydrohalogenation. Sulfurization of olefins with elemental sulfur or sulfur and hydrogen sulfide yields organic sulfides and polysulfides (Ref 20). Dialkyldithiocarbamate derivatives are prepared either by the neutralization of dithiocarbamic acid (resulting from the low-temperature reaction of a dialkylamine and carbon disulfide) with bases or by the addition of this acid to activated olefins such as alkyl acrylates (Ref 21). The synthesis of these materials is presented in Fig. 8.

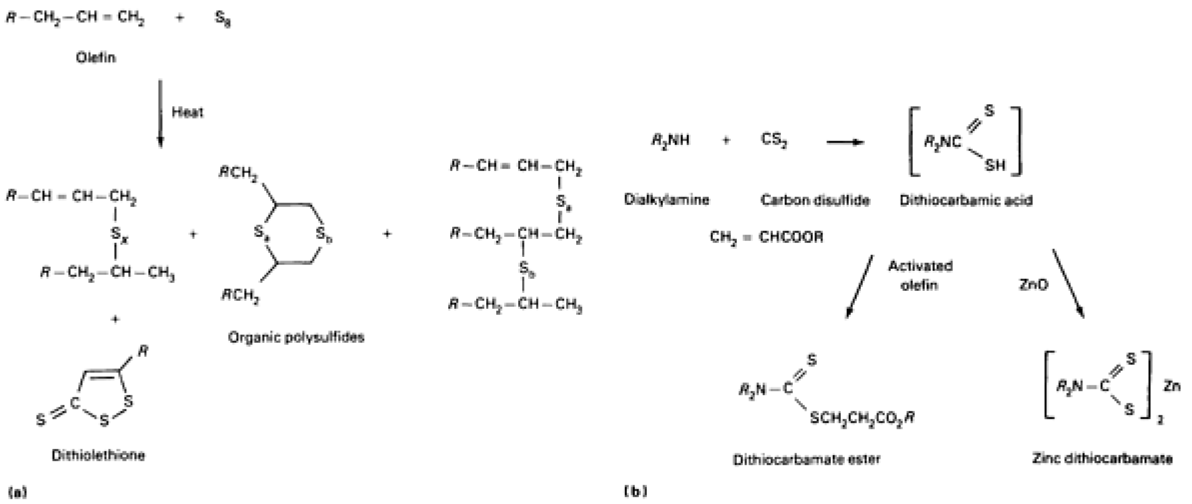

Fig. 8 Synthesis of sulfur EP agents. (a) Olefin sulfurization. (b) Dithiocarbamic acid derivatives

The phosphites are obtained either by reacting an alcohol or phenol with phosphorus trichloride or by a transesterification reaction (Ref 22). Alcohols and phenols react with phosphorus pentoxide to yield a mixture of alkyl(aryl)phosphoric acid and dialkyl(diaryl)phosphoric acid (Ref 23). These acids form salts, upon treatment with bases. Phosphates can also be prepared by the oxidation of phosphites. The preparation of these materials is outlined in Fig. 9.

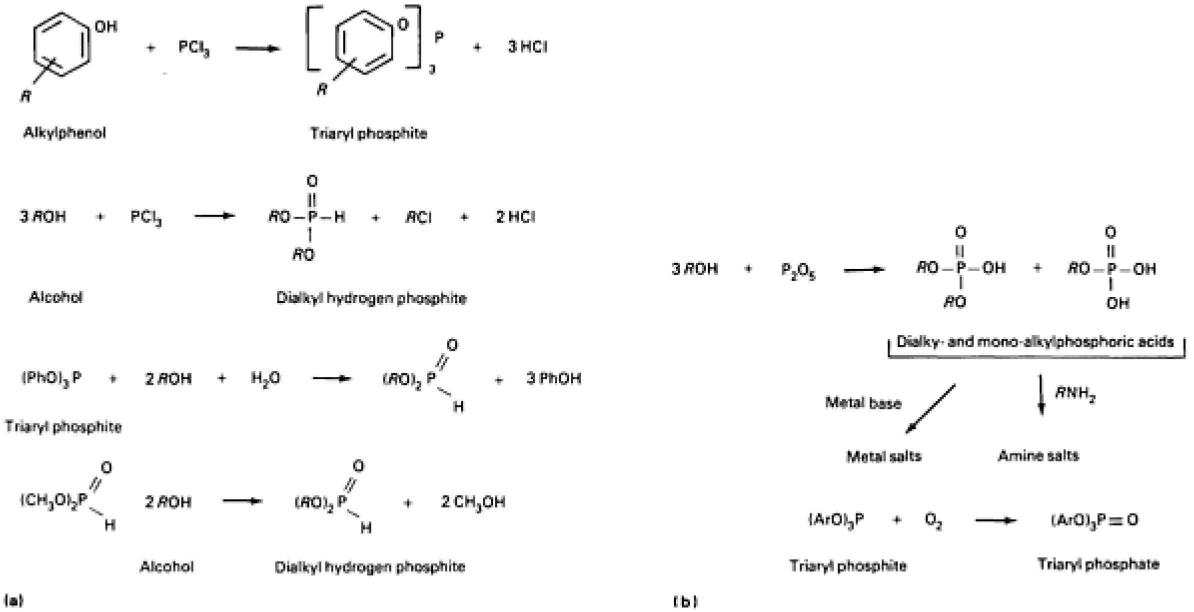

Fig. 9 Synthesis of phosphorus EP agents. (a) Phosphites. (b) Phosphates

Disulfide and polysulfides decompose to form a protective sulfide layer on the metal surfaces at temperatures above 200 °C (390 °F). The thickness of this layer depends on the quantity and lability of the sulfur in the additive. Sulfurized fatty oils and sulfurized olefins are the most commonly used products in this class.

Chlorine compounds provide protection through the formation of a metal chloride film under boundary lubrication conditions. A detrimental aspect of chlorine-based EP agents is the formation of hydrogen chloride in the presence of moisture, which can cause severe corrosion problems. Chlorinated paraffins with 40 to 70% chlorine by weight were popular. Environmental concerns about the negative effects of chlorine are minimizing the use of these additives.

Phosphorus compounds react with the metal surface to make a metal phosphite or phosphate protective film. This film is formed at a much higher temperature than that formed by the sulfur EP agents. Tricresyl phosphate is the best-known example of the phosphorus EP agents. Dialkyl hydrogen phosphites and phosphonic and phosphoric acid salts are further examples of these agents.

Friction Modifiers/Antisquawk Agents

Lubrication is necessary to facilitate the countermovement of two sliding surfaces. This function, which is usually performed by mineral oil, can be made more efficient by using friction modifiers. These agents control friction and thus prevent scoring, and reduce wear and noise, as well.

Friction modifiers are long-chain molecules with a polar end group and a nonpolar hydrocarbon chain. The polar end group physically adsorbs itself on the metal surface, whereas the hydrocarbon chain increases the strength of lubricant film through association. Under heavy load conditions, the EP agent replaces the friction modifier and takes over the function of damage prevention. The process is repeated again as the load eases off. Friction modifiers have a finite life related to their oxidative and thermal stability.

Friction modifiers are commonly used in gasoline engine oils, automatic transmission fluids, tractor hydraulic fluids, power steering fluids, shock absorber fluids, and metalworking fluids. In passenger car applications with federal government mandated fuel economy, the lubricant suppliers use these additives as a competitive marketing tool. In automatic transmission fluids and limited slip axle lubricants, friction modifiers are used to control torque application through clutch and band engagements. Antisquawk additives, which are functionally similar to friction modifiers, are used to reduce objectionable mechanical noises, such as squawk and chatter. Antisquawks are primarily used in automatic transmission and tractor hydraulic fluids, automotive gear oil, and industrial oils. This class of additives includes fatty

alcohols, fatty acids, fatty amides, and molybdenum compounds and graphite. Friction modifier and antisquawk performance specifications include evaluation of the product's load-carrying capacity.

In the case of fatty alcohol and fatty acid families, the friction-modifying properties are a function of the length and nature of the hydrocarbon chain and the nature of the functional group. Long and linear-chain materials are better friction modifiers than short and branched-chain materials. Fatty acids are better than fatty amides, which in turn are better than fatty alcohols. Saturated acids that contain a 13 to 18 carbon chain are generally preferred. Lower molecular weight fatty acids are avoided because of their corrosivity.

Fatty acid derivatives are the most commonly used friction modifiers. Because graphite presents problems when used in conventional lubricants, its use is currently limited to greases.

Oxidation Inhibitors

All modern lubricants, by virtue of being hydrocarbon based, are susceptible to oxidation (Ref 24, 25). Each type of base stock (mineral or synthetic) has a stable threshold, beyond which stabilizers or oxidation inhibitors are needed to retard oxidation.

Adequately refined base oils contain some sulfur- and nitrogen-base "natural" inhibitors. Under mild conditions, these inhibitors are sufficient to protect lubricants against oxidation. However, most modern uses require supplemental inhibitors to protect lubricants under increasingly hostile conditions.

Most lubrication applications expose lubricants to oxygen in some manner. The attack of oxygen on the weaker sites in the lubricant, predominantly allylic, benzylic, and tertiary hydrogens, produces peroxy or other radicals.

The process of oxidation proceeds in three stages. During the initiation stage, the lubricant and the fuel react with oxygen to form radicals. During the propagation stage, these radicals react with oxygen and the lubricant to form hydroperoxides. The hydroperoxides decompose to form a variety of additional radicals and oxygen-containing compounds such as alcohols, ketones, and carboxylic acids. The carboxylic acids attack iron metal and copper and lead bearings to form metal carboxylates, which further enhance the rate of oxidation. During the termination stage, the radicals either self-terminate or terminate by reacting with oxidation inhibitors (Ref 24). The mechanism of oxidation is illustrated in Fig. 10, whereas Fig. 11 depicts the mechanism of the hydroperoxide decomposition.

Initiation:

$RH + O_2$	$\longrightarrow$	$R^{\cdot} + HO_2$	(1)
$RH + O_2 + RH$	$\longrightarrow$	$R^{\cdot} + H_2O + R^{\cdot}$	(2)

Propagation:

$R^{\cdot} + O_2$	$\longrightarrow$	$ROO^{\cdot}$	(3)
$ROO^{\cdot} + RH$	$\longrightarrow$	$ROOH + R^{\cdot}$	(4)

Peroxide Decomposition

$ROOH$	$\longrightarrow$	$RO^{\cdot} + {}^{\cdot}OH$	(5)
$2ROOH$	$\longrightarrow$	$RO^{\cdot} + ROO^{\cdot} + H_2O$	(6)
$RO^{\cdot} + ROOH$	$\longrightarrow$	Various Products	(7)
$\left[\begin{array}{l}ROO^{\cdot}\\ ROOH\end{array}\right.$	$\longrightarrow$	Non-radical products	(8)
$X + ROOH$	$\longrightarrow$	Free radicals	(9)
$Y + ROOH$	$\longrightarrow$	$ROH + YO$	(10)
$Z + ROOH$	$\longrightarrow$	Inactive products + Z	(11)
$M + ROOH$	$\longrightarrow$	Free radicals	(12)

Termination:

$ROO^{\cdot} + ROO^{\cdot}$	$\longrightarrow$	Inactive products	(13)
$ROO^{\cdot} + IH$	$\longrightarrow$	$ROOH + I^{\cdot}$	(14)

RH = Organic substrate
$ROO^{\cdot}$ = Peroxy radical
ROOH = Hydroperoxide
X,Y,Z = Decomposers of organic peroxides
M = Metal
$I^{\cdot}$ = Stable or unreactive radical
IH = Chain breaking inhibitor

Fig. 10 Mechanism of oxidation. Source: Ref 24

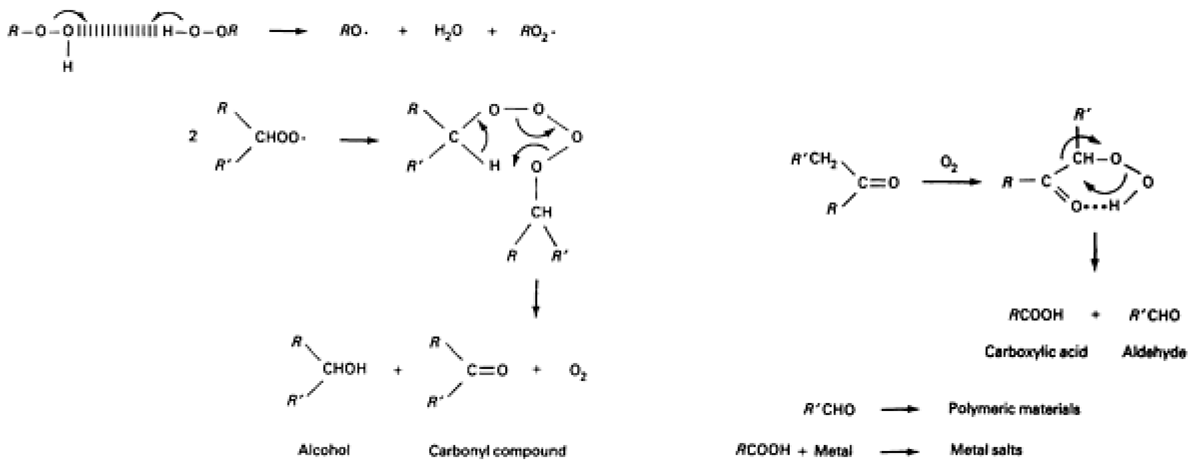

Fig. 11 Hydroperoxide decomposition

An increase in temperature affects the oxidation process most profoundly, with the rates of oxidation approximately doubling with every 10-degree rise in temperature. Wear metals can further enhance the rate of oxidation (Ref 26). If this process is not controlled, the lubricant decomposition will lead to oil thickening, sludge formation, and the formation of varnish, resin, and corrosive acids (Ref 3, 4). Oil thickening occurs primarily because of polymerization or association of certain oxidation products.

Oxidation inhibitors function by circumventing the radical chain mechanism of the oxidation process. Oxidation inhibitors can be classified as hydroperoxide decomposers and radical scavengers, depending on the mode of their controlling action. Sulfur- and phosphorus-containing inhibitors, such as sulfides, dithiocarbamates, phosphites, and dithiophosphates, act as hydroperoxide decomposers. Nitrogen- and oxygen-containing inhibitors, such as arylamines and phenols, act as radical scavengers (Ref 24, 25).

The hydroperoxide decomposers convert the chain-propagating hydroperoxides to alcohols while getting themselves oxidized to higher oxidation levels. The radical scavengers remove the radicals from the oxidation process by transferring a hydrogen atom to the radical, thereby making it innocuous. In the process, these materials do get converted into radicals, but unlike the radicals from the oxidation process, these radicals are incapable of propagating oxidation. The reason is that these new radicals are either too sterically hindered or delocalized to take part in the oxidation process. The mechanisms by which the hydroperoxide decomposers and radical scavengers perform are summarized in Fig. 12 and 13, respectively.

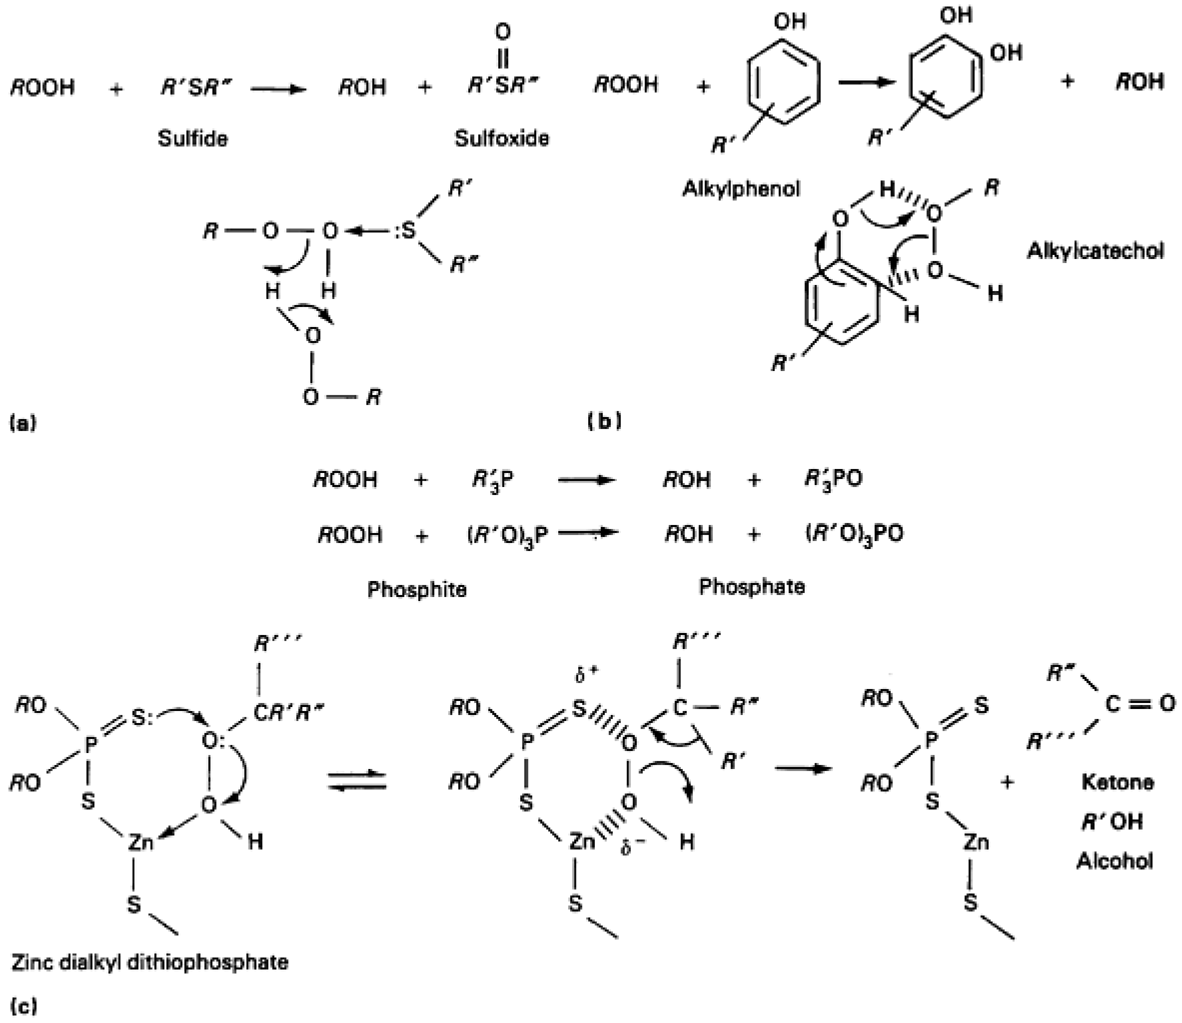

Fig. 12 Hydroperoxide decomposers and mode of action. (a) Sulfur compounds. (b) Phenols. (c) Phosphorus compounds

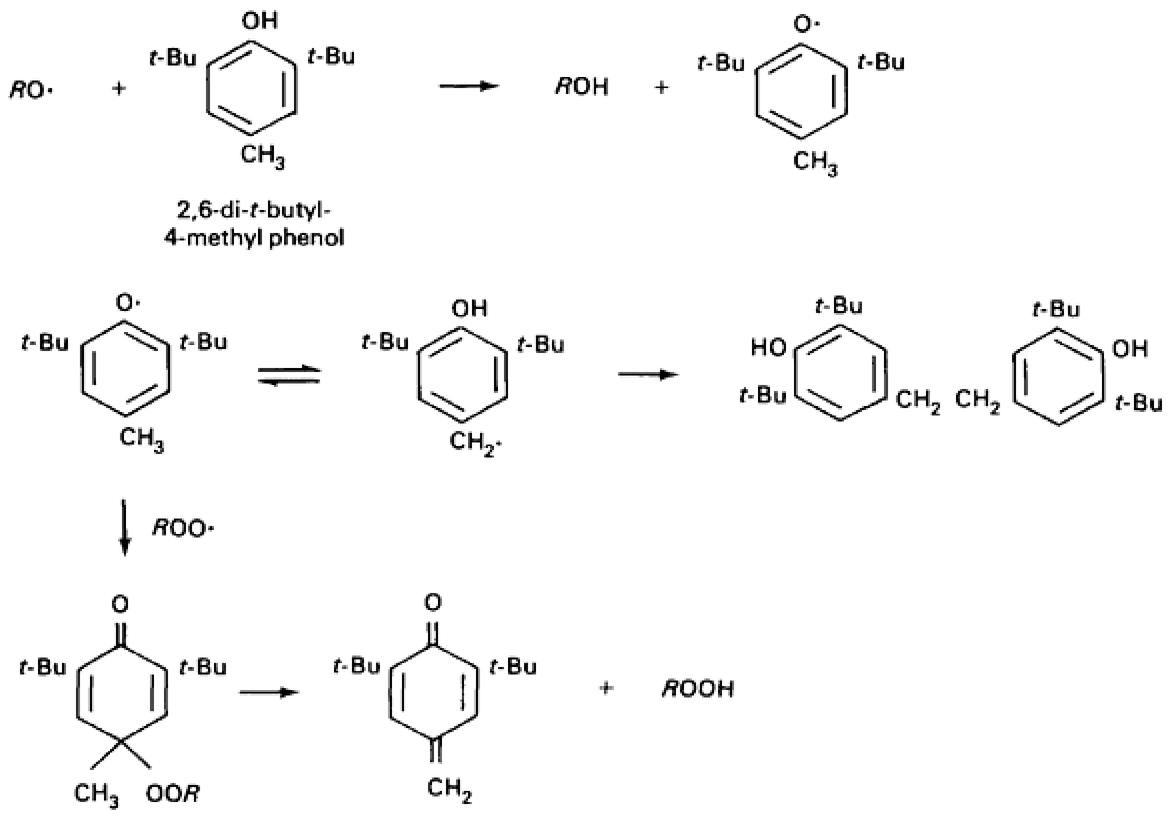
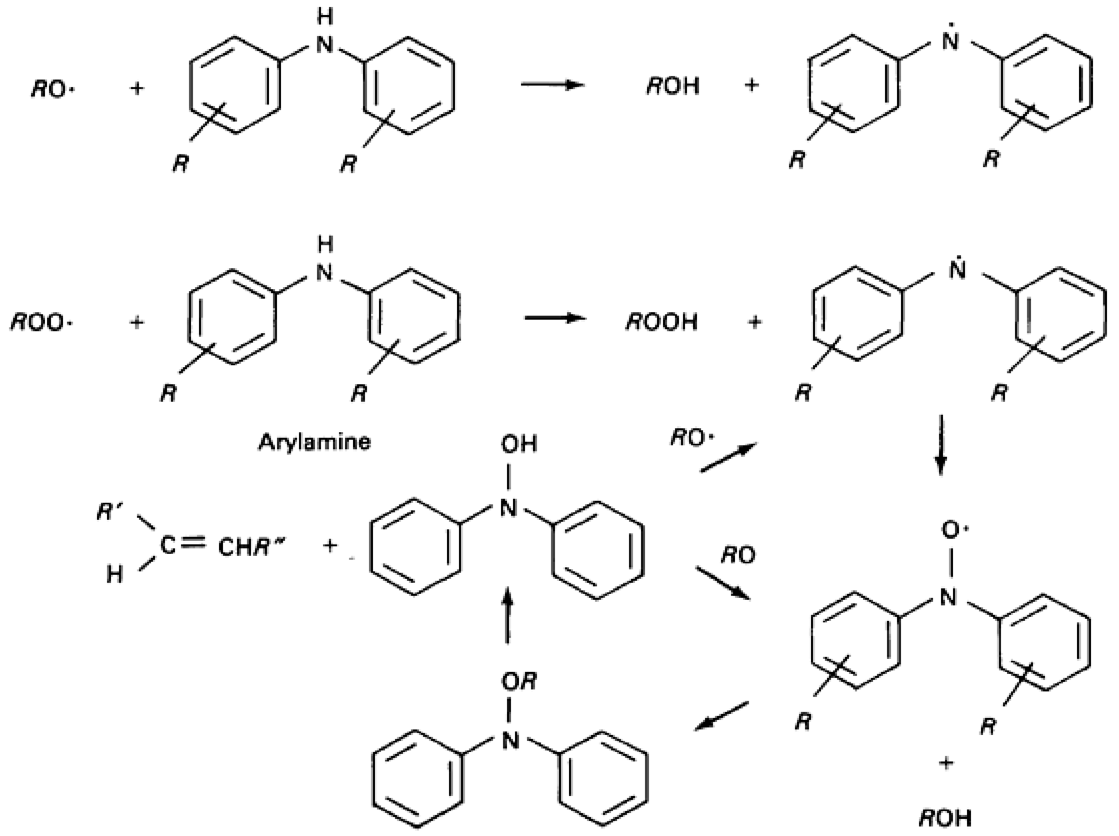


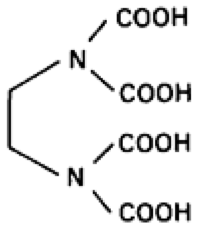
(a)



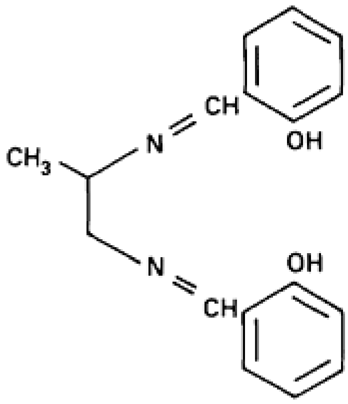
(b)

Fig. 13 Radical scavengers and mode of action. (a) Hindered phenols. (b) Arylamines

Ions of heavy metals, such as iron or copper, are known to promote oxidation (Ref 27). Metal deactivators, another class of oxidation inhibitors, slow down the oxidation process by forming complexes with these metal ions and taking them out of the chain reaction. Ethylenediam-inetetraacetic acid derivatives and N,N-disalicylidene-1,2-propanediamine fall under this class (Fig. 14). Sometimes, compounds that intercept oxidation by different mechanisms reflect synergism when present together. Synergism is an effect greater than the additive effect of the two or more compounds (Ref 28).



Ethylenediaminetetraacetic acid



N,N-disalicylidene-1,2-propanediamine

Fig. 14 Metal deactivators

Oxidation inhibitors are used in almost all lubricants. Gasoline and diesel engine oils and automatic transmission fluids account for 60% of the total use. High operating temperature and high air exposure applications require a high level of oxidation protection. Zinc dialkyl dithiophosphates are the primary inhibitor type, followed by aromatic amines, sulfurized olefins, and phenols.

A number of tests are used to assess the oxidation stability of a lubricant under conditions of accelerated oxidation. The ASTM sequence IIIE (viscosity increase), sequence VE (sludge and varnish formation), and CRC L-38 (bearing corrosion) tests are used for engine oils. The CRC L-60 test is used for gear oils, and ASTM D 943 and ASTM D 2272 tests are used for turbine oils.

Rust and Corrosion Inhibitors

Rust and corrosion represent the damage done to metal surfaces by the attack of atmospheric oxygen and acidic products. The rust and corrosion rate, which is usually low, increases greatly in the presence of water and polar impurities. Internal combustion engines contain all the elements necessary to promote these types of surface damage. Air is entrained in the oil and fuel, and water and organic acids form during the combustion and decomposition processes. Rust and corrosion inhibitors provide a barrier between the metal surface and these harmful elements. These inhibitors are of two types: those that neutralize acids and those that form protective films. The film formers attach themselves strongly to the metal surface and form an impenetrable protective film. The film formation can occur through either physical adsorption or chemical reaction. The first mechanism involves the formation of densely packed protective layers of a somewhat transient nature and the second, a more permanent protective film resulting from a chemical reaction between the inhibitor and the metal surface.

Long-chain organic molecules, such as alkanolamines and saturated and unsaturated fatty acid amides, are examples of physical adsorbers. Phosphoric acid, dithiophosphoric acid, and succinic acid derivatives are examples of chemical film formers. Basic detergents are excellent rust and corrosion inhibitors, because they provide protection both by neutralizing and by forming physically adsorbed films. For many applications, rust and corrosion inhibitor systems are required to provide both the vapor phase and the liquid phase protection, that is, for surfaces above and below the lubricant level.

Long-chain amines, basic sulfonates, carboxylic acid derivatives, and thiadiazole and triazole derivatives are the most commonly used rust and corrosion inhibitor types. These additives have major uses in engine oils, gear oils, metalworking fluids, and greases. Thiadiazole and triazole derivatives are especially useful in protecting against nonferrous or yellow metal corrosion. Figure 15 depicts common types of rust and corrosion inhibitors.

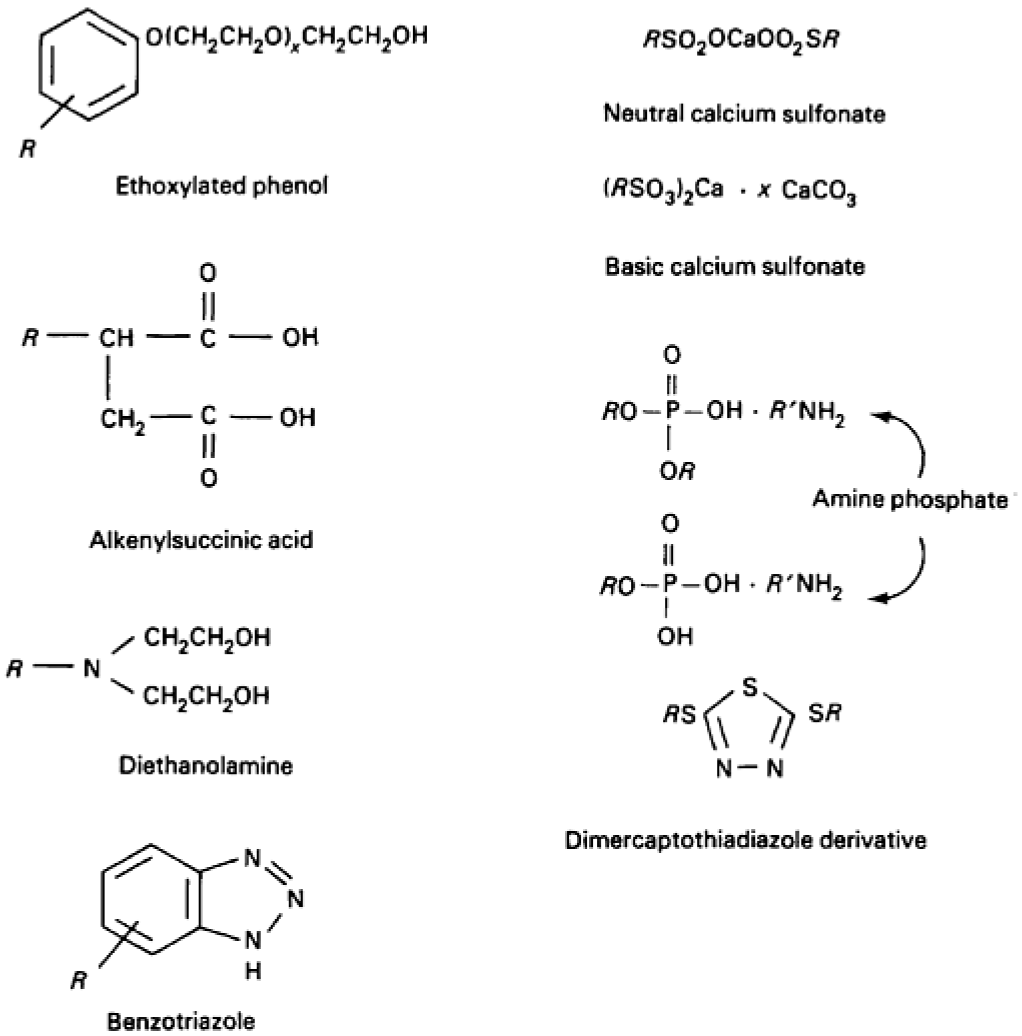


Fig. 15 Corrosion inhibitors

A number of ASTM-specified tests are used for hydraulic and metalworking fluids. For engine oils, the ASTM sequence IID engine test is used to assess the corrosion-inhibiting ability of the lubricant.

Emulsifiers and Demulsifiers

Emulsifiers are chemical compounds that enable two immiscible fluids to form an intimate mixture known as an emulsion. Water and oil mixtures are often used as lubricants in a number of industries for a variety of applications. Such lubricants are low cost, easy to dispose of, and have fire-retardant properties. Emulsions of water and mineral oil are primarily used in metal-working and hydraulic applications. Emulsions have to possess a number of desirable properties.

They should be stable over long periods of time, must possess good lubricating properties, should not attack seals and metals, and should be easy to demulsify for disposal.

Certain lubricant formulations, in the presence of water, have an increased tendency to form emulsions. This is due to the presence of chemical additives (such as detergents) that act as surfactants. Demulsifiers are added to such formulations to enhance water separation and suppress foam formation.

Emulsifiers and demulsifiers are basically surfactants and contain hydrophilic and hydrophobic moieties. The hydrophilic moiety is a hetero atom (N,O,S and P)-based polar functional group, which is attached to a hydrophobic portion, a hydrocarbon chain of sufficient length to provide proper solubility or dispersibility in the oil phase. The additives that belong to this group can be classified as being non-ionic or ionic, depending on whether the polar part is uncharged or charged. The ionic compounds can be subcategorized as cationic if the charge is positive, and anionic if the charge is negative (Ref 29). The generalized structures for emulsifiers and demulsifiers are given in Fig. 16.

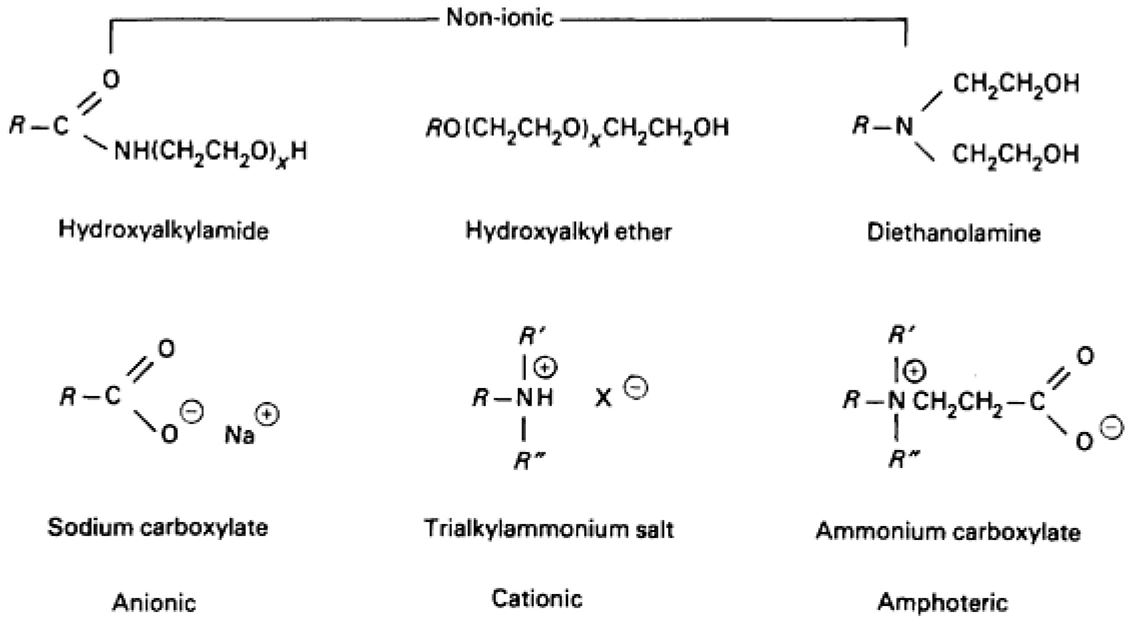

Fig. 16 Emulsifiers and demulsifiers

It is important to note that only the charge on the functional group attached to the carbon chain is used in this classification. The charge on the counterion, which is usually inorganic in origin, is ignored. The term amphoteric applies to a group of additives that contains both the cationic and anionic groups of organic origin. They possess the structural features and properties of both the cationic and anionic materials grouped together.

Emulsifiers reduce the surface tension of water, and thereby facilitate thorough mixing of oil and water to form an emulsion. The efficiency of the emulsifier depends on its molecular weight (usually less than 2000), its hydrophile-lipophile balance (HLB) value, both the pH and hardness of water, the nature of the oil, and operating conditions, such as temperature. The emulsifiers with an HLB value from 3 to 6 are suitable for water-in-oil emulsions, and those with an HLB value from 8 to 18 are suitable for oil-in-water emulsions.

Demulsifiers perform the opposite function and enhance water separation. Structurally, most demulsifiers are oligomers or polymers with a molecular weight of up to 100,000 and contain from 5 to 50% polyethylene oxide in a combined form. Demulsifiers are commonly block copolymers of propylene oxide or ethylene oxide, combined with initiators such as glycerol, phenol-formaldehyde resins, siloxanes, polyamines, and polyols (Ref 30). Lower molecular weight materials, such as alkali metal or alkaline earth metal salts of dialkylnaphthalenesulfonic acid, are also useful in lubricant-related applications. Polymers containing from 20 to 50% ethylene oxide are suitable for water-in-oil emulsions. These materials concentrate at the water-oil-interface and create low-viscosity zones, thereby promoting droplet coalescence and gravity-driven phase separation.

As a general rule, non-ionic emulsifiers are used in metalworking fluids based on naphthenic stocks, and fatty acid carboxylates in those based on paraffinic stocks. Polyalkylene glycols (hydroxyalkyl ethers) are sometimes avoided because their enhanced solubility in water does not allow clean separation for disposal.

Polyethylene oxide derivatives and salts of carboxylic and sulfonic acids are the most commonly used emulsifiers. Their major use is in metalworking. Demulsifiers are used in applications where water contamination of the lubricant is a problem and quick separation of water is desired. Automatic transmission fluids, hydraulic fluids, and industrial gear oils are examples of such lubricants.

Pour-Point Depressants

The pour point is the lowest temperature at which a fuel or an oil will pour when cooled under defined conditions. In general, the pour point is indicative of the amount of wax (straight-chain paraffins) in an oil. At low temperatures wax tends to separate as crystals with a lattice-type structure. These crystals can trap a substantial amount of oil via association, inhibit oil flow, and ultimately hinder proper lubrication of the equipment.

Base oil suppliers remove most of the wax during petroleum refining. However, complete dewaxing of the base oils is not practical because of process limitations, economics, and the desirable presence of wax, which offers a high viscosity index character (Ref 16). Additives called pour-point depressants are used to enable mineral oils to function efficiently at low temperatures. Current practice favors mild dewaxing in combination with the use of pour-point depressants.

A good pour-point depressant can lower the pour point by as much as 40 °C (70 °F). These additives are commonly used in applications that require the use of mineral oil, usually below 0 °C (32 °F). Pour-point depressants have virtually no effect on either the temperature at which the wax crystals start to precipitate (cloud point) or the amount of wax that separates. They essentially act as wax-crystal modifiers and function by altering the crystal size. They do this either by absorption onto the surface of newly formed crystals or by co-crystallizing with the precipitating wax. Both mechanisms inhibit lateral crystal growth and keep the bulk oil fluid. Of the commercial pour-point depressants, alkylaromatics are believed to perform via the absorption mechanism and aliphatic polymers via co-crystallization (Ref 31).

The molecular weight and structure of polymeric pour-point depressants enable them to be effective over a wider range than their low molecular weight counterparts. The extended range of performance, in the case of polymers, has been explained on the basis of their limited solubility in petroleum fractions. As the temperature decreases, different polymer segments become successively co-crystallizable.

A good pour-point depressant should possess one or more of the following structural features:

- Polymeric structure
- Waxy and nonwaxy components
- Comb structure (backbone with pendant groups
- Broad molecular weight distribution

Most commercial pour-point depressants are organic polymers, although some nonpolymeric substances have been shown to be effective. Tetra(long chain)alkyl silicates, phenyltristearyloxysilane, and pentaerythritol tetrastearate are examples of the nonpolymeric type. Commercial pour-point depressants include alkylated bicyclic aromatics, styrene esters, polymethacrylates, polyfumarates, oligomerized alkylphenols, dialkaryl esters of phthalic acid, ethylene-vinyl acetate copolymers, and other mixed hydrocarbon polymers. Figure 17 contains structures of common pour-point depressants. Polymethacrylates and polyfumarates are the most commonly used chemical types. High molecular weight polymethacrylate derivatives can act both as viscosity improvers and pour-point depressants. When this chemistry is used for viscosity improvement, the need for a pour-point depressant is minimized.

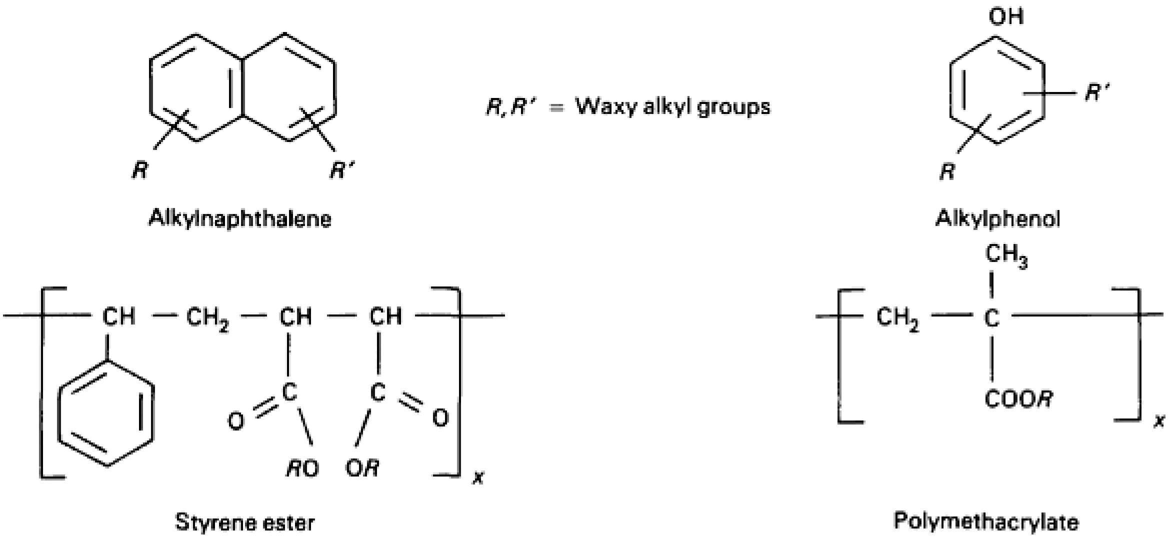

Fig. 17 Pour-point depressants

Pour-point depressants are used at treatment levels of 1% or lower. In nearly all cases, there is an optimum concentration above and below which the pour-point depressants become less effective.

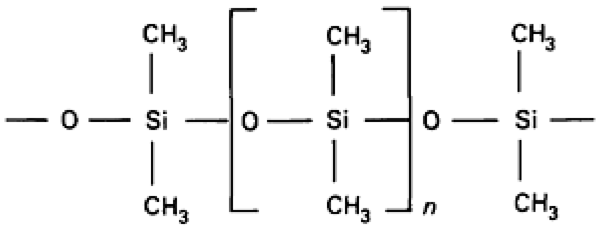
Pour-point depressants are used in crankcase engine oils, automatic and power transmission fluids, automotive gear oils, tractor fluids, hydraulic fluids, and circulating oils. The performance of pour-point depressant is determined in each base stock by using one or more of the following tests: ASTM D 97, pour point of petroleum oil; ASTM 3829, borderline pumping; and ASTM D 2602, apparent viscosity at low temperature using cold-cranking simulation.

Foam Inhibitors

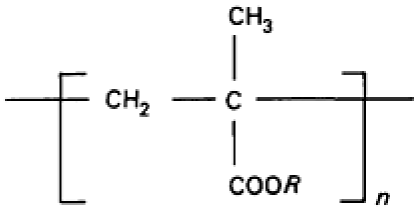
Almost every lubricant application involves some kind of agitation, which encourages foam formation through air entrainment. Excessive foaming will result in ineffective lubrication and, over time, will cause oxidative degradation of the lubricant. The viscosity of a lubricant and surface tension determine the stability of the foam. Low-viscosity oils produce foams with large bubbles that tend to break quickly. High-viscosity oils, on the other hand, generate stable foam that contain fine bubbles and are difficult to break. The presence of surface-active materials, such as dispersants and detergents, further increases the foaming tendency of the lubricant.

Foam inhibitors inhibit foam formation by altering the surface tension of the oil and by facilitating the separation of air bubbles from the oil phase. These additives generally have a limited solubility in oil, and therefore are added as very fine dispersions. Foam inhibitors are effective at very low levels (3 to 150 parts per million).

Silicones (polysiloxanes or dimethylsiloxanes) and polyacrylates are commonly used as foam inhibitors, with silicones being more popular. ASTM D 892 is used to assess the foaming tendency of a lubricant. Figure 18 shows the structures for the two types of additives.



Polydimethylsiloxane



Alkyl polymethacrylate

Fig. 18 Foam inhibitors

Viscosity Improvers

Mineral oils, which are effective lubricants at low temperatures, become less effective lubricants at high temperatures. At high temperatures, their film-forming ability (in the hydrodynamic lubrication regime) diminishes, because of a drop in viscosity. Prior to the use of viscosity improvers and the introduction of multigrade oils, this problem was partly overcome through seasonal oil changes.

The principal function of a viscosity improver is to minimize viscosity variations with temperature. Previously, viscosity index was used as a measure of the response of an oil to temperature changes. Viscosity index, which is derived from the viscosity of the oil at 40 °C (105 °F) and at 100 °C (212 °F), is no longer as meaningful. This is because modern equipment is operating at extreme temperatures (-40 to 150 °C, or -40 to 300 °F) and, at these temperatures, the viscosities do not conform to those predicted by the viscosity index (Ref 31).

Viscosity improvers are typically added to a low-viscosity oil to improve its high-temperature lubricating characteristics. These are organic polymers that minimize viscosity change with a change in temperature. This represents a practical means by which the operating range of mineral oils is extended to high temperatures without adversely affecting their low-temperature fluidity.

At low temperatures, the polymer molecules occupy a small volume (hydrodynamic volume) and therefore have a minimum association with the bulk oil. The effect is little or no viscosity increase. However, the situation is reversed at high temperatures because polymer chains extend or expand as a consequence of added thermal energy. This increases the association of the polymer with the bulk oil (Ref 16), because of an increase in surface area. The result is an effective increase in viscosity. Figure 19 illustrates oil thickening by viscosity improvers.

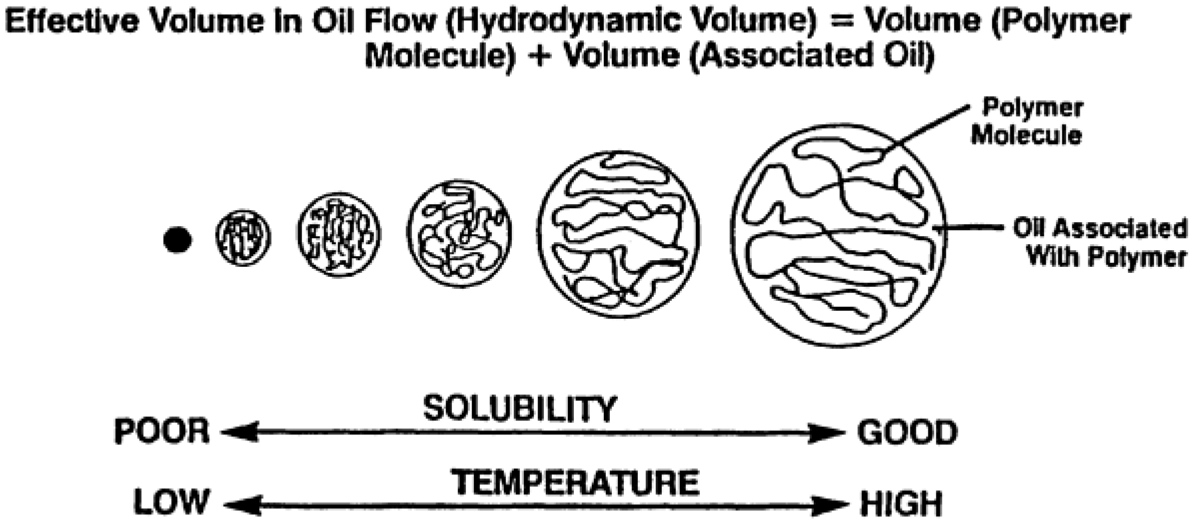


Fig. 19 Viscosity improvers and mechanism of thickening. Source: Ref 16

It is important to note that the superior viscosity-temperature relationship (as expressed by the viscosity index) of multigrade oils is not solely due to greater preferential swelling of the polymer at higher temperatures than at lower temperatures. The good viscosity-temperature behavior of low-viscosity oils that are used to prepare multigrade oils makes a substantial contribution toward the overall effect (Ref 32).

Olefin copolymers (OCP), polymethacrylates (PMA), hydrogenated styrene-diene (STD), and styrene-polyester (STPE) polymers are the common types of viscosity improvers used in modern lubricants. Olefin copolymers are rubber-like materials prepared from ethylene and propylene mixtures through vanadium-based Ziegler-Natta catalysis. The ethylene-to-propylene ratio and their proper distribution in the backbone are critical to the low-temperature properties of the polymer. The OCP products are inferior to polymethacrylates in low-temperature properties and generally require the use of pour-point depressants to improve the low-temperature performance of lubricants containing them.

Styrene-diene polymers are produced by an-ionic polymerization of styrene and butadiene or isoprene. This type of polymerization produces polymers with a narrower molecular weight distribution than those obtained by the use of Ziegler and Friedel-Crafts catalysts, or free radical initiators. These polymers, therefore, possess the best thickening power of the types discussed so far. However, the presence of aromatic rings and double bonds makes these polymers more susceptible to oxidation. This problem is somewhat overcome by catalytically hydrogenating the double bonds.

A different type of polymer, called a star polymer, with a thickening power similar to that of the styrene-diene type, but a better shear stability, has recently become commercially available. A clustered polyanion (prepared from divinylbenzene and styrene) forms the center of the star, and the rays are composed of polymerized diene monomers. Figure 20 depicts the synthesis of olefin and styrene-diene copolymers.

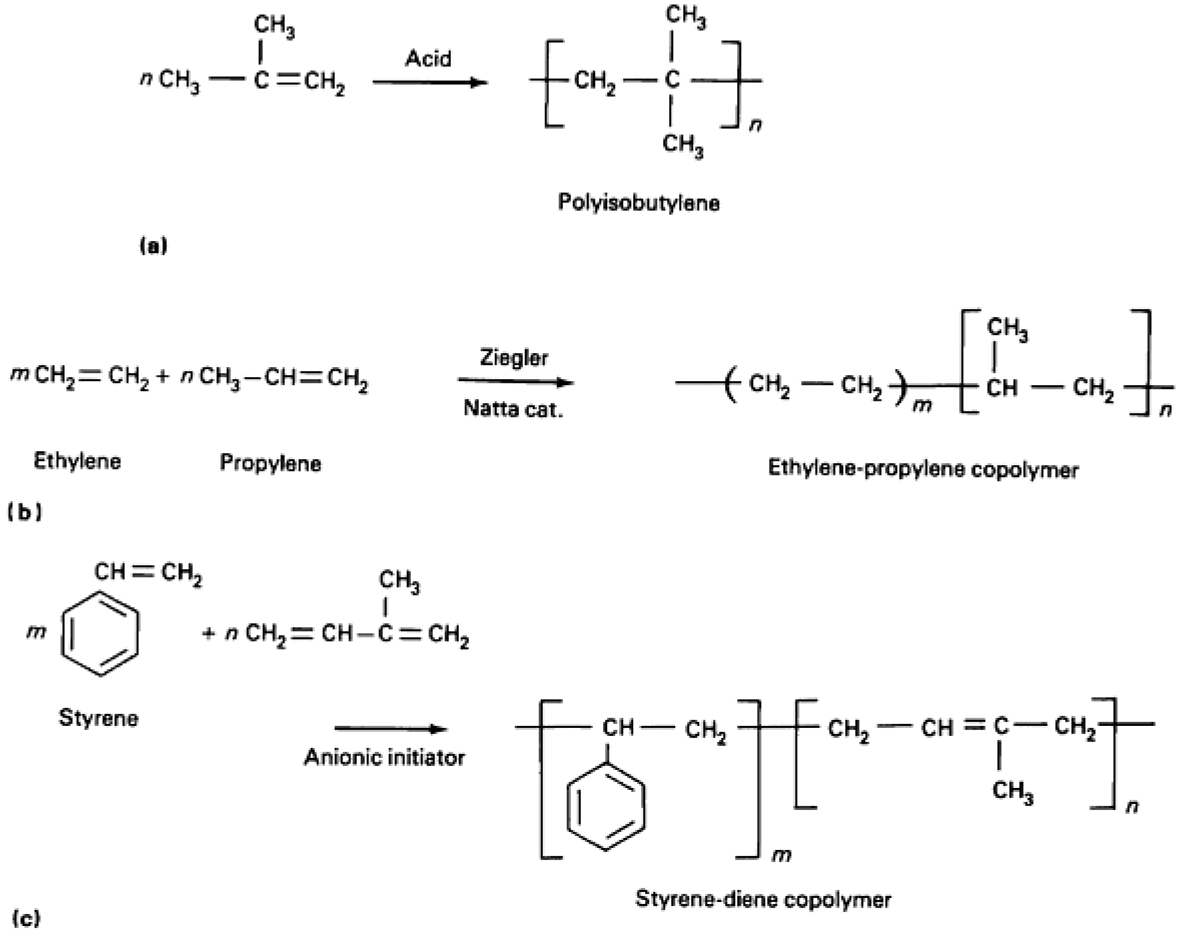

Fig. 20 Synthesis of polyolefins (a), olefin copolymers (b), and styrene-diene copolymers (c)

Polymethacrylates are produced by free radical polymerization of alkyl methacrylates. The alkyl group can be altered so as to obtain a product with the best oil solubility and the optimum viscosity-improving properties. Free radical polymerization produces polymers with a relatively broad molecular weight distribution, thereby reducing their thickening efficiency. Although polymethacrylates are superior to olefin copolymers in being oxidatively and thermally more stable and possessing better low-temperature properties, they have only moderate viscosity-improving ability on an equal molecular weight basis.

Styrene-polyester polymers are prepared by first co-polymerizing styrene and maleic anhydride and then esterifying the intermediate using a mixture of alcohols. Normally, the esterification step is taken to about 90 percent or more, followed by postneutralization using a bifunctional or polyfunctional amine. Because of the presence of basic nitrogen, these polymers function both as a dispersant and as a viscosity improver. Hence, they are called dispersant-viscosity improvers. Figure 21 summarizes the methods of synthesis for the polyacrylate and styrene-polyester type viscosity improvers.

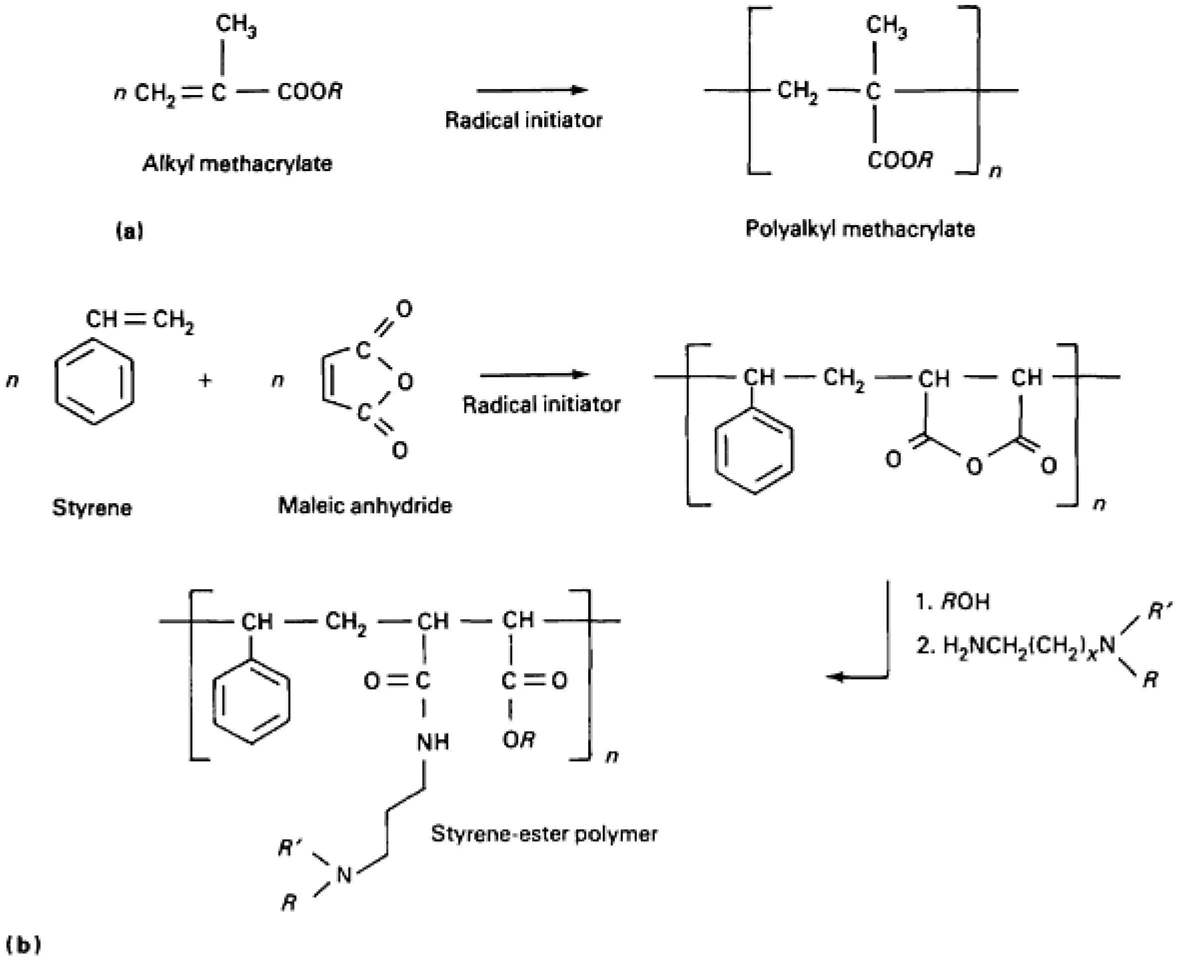

Fig. 21 Synthesis of polyacrylates (a) and styrene-esters (b)

Dispersant-viscosity improvers based on polyacrylate and OCP are also commercially available. Dispersancy is obtained by including basic nitrogen-containing monomers during the polymerization process. N-Vinylpyrrolidinone, vinylpyridines, and dimethylaminoethyl methacrylate are examples of such monomers (Fig. 22).

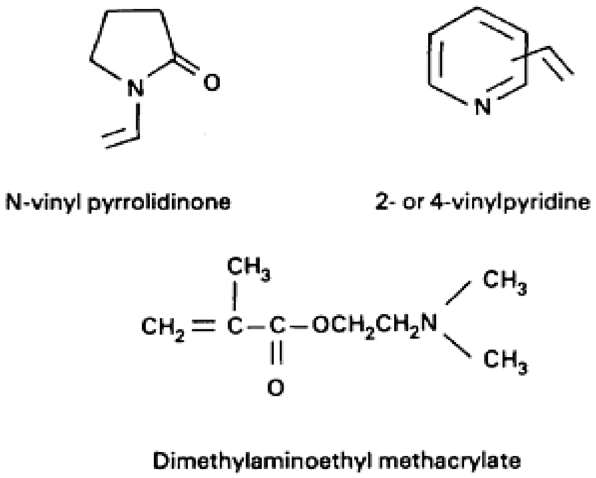

Fig. 22 Nitrogen-containing monomers

Thickening efficiency and shear stability are two important considerations when selecting a polymer for use as a viscosity improver. The thickening efficiency of a polymer is a direct function of its molecular weight. On an equal weight basis, a high molecular weight polymer provides higher viscosity than a low molecular weight polymer. Shear stability, the ability of the polymer to withstand the mechanical shearing forces encountered during use, is inversely related to its molecular weight; the lower the molecular weight, the higher the shear stability. A number of tests are available for measuring the viscosity-improving properties and the shear stability of polymers in a finished oil.

Unlike mineral oils, which primarily exhibit Newtonian rheology, polymer-thickened oils exhibit viscoelastic rheology, that is, the viscosity is dependent on shear stress. When oils containing viscosity improvers are subjected to moderate shear stress, the viscosity decreases until it approaches the viscosity of polymer-free oil. When the stress is removed, the viscosity bounces back to the original viscosity level (Fig. 23). Known as temporary viscosity loss, this characteristic is desired in lubricants because it decreases the viscous drag at low temperatures and, hence, could contribute to fuel economy (Ref 33).

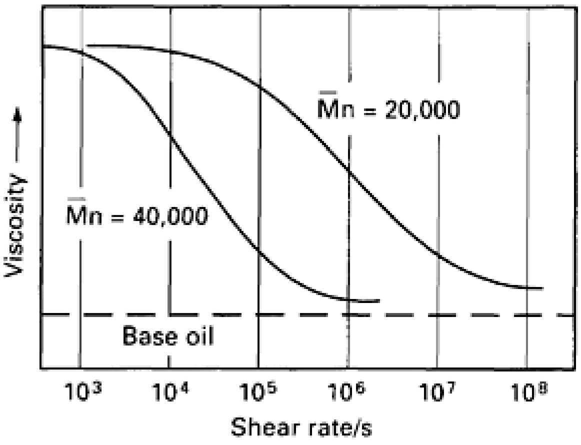

Fig. 23 Temporary shear loss. Source: Ref 32

When the viscosity-modified oil is subjected to a high shear stress, the polymer breaks down to lower molecular weight fragments, thereby causing a permanent viscosity loss, as shown in Fig. 24 (Ref 33). This type of loss is not desired because a formulated lubricant will not stay in its viscosity grade. The problem can be alleviated by preshearing the polymer prior to blending or by choosing a more shear-stable polymer.

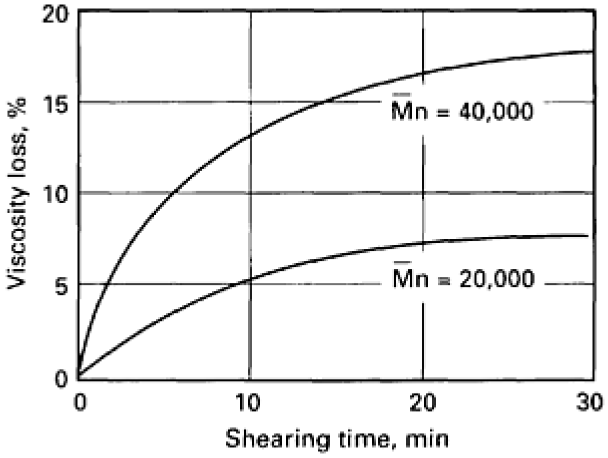

Fig. 24 Permanent shear loss. Source: Ref 32

In addition to mechanical breakdown (shear), polymers can undergo thermal and oxidative degradation. Thermally, polymers break down through chain scission and, ultimately, the polymer chains "unzip" back to the monomers. Oxidative degradation results from the breakdown of hydroperoxides, which are formed by the attack of oxygen on weak carbon-hydrogen bonds in the polymer molecule.

Viscosity improvers are primarily used in multigrade engine oils, gear oils, automatic transmission fluids, power steering fluids, greases, and some hydraulic fluids. Olefin copolymers are of the most popular type, followed by polymethacrylates, styrene-diene polymers, and styrene-polyesters.

Other Additives

In addition to the major classes of additives described above, lubricants contain a number of other additives. These include seal-swell agents, dyes, biocides, and couplers.

Seals are used in modern machinery for a variety of reasons. Their functions within lubrication systems are to:

- Isolate various lubrication environments from harmful elements
- Help maintain hydraulic pressure
- Allow removal and replacement of malfunctioning parts without necessitating the total dismantling of equipment
- Minimize contamination and the loss of lubricant

Seals are commonly made from polymeric materials, such as fluoro-elastomers, nitrile-rubber, polyacrylates, and silicones.

Certain base stocks and additive systems in lubricants can cause shrinkage, brittleness, and deterioration of the seals and impair the performance of the lubricating system. Seal-swell agents are additives that maintain the integrity of the seals. They include polyesters, some phosphorus derivatives, and a number of proprietary chemicals. These materials are commonly used in transmission and hydraulic fluids.

Dyes are used in lubricants as a color-code to ensure that the lubricant is used in the proper application and as a leak detection aid for the consumer. Automatic transmission fluids contain a red dye, whereas the two-stroke cycle oils contain a blue or purple dye. These dyes are oil-soluble organic compounds.

In general, mineral oil-based lubricants resist microbial attack because of their high-temperature operation and the presence of additives with biocidal action. However, high water-based lubricants, such as certain metalworking fluids and hydraulic fluids, are easily attacked by microbes. Control of bacterial growth is essential to minimize product deterioration and possible worker health hazards. This is accomplished by using water-soluble triazine, morpholine, and thiazoline derivatives, which possess biocidal properties. Triazines, which owe their biocidal action to their formaldehyde-releasing ability, find extensive use in this application.

Couplers are additives that are used in water-based lubricants to help stabilize microemulsions. Glycols are commonly used to fulfill this function.

Multifunctional Nature of Additives

There are a number of additives that perform more than one function. Zinc dithiophosphates, known mainly for their antiwear action, are also potent oxidation and corrosion inhibitors (Ref 25). Polyacrylates and styrene-polyesters can act as viscosity improvers, dispersants, and pour-point depressants. Basic sulfonates, in addition to acting as detergents, perform as rust and corrosion inhibitors, because they neutralize acidic products of fuel combustion and lubricant oxidation.

Lubricant Formulation

Lubricants are commonly formulated by using mineral oils and synthetic or partially synthetic base stocks (Ref 2). Recently, there has been a great deal of renewed interest in the use of base stocks of biological origin (vegetable oils and animal fats). Their biodegradable nature and nonpetroleum origin are two major reasons for this impetus.

Lubricant additives are usually supplied as performance packages that are blended in base stocks to yield formulated lubricants. These lubricants are expected to meet the performance requirements established by the SAE, API, and OEMs, as well as the end user. At high concentrations, the additives exist as association structures, with the polar ends being associated together. Upon dilution, de-aggregation occurs, and additive molecules attain a more active form.

Because the additives are reactive chemicals, they can interact with one another in the package, either synergistically or antagonistically (Ref 34). The job of the formulator is to deliver the intended performance by minimizing the antagonistic effects and by maximizing the synergistic effects of additives through careful balancing.

The performance package and the viscosity improver are usually sold separately. This is because the two are not always compatible when in concentrate form (Ref 31). When applications require a viscosity improver, it is blended in the base fluid, along with the performance package, to formulate the finished lubricant. Lubricant additive suppliers develop general-purpose performance packages that meet industry specifications using widely available base stocks. The supplier may tailor them for the individual company's use.

Tables 1 and 2 show the classes of additives used to formulate engine and nonengine lubricants for a variety of applications. All formulations do not contain all the additives identified in these figures.

Introduction of a New Additive

The development of a new additive is initiated after a new product (lubricant) need is identified. The need for a new product, usually expressed by the OEMs and the end users, relates to either inadequate performance of existing products in current equipment or perceived needs of equipment under development. To fulfill this need, various organizations (such as SAE, API, ASTM, and OEMs) initiate the development of new performance specifications and the test methods.

The additive companies, either on their own or by collaborating with the lubricant supplier, try to satisfy the performance requirements established for the new product. If the additive company is unable to come up with the additive system based on their existing technology base, they initiate a project to develop and test a new additive.

The newly developed additives are blended with other additives in the base oil of a customer and are screened in a number of proprietary bench tests. The bench tests are accelerated tests that are devised to closely simulate the conditions the lubricant is expected to experience in actual service. This kind of testing is quite common, because it allows the evaluation of a large number of additives inexpensively.

Once the lubricant satisfies the performance criteria in the bench tests, full-fledged testing using actual equipment is carried out. This can be done in a laboratory or in collaboration with an end user. For additives used in automotive products, field trials may also be necessary. The costs associated with the development and testing of new additives can be phenomenal. The performance package that has successfully met all the performance requirements is ready to be marketed, either through factory-fill or the service-fill lubricant blenders.

Solid Lubricants

Harold E. Sliney, National Aeronautics and Space Administration, Lewis Research Center

Introduction

SOLID LUBRICANTS are thin films composed of a single solid or a combination of solids introduced between two rubbing surfaces for the purpose of reducing friction and wear. Applications or operations involving severe temperatures, pressures, and environments, which preclude the use of organic fluids, have promoted the development of solid lubricants. Graphite and molybdenum disulfide (MoS_2) are the most frequently used inorganic solid lubricants. Graphite and molybdenite (the naturally occurring form of MoS_2) were used for lubrication purposes prior to the Industrial Revolution. In the early applications, molybdenite was probably used because it looks like graphite and was mistaken for it.

A significant amount of technical literature on the subject of solid lubricants is of relatively recent origin. Some sporadic technical references to solid lubricants appeared prior to 1940. For example, Paxton (Ref 1) cited an account by Salto in 1906 (Ref 2) that described the use of carbon as a brush material for electric motors, with an observation concerning the "unique self-lubricating properties of carbon." Winer (Ref 3) in his literature review of MoS_2 as a lubricant, cites some early (1939) patent literature that suggests the use of molybdenite as a lubricant; see for example, the work of Cooper and Damerell (Ref 4). The first technical journal article cited by Winer describes MoS_2 as a lubricant for vacuum (Ref 5). The earliest substantial body of technical literature on solid lubricants appeared in the middle and late 1940s. The solid lubricants research of that era to the present is well-documented. An extensive review of the subject is given in the chapter "Nonconventional Lubricants" in the book *Advanced Bearing Technology*, published by Bisson and Anderson in 1964 (Ref 6). More recent examples of reviews of solid lubrication were authored by Sliney (Ref 7) and Lancaster (Ref 8).

This article encompasses the period from about 1948 to the present (1991). Emphasis is placed largely, but not exclusively, on work performed at the NASA Lewis Research Center with a natural focus on aerospace applications. However, because of the generic nature of the research, the information presented in this article is applicable to most areas where solid lubricant technology is useful. The solid lubricants discussed include dichalcogenides (such as MoS_2), graphite, graphite fluoride, and polyimides. Less-conventional solid lubricants used under extreme temperature conditions, which include stable fluorides and lubricious oxides, are also described. Preparation techniques include air spraying, physical vapor deposition, plasma spraying, and powder metallurgy processes such as sintering and hot isostatic pressing.

Characteristic of Solid Lubricant Materials

There are some material properties that are characteristic of solid lubricants. Direct microscopic observations of the dynamics of solid lubrication show that sliding is accompanied by severe ductile shear of the solid lubricant film (Ref 9). This implies that to provide a low friction coefficient, the solid lubricant must have low shear strength. If the lubricant is crystalline, shear occurs by slip along preferred crystallographic planes. This slip is observed as a severe plastic flow in which the individual solid lubricant particles coalesce into a continuous, crystallographically oriented thin film that adheres to the lubricated surfaces and shears within the film. Low shear strength alone does not ensure lubrication if the material does not adhere to the lubricated surface. The importance of adherence of the solid lubricant film was emphasized by Peterson and Johnson (Ref 10) in a paper on the effect of crystal structure on the friction of possible solid lubricants.

Another property of importance is low abrasivity. This is a relative property that is a function of the hardness ratio of the lubricant and the bearing material. Obviously, the lubricant particles should be softer than the bearing material to avoid abrasive wear.

Finally, the solid lubricant must be thermodynamically stable in the environment of the application. A consideration of this property is important when selecting solid lubricants for high-temperature applications, but is equally important for moderate-temperature applications to ensure adequate storage stability and to avoid corrosion by atmospheric components such as oxygen and salt spray.

Layer Lattice Solid Lubricants

Layer lattice is a term used to describe crystal structures that consist of basal planes that are parallel to each other and consist of hexagonally oriented atoms (Fig. 1). The spacing between the planes is the *c*-spacing. The spacing between the atoms within the basal planes is the *a*-spacing. Compounds with a high c/a ratio have very an-isotropic shear properties with preferred shear parallel to the basal planes or perpendicular to the *c*-axis of the crystal structure. The dichalcogenides (disulfides, diselenides, and ditellurides) of molybdenum and tungsten have this structure. Brainard (Ref 11) showed that with the possible exception of tungsten diselenide, all of these compounds have lubricating properties, especially in vacuum. Table 1 lists these data giving the maximum temperature for lubrication with burnished dichalcogenide films in vacuum.

Table 1 Results of thermal stability and frictional experiments in vacuum of 10^{-7} to 10^{-4} MPa

Compound	Probable onset of thermal dissociation as detected by thermogravimetric analysis		Dissociation products first detected by mass spectrometry		Maximum temperature at which burnished films provided effective lubrication	
	°C	**°F**	**°C**	**°F**	**°C**	**°F**
MoS_2	930	1705	1090	1995	650	1200
WS_2	870	1600	1040	1905	730	1345
$MoSe_2$	760	1400	980	1795	760	1400
WS_2	700	1290	930	1705	760	1400
$MoTe_2$	700	1290	700	1290	540	1005

(a) Friction coefficient greater than 0.2 at all temperatures

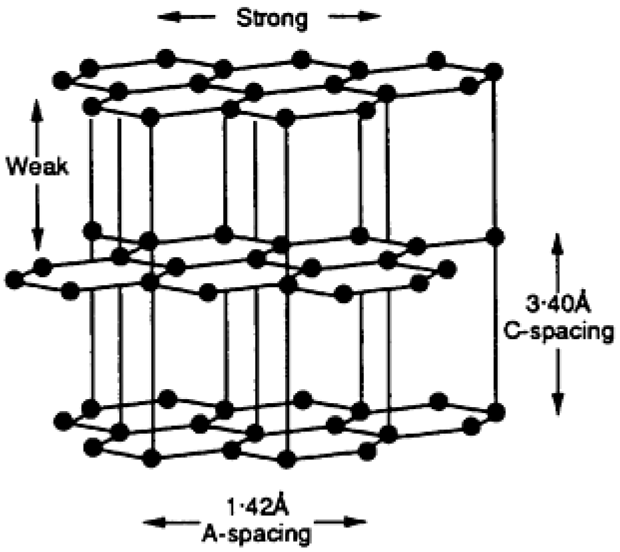

Fig. 1 Structure of graphite. The individual sheets consist of closely packed atoms, separated by a relatively large distance from neighboring sheets.

Compounds of this type have an AX_2 stoichiometry. Their crystal structures consist of hexagonal arrays of cations, each bonded to a pair of pendant anions (one on each side of the basal plane). Thus, a double layer of anions is present between each plane of cations. Strong, ionic bonding exists within each basal plane, but there are primarily weak Van der Waals forces within the double anion layers. Therefore, these compounds easily preferentially orient during sliding to allow slip of the basal planes nearly parallel to the sliding surfaces. This orientation behavior during sliding was demonstrated by electron and x-ray diffraction techniques early in the scientific investigation of MoS_2 (Ref 12, 13). Recent fundamental studies of sputtered MoS_2 films have shown that, even though reorientation occurs during sliding, the as-deposited crystal orientation has an influence on the wear life and chemical durability of the films (Ref 14, 15). Graphite also has a layered, hexagonal crystal structure, but does not appear to be an intrinsic solid lubricant. As will be discussed later, graphite requires adsorbed moisture or additions to develop lubricating ability.

It is also relevant that metals with a hexagonal crystal structure and a c/a ratio greater than about 1.6 exhibit predominantly basal plane slip, whereas those with a lower c/a ratio exhibit predominantly prismatic and pyramidal slip. Buckley (Ref 16) showed that those hexagonal metals that exhibit basal slip have lower friction coefficients in vacuum than the others.

MoS_2 and Other Dichalcogenides. The most widely used solid lubricant of this chemical class is MoS_2, the second is tungsten disulfide (WS_2), and the other dichalcogenides are found in scattered specialty applications. Both MoS_2 and WS_2 are intrinsic solid lubricants in that, unlike graphite, they do not require adsorbed materials or additives to develop lubricating capability. In fact, they lubricate best in the absence of such materials and are therefore lubricants of choice

for vacuum applications. Molybdenum disulfide is commonly used to lubricate moving mechanical components in space vehicles.

Molybdenum disulfide is applied to surfaces by a number of methods, including simple rubbing or burnishing, air spraying of resin-bonded or inorganically bonded coatings, and more recently, physical vapor deposition (PVD) techniques such as sputtering.

Burnished films are the easiest and least expensive to apply, but have very limited wear life. Resin-bonded spray coatings, especially the heat-cured variety, have superior wear life and are frequently used in ordinary air environments. They are typically 5 to 15 μm thick and have friction coefficients of about 0.06 to 0.15, depending on humidity and sliding conditions.

Early research with sputtered MoS_2 was reported by Spalvins and Przybyszewski (Ref 17). Their MoS_2 films, which they deposited in a direct current (dc) sputtering apparatus, were about 0.2 μm thick and were nearly stoichiometric. Figure 2 shows that the coatings had good frictional characteristics and good endurance in pin-on-disk tests in vacuum. However, the endurance life and friction coefficients of sputtered MoS_2 are not as good in air as they are in vacuum. The effect of atmospheric pressure on the friction of MoS_2-lubricated nickel is shown in Fig. 3; the friction coefficient increases from about 0.04 to 0.15 as the vacuum chamber pressure is increased above 13×10^3 Pa (100 torr).

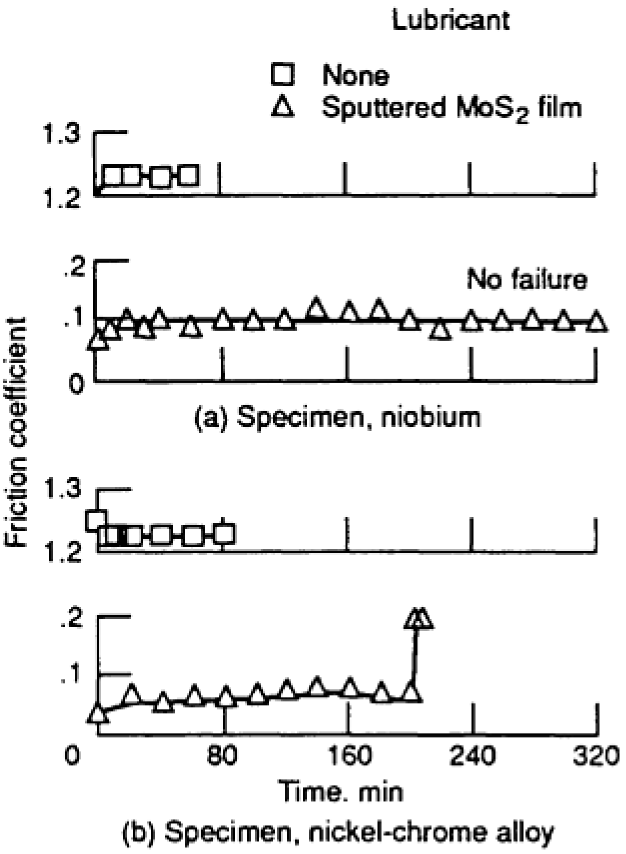

Fig. 2 Average friction coefficients of niobium sliding on two different specimens coated with sputtered MoS_2 in vacuum (10^{-11} torr, or 1.33×10^{-9} MPa). Load, 2 to 5 N (0.45 to 1.12 lbf); speed, 1.5 m/s (5 ft/min); ambient temperature

Friction coefficients for sputtered MoS_2 as low as 0.01 in vacuum have been reported by Roberts (Ref 19). In the same reference, he also reports on the adverse effects of atmospheric contaminants. Oxygen and especially water vapor in room air causes a slow oxidative degradation of MoS_2, leading to early failure (Fig. 4). On the other hand, resin-bonded coatings of high quality have good shelf life and superior wear life in air, probably because of the oxidation protection afforded by the resin binder.

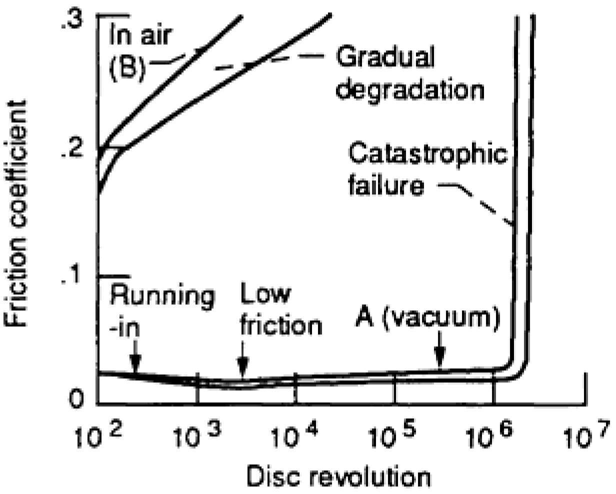

Fig. 4 Failure modes of sputtered MoS_2 under sliding motion. Source: Ref 19

Oxidation kinetic data for MoS_2 and WS_2, as determined by high-temperature x-ray diffraction, were reported by Sliney (Ref 20). Some oxidation kinetics data from this study for loosely compacted MoS_2 powders of 1 μm particle size are given in Fig. 5(a). The data show that the oxidation rate is strongly influenced by airflow rate through the reaction chamber. Increasing the airflow rate by a factor of about 6 increased the oxidation rate by a factor of 10 or more. At the lower flow of 5.5×10^{-6} mm^3/s (194×10^{-6} ft^3/s), MoS_2 was oxidized to molybdic oxide (MoO_3) in 1 h at 400 ° (750 °F). At the higher airflow rate, the temperature for an oxidation half-life of 1 h was reduced to 300 °C (570 °F). Figure 5(b) compares the oxidation kinetics of MoS_2 and WS_2 at the lower airflow rate. The curves intersect with MoS_2 oxidizing more rapidly than WS_2 above 340 °C (645 °F). Comparison of these data with the results of friction experiments shows that the loss of lubricating ability of these compounds in air coincides with the temperatures at which rapid oxidation occurs (Fig. 6).

disk tests using steel pins with 4.576 mm (0.183 in.) hemispherical tip radius. Force, 9.6 N (2.2 lbf); speed, 0.025 m/s (0.082 ft/s)

Graphite. The largest-volume tribological uses of carbon are as electrically conducting brushes for motors and generators and as the rubbing element in mechanical seals. The graphite form of carbon, which has a hexagonal, layered crystal structure (Fig. 1), also has application as a powder or bonded solid-lubricant coating. In spite of its desirable crystal structure, graphite is not an intrinsic solid lubricant. It lubricates in a normal air atmosphere, but fails to lubricate at high altitudes or in vacuum. Savage (Ref 21) reported convincing experimental evidence that graphite must adsorb moisture or some other condensable vapor such as hydrocarbons in order to be lubricative. This model appeared to be substantiated by the observation that, even in the presence of condensable vapors, graphite failed to lubricate above the desorption temperature.

However, Peterson and Johnson (Ref 10) observed that graphite again becomes lubricative at high temperatures when the lubricated metal becomes visibly oxidized. Some of their results showing the effect of temperature on the friction coefficient of graphite-lubricated cast Inconel sliding on Inconel X-750 in air are shown in Fig. 7. The authors postulate that restoration of lubrication at about 425 °C (800 °F) was due to interaction of graphite with oxides of the metal. The surface oxides were thought to promote adhesion of the graphite to the lubricated surfaces. The maximum temperature for lubrication with graphite films is limited by oxidation to about 550 °C (1020 °F).

Physical Vapor Deposition (PVD) of Tribological Coatings. Vapor-deposited coatings for tribological applications are of two major types: soft solid-lubricant coatings, and hard wear-resistant coatings. The basic processes for applying PVD coatings are simple vapor deposition, sputtering, and ion plating (see the article "PVD and CVD Coatings" in this Volume). In recent years various ion beam assisted deposition methods, which are modifications of the more basic process, have been used to deposit very adherent tribological coatings (Ref 22, 23). Sputtered MoS_2 was discussed earlier in the section on dichalcogenide solid lubricants. Two other categories of PVD coatings that are tribologically significant are sputtered hard coatings for wear control and ion-plated soft metals for lubrication.

Sputtered Hard Coatings. The hardness and oxidation characteristics of some hard coating materials are given in Table 2. These very hard materials are brittle. Therefore, they must have very good adhesion to the substrate to avoid delamination, and they must not be too thick if they are to withstand bearing surface stresses and substrate elastic deformations under dynamic (sliding, rolling) contact conditions. Acceptable coating thicknesses are typically 0.2 to 1.0 μm. Hard coatings alone can provide wear resistance. They are also used as an intermediate coating between the substrate and a solid-lubricant film.

Table 2 Bulk properties of some hard coat materials

Data from *Engineering Properties of Ceramic Materials,* Battelle Memorial Institute, published by American Ceramic Society, Columbus, OH, 1966

Material	Microhardness, kg/mm^2	Oxidation temperature[(a)]	
		°C	**°F**

Figure 8 compares the endurance lives in vacuum of MoS_2 lubricated ball bearings with and without an intermediate 0.1 μm hard coating of sputtered Cr_3Si_2 on the raceways. Sputtered 0.2 μm thick MoS_2 coatings were applied to the raceways and the cages of the bearings. The bearings without the intermediate coating had reasonably good life of about 200 h, but those with the hard coating did not fail in 1000 h, at which time the tests were stopped. Figure 9 shows that 1000+ h bearing life can also be achieved without the intermediate hard coating by sputter coating the bearing balls, in addition to the cage and raceways, with MoS_2. The combined effect of MoS_2 on all surfaces and an intermediate hard coating on the raceways and/or the balls was not investigated.

Graphite fluoride (CF_x) is not as well known as MoS_2 and graphite, but it has some unique properties that make it attractive as a solid lubricant. It is an electrical insulator (unlike graphite) and is nonwettable by water. The frictional properties are less influenced by humidity than either MoS_2 or graphite. Graphite fluoride is also known as carbon monofluoride because of its nominal 1:1 carbon-to-fluorine stoichiometry. However, the stoichiometry can be controlled from about x = 0.25 to 1.1. For x = 1.0 to 1.1, the compound is pure white and is preferred for applications were discoloration by the lubricant must be avoided.

Wear life and friction coefficient data from pin-on-disk tests reported by Fusaro and Sliney (Ref 25) for burnished films of CF_x on sand-blasted type 440C steel are shown in Fig. 10. The corresponding data for MoS_2 are included as a baseline for comparison. Film failure was taken as the time at which the friction coefficient reached 0.3. A very dry air atmosphere was used because of the deleterious effect of moisture on lubrication with burnished MoS_2. The CF_x films were the more durable over the entire temperature range. Friction coefficients were well below 0.1 for both compounds up to their failure time or temperature. Failure temperatures of 400 °C (750 °F) for MoS_2 and 480 °C (895 °F) for CF_x correlate well with the oxidation kinetics results for MoS_2 shown in Fig. 5 and the thermal decomposition temperature for CF_x reported by Kuriakose and Margrave (Ref 26). Therefore, CF_x was the better lubricant under the conditions of these tests. McConnell *et al.* (Ref 27) reported that MoS_2 had superior load-bearing capacity in tests on a Falex test machine in which double V-blocks are loaded against a rotating cylinder coated with the test lubricant. However, the load-carrying capacity of CF_x is considered by this author to be adequate for most conforming sliding contacts, especially when combined with a suitable binder such as a polyimide varnish. Fusaro (Ref 28) in his paper on the mechanism of graphite fluoride lubrication describes the lubricating process with this material as consisting of plastic flow of thin films of graphite fluoride between the sliding surfaces.

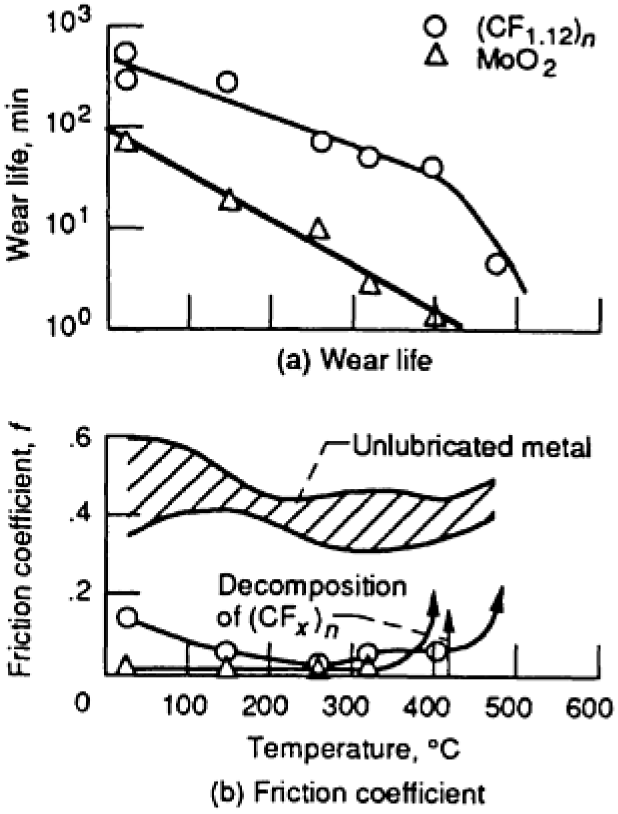

Fig. 10 Effect of temperature on wear life and friction coefficient of graphite fluoride [$(CF_{1.12})_n$] and MoS_2 powders burnished on sand-blasted type 440C stainless steel disks. Riders, 440C stainless steel with 4.76 mm (0.19 in.) hemispherical tip radius; linear sliding speed, 1.6 m/s (5.2 ft/s); load, 5 N (1.1 lbf); atmosphere, dry air (20 ppm H_2O). Source: Ref 25

Polyimide and Polyimide-Bonded CF_x Coatings. Data reported by Fusaro (Ref 29) from pin-on-disk experiments with polyimide varnish coatings on type 440C steel are given on Fig. 11, where the endurance lives and friction coefficients are shown as a function of temperature. Results are compared for three different controlled atmospheres: dry argon, dry air, and air containing 10^4 ppm water vapor. The data show that there is a sharp transition in the life and friction between 25 and 100 °C (75 and 212 °F), above which lower friction and much longer wear life were observed. This transition in the friction and endurance of polyimide coatings has been attributed to a second order relaxation in the molecular bonds of the polymer (Ref 30).

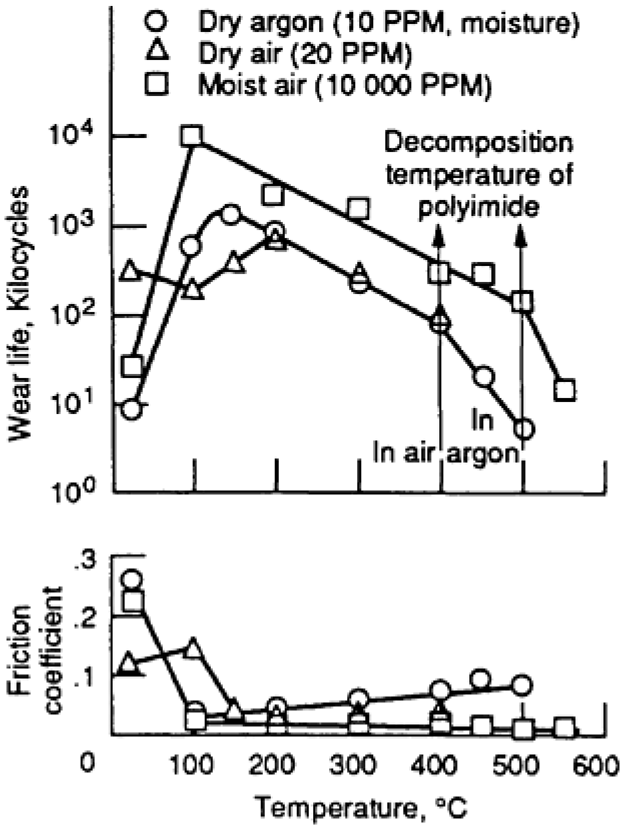

Fig. 11 Friction coefficient and wear life as a function of temperature for polyimide thin films in various atmospheres. Pin-on-disk tests run with type 440C stainless steel pins with 4.76 mm (0.19 in.) hemispherical tip radius. Load, 9.6 N (2.2 lbf); speed, 2.7 m/s (8.9 ft/s). Source: Ref 29

The effect of adding graphite fluoride or MoS_2 to the polyimide varnish is shown in Fig. 12. The coating formulations contained three parts by weight MoS_2 to one part polyimide solids dissolved in a solvent, or three parts of CF_x to two parts of polyimide solids. The density of CF_x is about one-half that of MoS_2; therefore, the two formulations contained equal volume percentages of solid lubricant. The solid lubricant additions clearly reduce the friction and greatly increase the wear life of the coatings at room temperature. The effect of the molecular relaxation transition on the tribological properties is completely eliminated by the solid-lubricant additions. The CF_x addition also resulted in improved coating endurance at all temperatures to 500 °C (930 °F), whereas MoS_2 addition deteriorated the endurance of the coating relative to the base polyimide films.

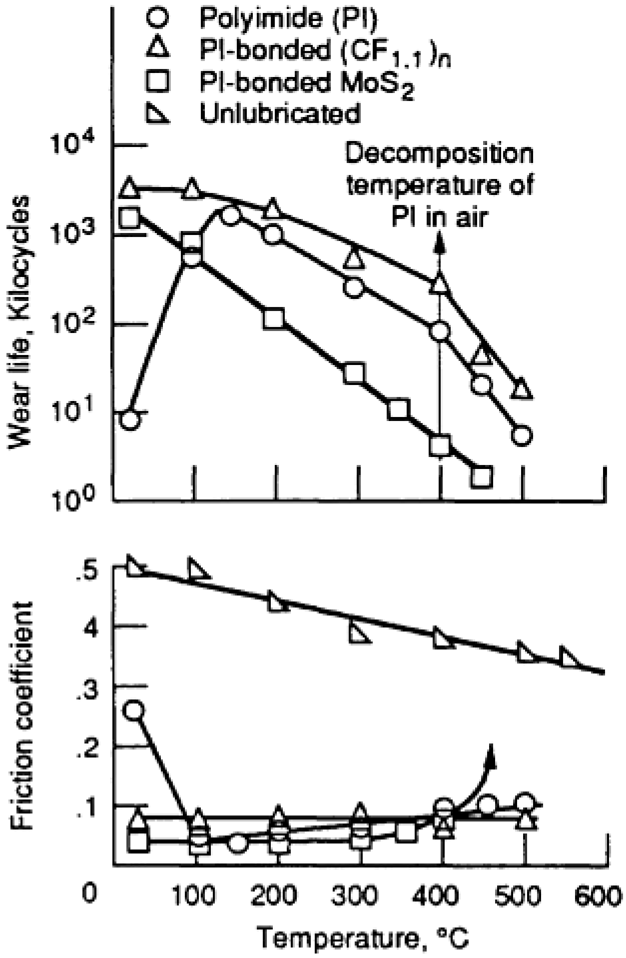

Fig. 12 Friction coefficient and wear life as a function of temperature for three solid lubricant films run in dry air and moist air (10 × 10^4 ppm H_2O) against type 440C stainless steel pins with 4.76 mm (0.19 in.) hemispherical tip radius. Load, 9.6 N (2.2 lbf); speed, 2.7 m/s (8.9 ft/s). Source: Ref 31

Wagner and Sliney (Ref 32) have reported on polyimide-bonded CF_x films that are excellent back-up lubricants for compliant (foil) gas bearings at temperatures up to about 350 °C (660 °F). This is about 100 °C (180 °F) higher than the limit for PTFE films that are commonly used in foil bearing applications.

Fusaro (Ref 33) has published a comprehensive review of the tribological properties of polyimide coatings and polyimide-base self-lubricating composites.

Polymer Composites. Many polymers, including nylon, acetal, polyethylene, and polytetrafluoroethylene (PTFE), are used in the unfilled or filled forms as bearing materials. Solid-lubricant fillers are typically powdered graphite, MoS_2, or CF_x. The powdered additives can improve the friction and wear properties, but usually weaken the material and, as a consequence, reduce their load-carrying capability. Where maximum load capacity is needed, fiber reinforcement is used. The fibers are in the form of woven fabric, chopped fibers, or filament windings. Glass fabric is often used to reduce creep of bonded PTFE liners in airframe bearings and other heavily loaded bearings. Polyester fibers have been found to be an effective nonabrasive reinforcement for PTFE bearing liners.

Sliney and Williams (Ref 34) reported on tests of nonmetallic plain cylindrical bearings consisting of an aramid (Kevlar) fiber-reinforced shell with a bonded, self-lubricating woven liner of polyester fiber-reinforced PTFE. The results are summarized in Fig. 13 and show that low friction and wear and load capacities in excess of 207 MPa (30 ksi) are achieved from -23 to 121 °C (-9 to 250 °F). The bearings are limited by creep deformation at higher temperatures.

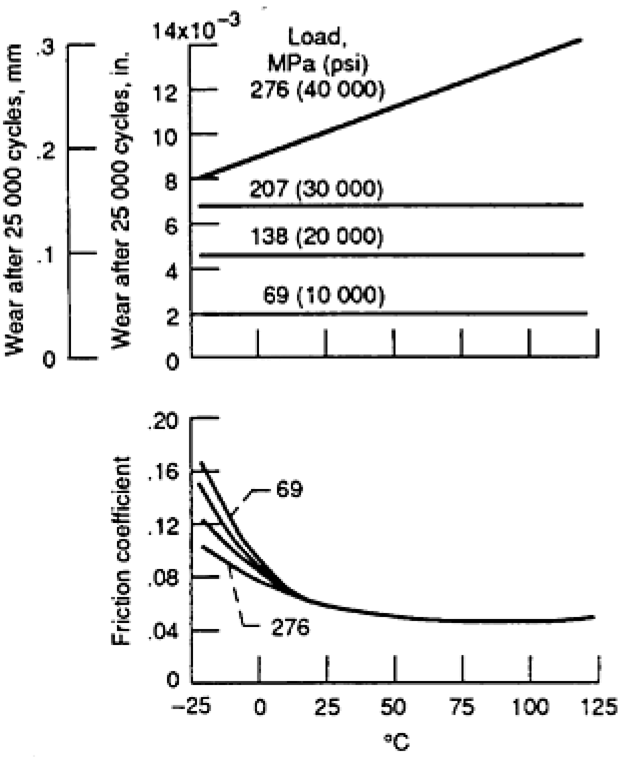

Fig. 13 Effect of temperature on wear and friction of PTFE-lined composite bushings. Bore diameter, 0.025 m (0.082 ft); journal oscillation at ±25° and 10 cycles/min. Source: Ref 34

Considerable research has been done on graphite fiber-reinforced polymers as self-lubricating bearing materials. Giltrow and Lancaster (Ref 35, 36) reported on the friction and wear properties of composites incorporating chopped graphite fibers in thermoplastic and thermosetting resins including high-temperature polyimide. In addition to high strength, graphite fibers have the additional advantages of high thermal conductivity and lubricating ability. Graphite fiber-reinforced polyimide (GFRPI) is of particular interest for aeronautics applications and has been extensively researched for airframe and gas turbine engine applications. The GFRPI composites investigated at the NASA Lewis facility contained chopped graphite fibers and were prepared by transfer molding and curing under heat and pressure.

The results of pin-on-disk bench tests for type 440C steel pins sliding against GFRPI were reported by Fusaro and Sliney (Ref 37). Favorable tribological properties were observed with several combinations of addition (A)-type and condensation (C)-type polyimides and low-modulus (L-type) and high-modulus (H-type) fibers. Figure 14 gives the friction coefficients and wear track profiles of the various composites at room temperature and at 300 °C (570 °F). In these tests, the best results were obtained with an addition-type polyimide reinforced with low-modulus graphite fibers (AL composite).

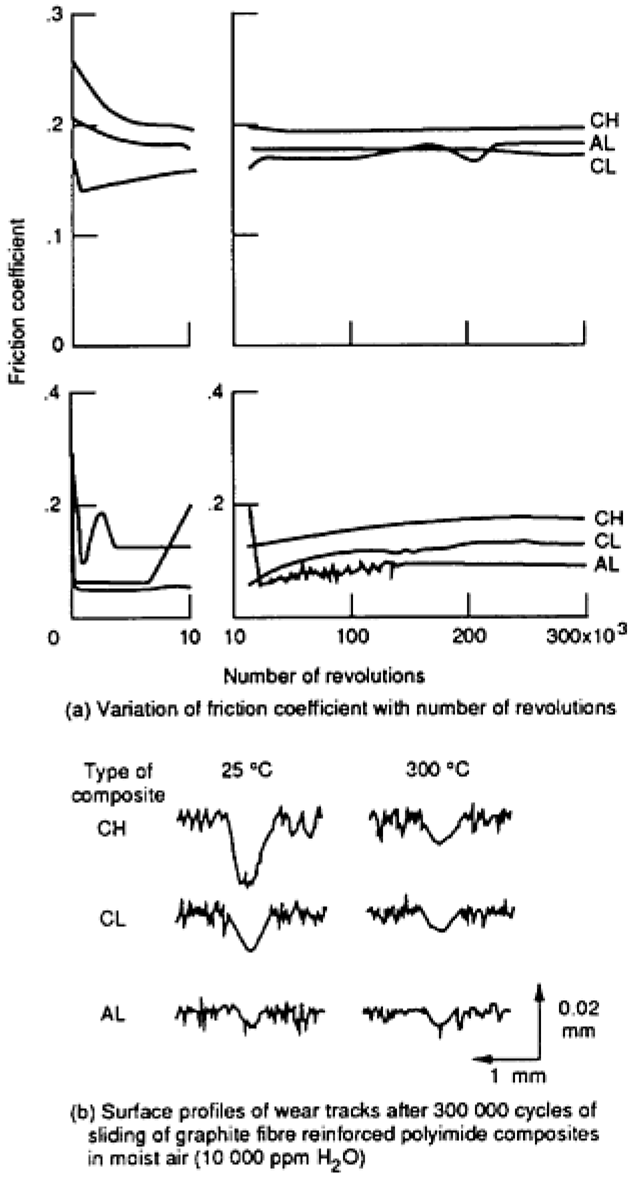

Fig. 14 Tribological performance of polyimide composite disks sliding against type 440C stainless steel pins with 4.76 mm (0.19 in.) hemispherical tip radius. Load, 9.6 N (2.2 lbf); speed, 2.5 m/s (8.2 ft/s). Source: Ref 37

Bearing Tests of GFRPI. Plain cylindrical and plain spherical bearing designs with self-lubricating GFRPI surfaces were tested to 350 °C (660 °F) in several test programs at NASA Lewis. The spherical bearing designs evaluated are shown in Fig. 15. The first bearings tested had molded spherical elements of AL-type GFRPI with various graphite contents in steel outer rings. Friction coefficients for various fiber loadings are shown in Fig. 16 for bearing temperatures from 25 to 350 °C (75 to 660 °F). The results for a conventional glass fiber reinforced bearing are included for comparison. The composite with the highest graphite fiber content provided the lowest bearing torque but failed by brittle fracture at 315 °C (600 °F). The next lowest bearing torque was provided by the composite with 45 wt% of graphite fibers and no failures occurred with a 35 MPa (5000 psi) radial load. A 1:1 fiber-to-polymer ratio was used in all subsequent tests. The standard PTFE-lined bearing had very low torque to 200 °C (390 °F), but failed when the liner extruded out of the bearing at 250 °C (480 °F).

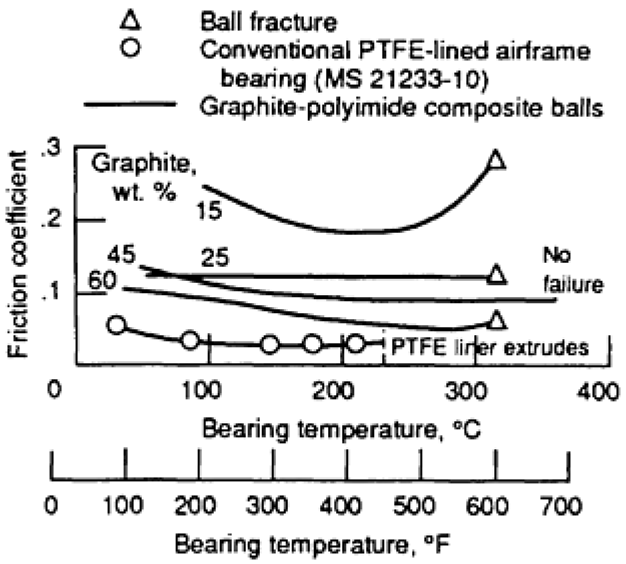

Fig. 16 Friction of spherical bearings with polyimide-graphite fiber composites of various fiber contents. Stellite 6B journal. Radial unit load, 35 MPa (5000 psi); journal oscillation in cylindrical bore at 1 Hz, ±15°

Several modifications of the bearing designs shown in Fig. 15 were compared (Ref 39). Figure 17 shows that no significant difference was noted in bearing friction for the two bearing designs. However, a much higher load capacity is achieved with the design shown in Fig. 15(b), which consists of a steel ball and a thin (1.5 mm, or 0.06 in.) GFRPI liner bonded to a steel outer ring (Ref 40). The dynamic load capacities of cylindrical bushings with GFRPI liners had about the same dynamic load capacities as the GFRPI-lined sphericals if a liner retention step was provided at each end of the bushing (Ref 41).

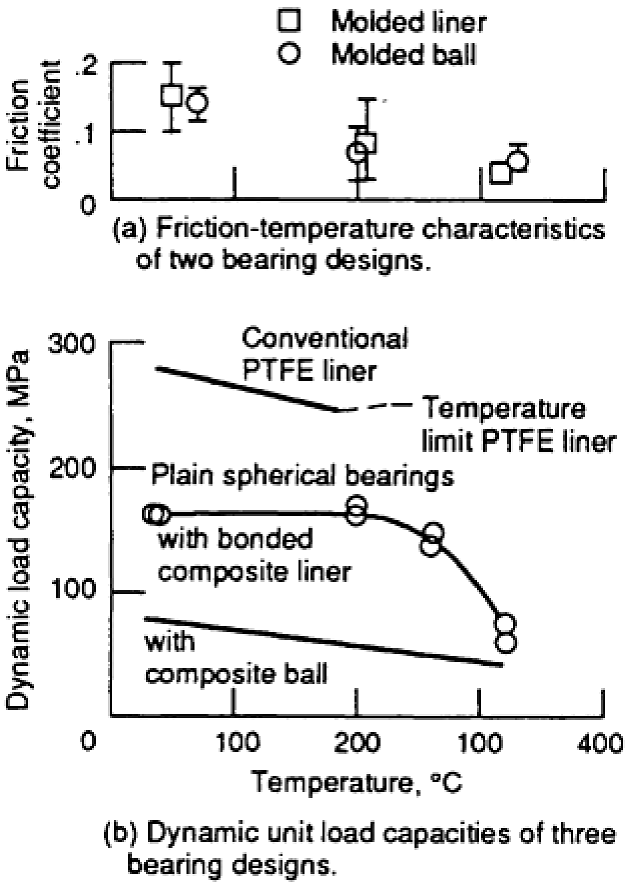

Fig. 17 Friction and dynamic load capacities of bearings lubricated with GFRPI composite. Source: Ref 39

Gardos and McConnell (Ref 42) have published an extensive four-part report on the preparation and performance of self-lubricating polyimide composites reinforced with three-dimensional woven graphite fibers. The purpose of the three-dimensional weave is to afford maximum strength and load capacity. Load capacities up to 200 MPa (29 ksi) were obtained during low-speed oscillating tests.

Extreme-Temperature Solid Lubricants

All of the solid lubricants so far discussed suffer thermal decomposition or oxidative degradation at or below 550 °C (1020 °F). For higher temperatures, classes of materials that have shown some promise are lubricious oxides and some fluorides of alkali metals, alkaline earth metals, and rare earth metals.

The tenacious oxides formed on nickel-base and cobalt-base superalloys at high temperatures have a profound effect on reducing friction and wear (Ref 43). Lankford *et al.* (Ref 44) showed that certain metals, when ion beam mixed into the surface of zirconia and silicon nitride ceramics, reduce their friction against some counterface materials at 800 °C (1470 °F). The beneficial effect is attributed to oxidized films of the implanted metals.

Oxidatively stable fluorides, such as CaF_2 and BaF_2, are lubricious from about 400 to 900 °C (750 to 1650 °F) (Ref 45). Other fluorides that have shown some lubricating capability at high temperatures are LiF, MgF_2, and fluorides of some rare earth metals, particularly, LaF_3 and CeF_3 (Ref 46, 47). Fluorides have been applied as (1) ceramic-bonded coatings using a porcelain enameling process, (2) fusion-bonded all-fluoride coatings, and (3) constituents of plasma-sprayed composite coatings. Most recently, they have been incorporated as components of free-standing powder metallurgy composites. The results of this research are summarized in the following section.

Ceramic-Bonded Fluorides. Early research on ceramic coatings and ceramic-bonded CaF_2 coatings at NASA Lewis was summarized by Johnson and Sliney (Ref 43) and Sliney (Ref 48). Detailed references are given in the bibliographies of those papers. The coatings are prepared by spraying and firing procedures similar to those used in porcelain enameling,

but the compositions are very different compared to conventional porcelain enamels and are specially formulated with the objective of achieving good tribological properties. Because at least some of the components of these coatings melt during the firing process, they are referred to as "fusion-bonded" coatings. In most cases the coating thickness is 0.02 mm, ±0.01 mm (0.0008 in., ±0.0004 in.).

In a formulation study of ceramic compositions, a CoO-base coating and a BaO-base coating for nickel-chromium superalloys were developed, both of which provided tribological benefit to at least 800 °C (1500 °F). High surface temperatures due to frictional heating at high sliding velocities or high bulk specimen temperatures were beneficial to lubrication with these coatings. The friction and wear for cast Inconel sliding on uncoated and on coated Inconel X-750 at a sliding velocity of 2.2 m/s (7.2 ft/s) are shown in Fig. 18. Both coatings provided a considerable reduction in pin wear compared to the unlubricated specimen. Friction was reduced over the entire temperature range with CoO-base coating and up to about 600 °C (1110 °F) with the BaO-base coating. Lower friction was obtained when the CoO-base composition was used as a binder for CaF_2. Friction and wear for coatings prepared from blended powders with a 3:1 CaF_2-to-binder ratio (where the binder is CoO-base ceramic) are shown in Fig. 19. Friction coefficients were about 0.25 at room temperature and gradually decreased to about 0.15 at 800 °C (1470 °F). Very careful coating procedures are necessary to achieve a uniform distribution of CaF_2 throughout the ceramic binder. The CoO-base ceramic is highly vitrified (glassy) and is temperature-limited to the maximum temperature at which the glass phase will not act as an adhesive upon subsequent cooling below its softening point.

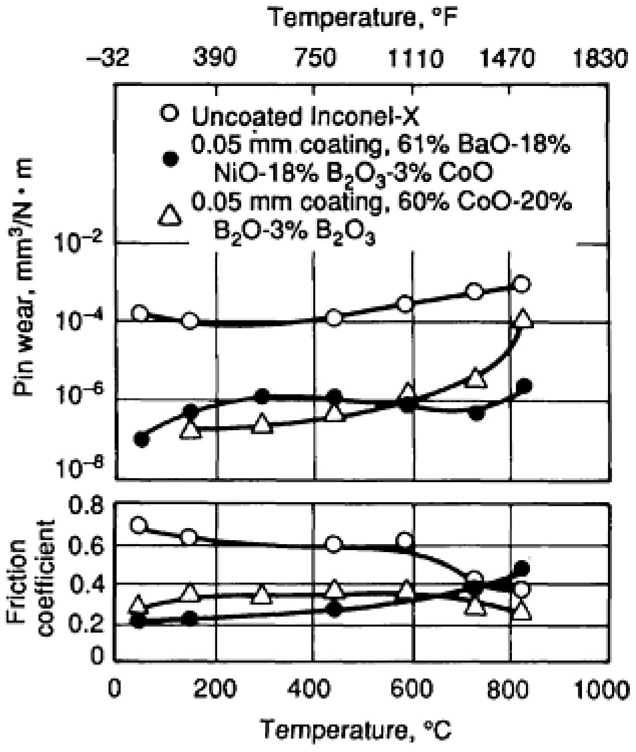

Fig. 18 Effect of temperature on lubricating properties of CoO-base and BaO-base coatings on Inconel X-750 sliding against Inconel X-750 pins with a 4.76 mm (0.19 in.) hemispherical tip radius. Load, 9.6 N (2.2 lbf); speed, 2.2 m/s (7.2 ft/s)

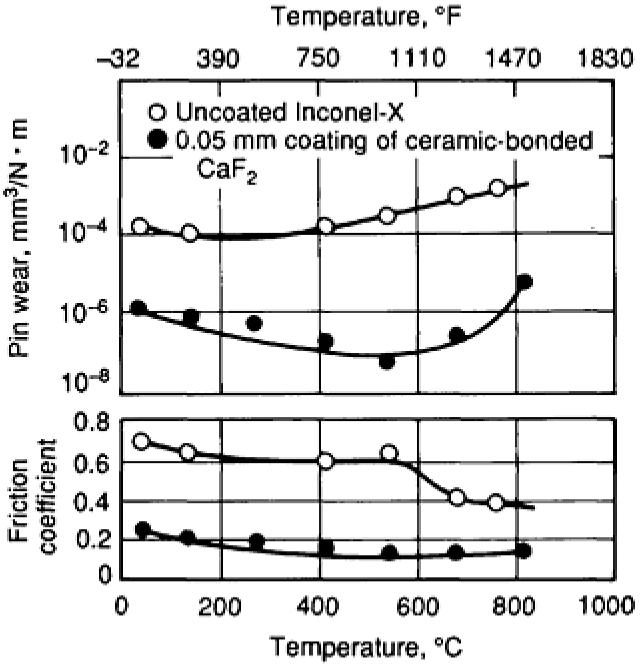

Fig. 19 Effect of temperature on lubricating properties of ceramic-bonded CaF_2 coatings on Inconel X-750 sliding against Inconel X-750 pins with a 4.76 mm (0.19 in.) hemispherical tip radius. Load, 9.6 N (2.2 lbf); speed, 2.2 m/s (7.2 ft/s)

Another approach involved preparing coatings from composite powders to avoid segregation during spraying and firing (fusion bonding) of the coatings. A composition near the melting point for the CaF_2-Ca_2SiO_4-CaO ternary system was chosen, and the CaF_2-BaF_2 binary eutectic was substituted for CaF_2 in order to lower the melting point. The coating was fusion bonded by firing in air at 980 °C (1795 °F). The friction coefficient as a function of temperature at two sliding velocities is shown in Fig. 20. Friction was quite high at the lower sliding velocity of 2.5 m/s (8.2 ft/s); the friction coefficient was 0.5 at room temperature and gradually decreased to about 0.3 at 600 to 800 °C (1110 to 1470 °F). However, at 10 m/s (33 ft/s), friction coefficients were less than 0.2 at all temperatures. Even at the lower speed, the pin wear factors were 1/1000th those of the uncoated metal, or about 10^{-6} $mm^3/N \cdot m$.

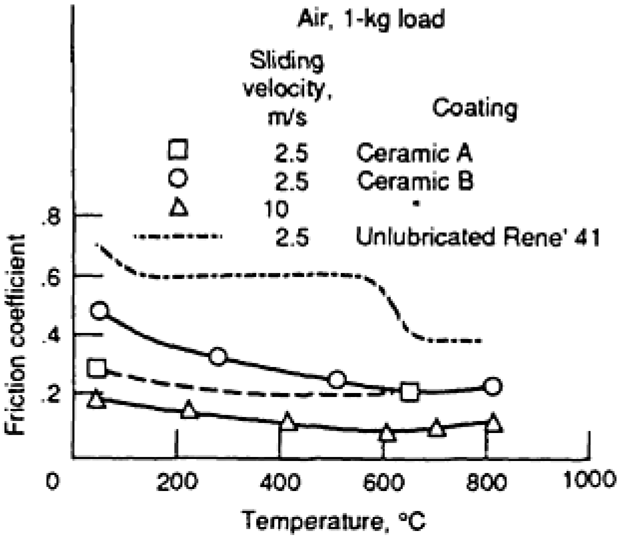

Fig. 20 Friction-temperature characteristics of fluoride coatings modified with silicate and oxide additions. Ceramic A: 60.8CaF_2-13.1LiF-17.4Ca_2SiO_4-8.7CaO. Ceramic B: 48.3 BaF_2-21.7CaF_2-20Ca_2SiO_4-10CaO

Fused Fluoride Coatings. Sliney *et al.* (Ref 45) reported on the performance of coatings consisting entirely of stable fluorides with emphasis on compositions from the BaF_2-CaF_2 binary system. Results of friction and wear tests are shown in Fig. 21. Over the entire temperature range of 25 to 816 °C (75 to 1500 °F) and at two sliding velocities of 2.3 and 10 m/s (7.5 and 33 ft/s), the coatings were responsible for very substantial reductions in friction and wear relative to the uncoated metals. At 2.2 m/s (7.2 ft/s), the friction coefficient at room temperature was rather high at 0.4 and decreased with temperature to 0.2 at 260 °C (500 °F) and 0.11 at 800 °C (1470 °F). At 10 m/s (33 ft/s), friction coefficients were 0.2 at room temperature, gradually decreasing to about 0.15 at 800 °C (1470 °F). No coating failures occurred in one hour tests--52.2 × 10^3 cycles at 2.3 m/s (7.5 ft/s) and 227 × 10^3 cycles at 10 m/s (33 ft/s).

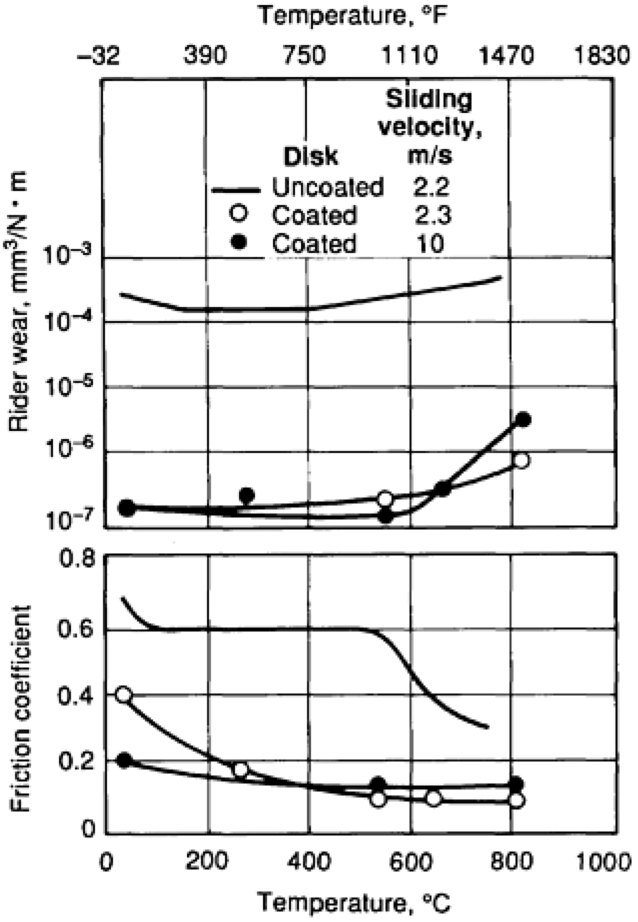

Fig. 21 Lubricating properties of fused fluoride coating composition in air at two sliding velocities. Coating composition, $38CaF_2$-$62BaF_2$; coating thickness, 0.025 to 0.050 mm (0.001 to 0.002 in.); duration of run, 1 h; load, 500 gf (1.1 lbf); specimens, pins with 4.76 mm (0.19 in.) hemispherical tip radius sliding against coated disks. Source: Ref 45

The relatively high friction at low temperature and sliding velocities led to an investigation in which it was found that the addition of silver to the BaF_2-CaF_2 coatings could result in a uniformly low friction from room temperature to 800 °C (1470 °F). This is illustrated in Fig. 22, which compares the friction-temperature characteristics of fluoride coatings with and without a 35 wt% silver addition (Ref 49).

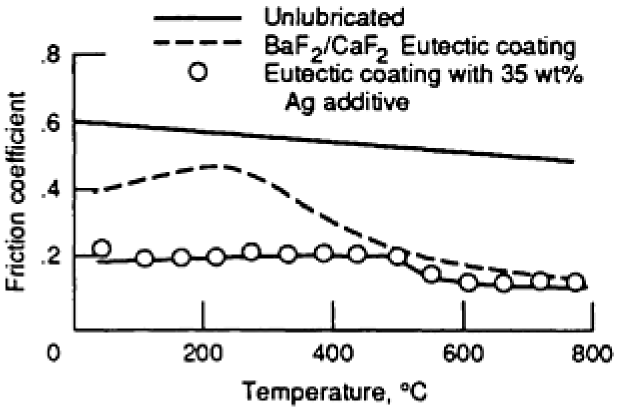

Fig. 22 Effect of temperature on friction coefficients of fused fluoride coatings (0.04 mm, or 0.0016 in., thick) sliding against cast Inconel pins with 4.76 mm (0.19 in.) hemispherical tip radius. Load, 5 N (1.1 lbf); speed, 2.3 m/s (7.5 ft/s). Source: Ref 49

Comparison of Ceramic-Bonded and Fused Fluoride Coatings. The ceramic-bonded coatings studied have good friction and wear properties at high surface temperatures that encourage the formation of a smooth, in some cases, vitreous, glaze on the sliding surfaces. They are not generally effective at low ambient temperatures except at high sliding velocities where frictional heating generates high surface temperature. Unfortunately, some vitreous glazes, which provide lubrication by viscous shear at high temperature, develop very high viscosity below their softening temperature. Below this temperature, the high viscosity of the glaze can result in very high bearing torque or even "lockup" of the bearing. A restart cannot occur until the bearing is heated above the softening point of the glaze. This phenomenon is not generally observed in pin-on-disk tests, where the contact area is very small and the adhesive bond is easily broken, but it has been observed in conforming-contact plane spherical bearings. This problem has not been observed with the nonvitreous glazes formed on the sliding surfaces of fused fluoride coatings that have no vitrifying oxides in their composition.

Plasma-Sprayed Coatings. When coatings are fusion bonded in a furnace, the entire part is heated above the melting point of at least one of the coating components. The high temperatures involved are not acceptable for some substrates, for example, titanium. An alternative method is plasma spraying, which only minimally heats the substrate. Plasma spraying is also more convenient (after the optimum plasma spray equipment parameters are determined), and can be used to deposit combinations of materials that are not amenable to furnace heat treatment. The first reported plasma spray tribological coatings developed at NASA Lewis were designated PS100 and PS101 (Ref 50). The former is a three-component composite coating of CaF_2, sodium-free, glass, and a nickel-chromium alloy binder. The PS101 designation also contains silver to improve low-temperature friction. Figure 23 shows the wear and friction-temperature characteristics of these coatings in low-speed, oscillating, plain spherical bearings. It is clear that the silver addition reduces friction at low temperatures without an adverse effect on lubrication at high temperatures. Both coatings are somewhat conformable, or ductile, and have moderately good wear characteristics. Coating and counterface wear factors are typically on the order of 10^{-5} $mm^3/N \cdot m$. PS100 and PS101 are used for high-temperature applications involving moderately loaded (up to at least 34 MPa, or 4900 psi) sliding contact bearings, and for shaft seals requiring a degree of conformability.

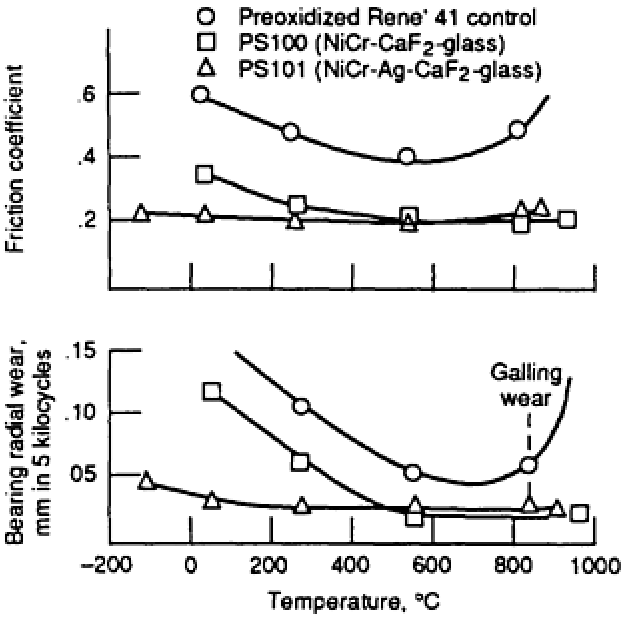

Fig. 23 Friction and wear properties of plasma spray coatings for self-lubricating oscillating (1 Hz, ±15°) bearings. Radial load, 34 MPa (5000 psi)

The PS200 series of plasma spray coatings were subsequently developed (Ref 51, 52). In this coating, the lubricating solids are distributed throughout a wear-resistant matrix of Ni-Co alloy-bonded chromium carbide (Cr_3C_2). The two most-studied compositions are PS200, which contains 10 wt% each of Ag and CaF_2-BaF_2 eutectic, and PS212, which contains 15 wt% each of the two lubricants in the bonded carbide matrix. The friction coefficients for these coatings are typically 0.30 to 0.35 from room temperature to 900 °C (1650 °F) at a sliding velocity of 2.7 m/s (8.9 ft/s) and tend to decrease at very high sliding velocities. Wear factors are about one-tenth of those for the PS100 series of coatings. In a composition-optimization study, PS212 had somewhat lower friction and wear in pin-on-disk tests than PS200; however, PS200 may be of interest where a harder coating is preferred.

Promising results have been obtained in a number of prototype tests of high-temperature mechanical components coated with PS200 or PS212. These include (1) start/stop tests of hydrodynamic gas bearings at temperatures up to 650 °C (1200 °F) (Ref 51, 53) and (2) a test of a four-cylinder Stirling engine with PS200-lined cylinders (Ref 51, 54).

Self-Lubricating Powder Metallurgy Composites. Plasma spray coatings are appropriate for flat surfaces and outside diameter surfaces that are readily accessible for spraying with a plasma spray gun. However, it is difficult or impossible to spray the inside surfaces of components such as small cylindrical bearings, valve guides, and bushings. These are the types of components that lend themselves to being made by powder metallurgy processes. The PS212 composition was used to make free-standing powder metallurgy (PM212) parts by sintering and by hot isostatic pressing (HIPing). The HIPed version is fully dense, whereas the sintered version is about 75% of theoretical density. The compressive strength at 900 °C (1650 °F) and the coefficient of thermal expansion of sintered PM212 and of HIPed PM212 are given in Fig. 24. The HIPed version is about three times stronger than the sintered version, but both materials retain compressive strength to at least 700 °C (1290 °F), thereby equalling or exceeding the room-temperature strength of many grades of bearing bronze and carbon sliding-contact bearing materials. The thermal expansion coefficient of PM212 is bracketed by those of such common alloys as cast iron and nickel-base superalloys in Fig. 24.

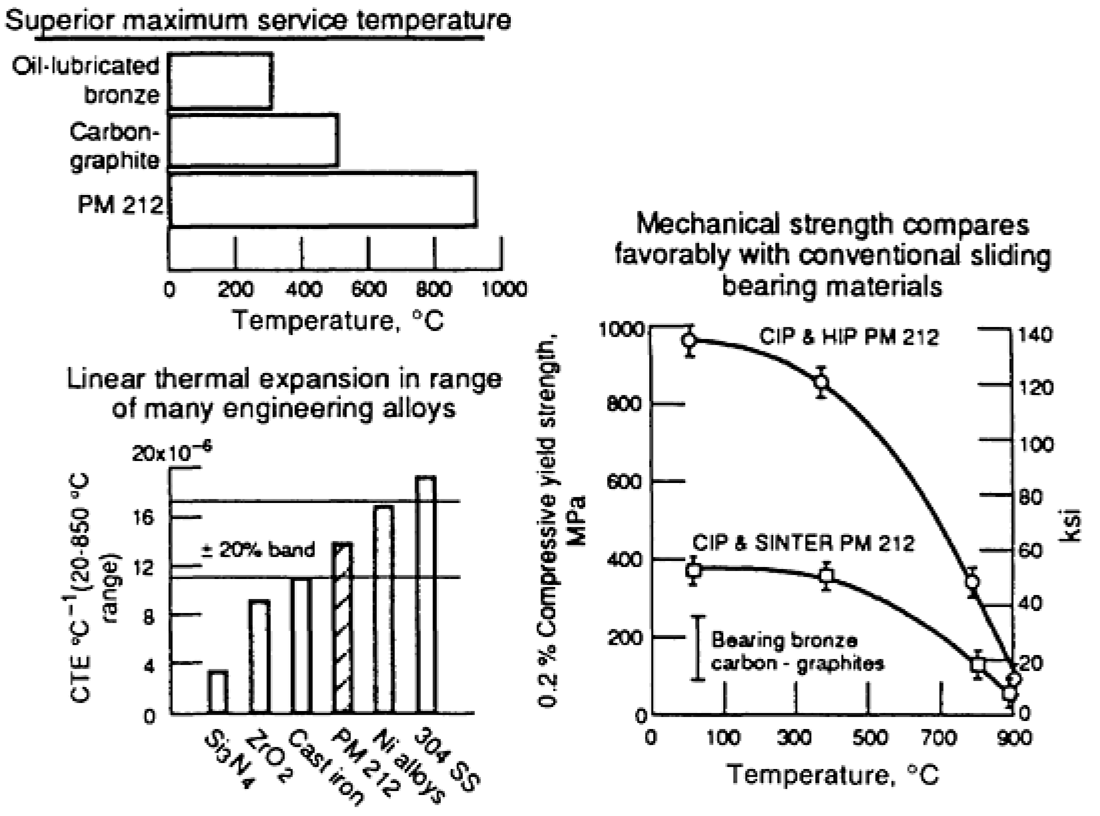

Fig. 24 Properties of PM212 self-lubricating P/M composite. Source: Ref 55

The tribological properties of sintered PM212 pins sliding on uncoated René 41 disks were reported by DellaCorte and Sliney (Ref 56). Figure 25 shows that friction coefficients at a sliding velocity of 2.7 m/s (8.9 ft/s) are about the same for sintered PM212 pins sliding on René 41 disks as they are for René 41 pins sliding on PS212-coated disks. The effect of sliding velocity on the friction coefficient of sintered PM212 is given in Fig. 26. At 760 and 900 °C (1400 and 1650 °F), the friction coefficient decreases with increasing sliding velocity and is 0.2 at the highest sliding velocity of 8.1 m/s (26.6 ft/s). Friction behavior is less straightforward at the lower temperatures, but friction coefficients are typically 0.30 to 0.35, except at the lowest velocity at room temperature. The trend of decreasing friction with increasing velocity suggests that friction coefficients considerably lower than 0.2 may be expected at the very high sliding velocities characteristic of shaft seals in turbomachinery. This effect may be due to the increased localized heating at high sliding velocities, which soften the silver and fluoride surface films, thus reducing their shear strength without appreciably reducing the hardness and flow pressure of the material below the near-surface region.

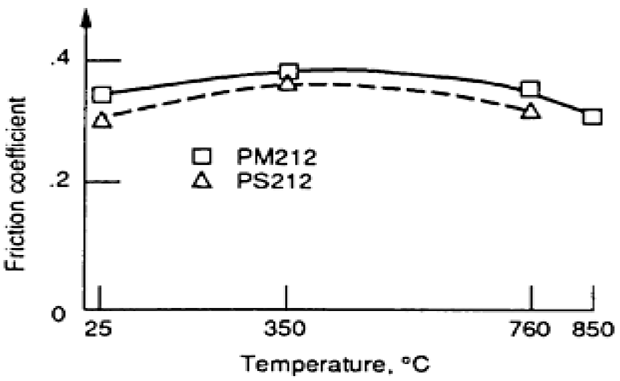

Fig. 25 Friction coefficient comparison of plasma spray coatings. Results from sintered PM212 pins sliding on René 41 disks and René 41 pins sliding on PS212 coated disks are given. Environment, air with 35% relative

humidity at 25% °C (75 °F); load, 0.5 kg (1.1 lbf); speed, 2.7 m/s (8.9 ft/s). Source: Ref 56

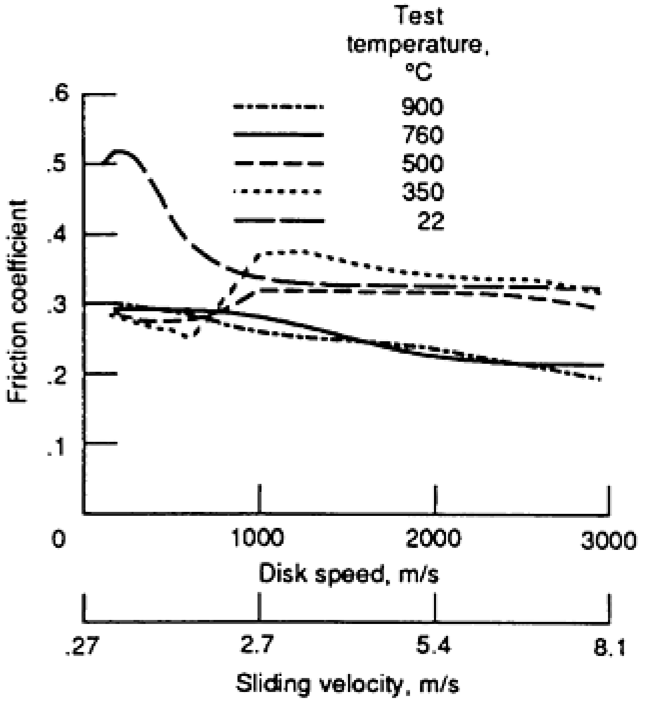

Fig. 26 Effect of sliding velocity on the friction coefficient of sintered PM212 sliding against René 41. source: Ref 56

Wear factors for sintered PM212 are in the 10^{-6} to 10^{-5} $mm^3/N \cdot m$ range. Wear factors for HIPed PM212 pins are about one-half those of sintered pins from 25 to 760 °C (75 to 1400 °F), and René 41 disk wear appears to be independent of whether the composite is sintered or HIPed.

Grease

Raymond H. Boehringer, DuBois Chemicals, Inc.

Introduction

GREASE, in the form of mutton or beef fat (tallow), was used as early as 1400 BC to reduce axle friction in chariots. The semisolid consistency of fat allowed it to remain in place longer than liquids such as vegetable oil. Mutton and beef tallow were used until 1859, when Colonel Drake drilled his first oil well. Since that time, most lubricants have been based on petroleum (mineral) oil (Ref 1).

As defined by ASTM (Ref 2), lubricating grease is "a solid to semifluid product of dispersion of a thickening agent in a liquid lubricant. Other ingredients imparting special properties may be included." The function of a grease, according to Ref 3, is to remain in contact with moving surfaces and not leak out under gravity or centrifugal action, nor be squeezed out under pressure. Its major practical requirement is that it must retain its properties under shear at all temperatures to which it may be subjected during use. At the same time, the grease must be able to flow into the bearing through grease guns and from spot to spot in the lubricated machine as needed, but must not add significantly to the power required to operate the machine, particularly at the start. These parameters represent an exacting set of rheological requirements (Ref 3). Because of the solid nature of grease, it does not perform the cooling and cleaning functions of a fluid lubricant.

Greases are used in place of oils because (Ref 4):

- They stay put, either with less-expensive seals or no seals
- They reduce dripping and spattering
- They require less-frequent application
- They resist the washing action of water
- They seal out contaminants
- They can prolong the life of worn parts
- They provide a better mechanical lubrication cushion for extreme conditions, such as shock loading, reversing operations, low speeds, and high speeds

The lubricating grease industry has made a major contribution to the U.S. economy in the automotive, industrial, steel mill, farming, railroad, other transportation, and military sectors. Rugged industries, such as steel mills, test the maximum capability of new greases and the ingenuity of their manufacturers. Aircraft and military applications, which are beyond the capabilities of petroleum-based greases, utilize synthetic greases, which can sustain temperature extremes ranging from -54 to 315 °C (-65 to 600 °F).

Grease Basics

Grease consists of a thickening agent, base stocks, and additives (Fig. 1). Good sources for explanations of grease-related terminology are Ref 1 and 5. The base stock (oil) is the primary lubricant, although additives dramatically influence grease performance. Most thickeners do not contribute to lubrication, with the exception of calcium soap.

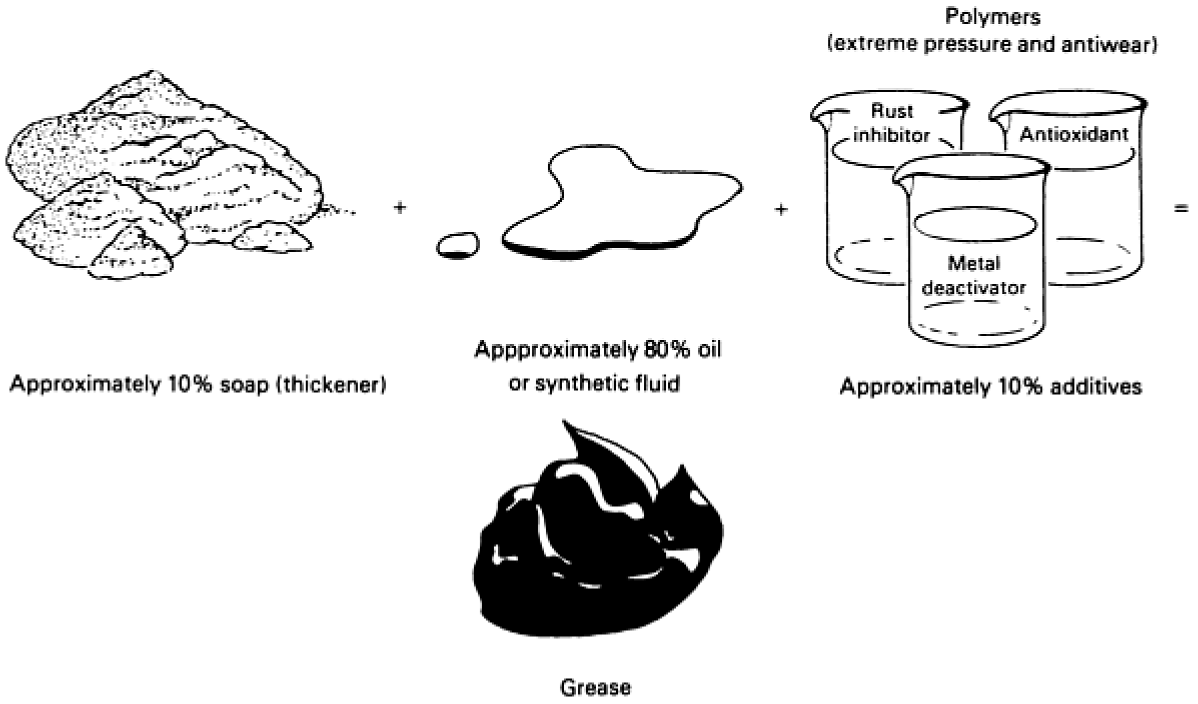

Fig. 1 Grease composition

Base Stocks

Base stocks can be either petroleum or synthetic liquid products; each category is described below.

Petroleum. Primary base stocks are petroleum based (mineral oil). Specifically, the stocks used in greases are petroleum oils separated from crude oil (Fig. 2), which is produced by oil wells. Crude oil is a black-colored mixture of fuels, petroleum lubricating oils of varying viscosities, and asphalt (tar-like products.) Fuels are a major part of crude oil and are maximized to 98 or 99% in quantity by chemical cracking.

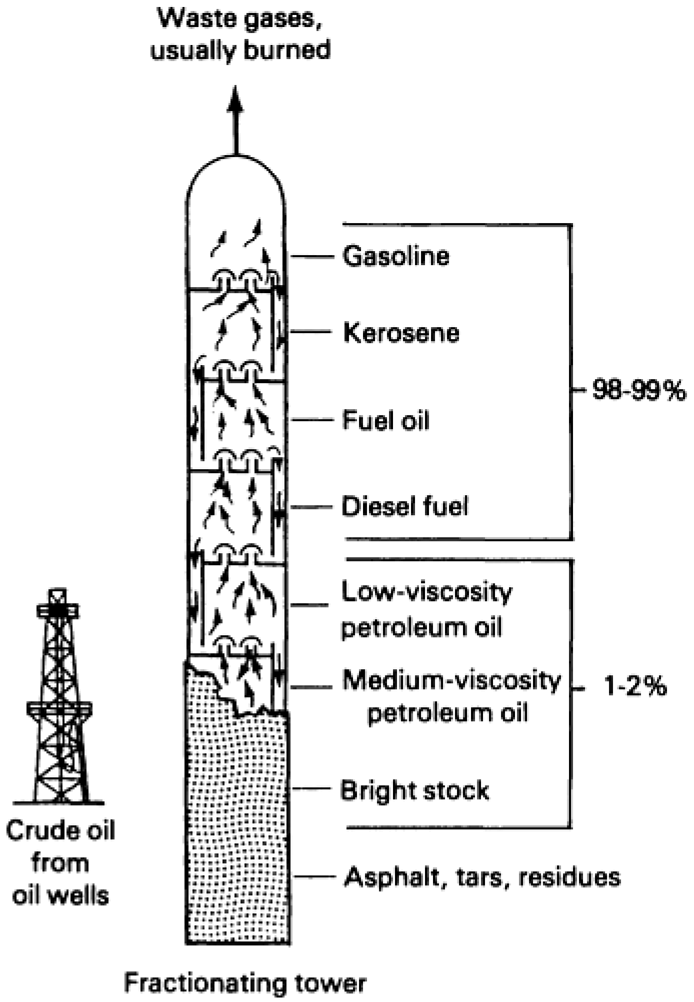

Fig. 2 Processing of crude oil by major oil companies

One of the major processes used to divide crude oil into its components occurs in the tall, thin fractionating towers associated with all petroleum refineries (Fig. 2). Flames are often seen at the top of these towers, because waste gases are frequently burned off. The petroleum oil fractions produced by this distillation tower can be used in grease manufacturing. The petroleum fractions range from light (low viscosity) petroleum to heavy, bright stocks (high viscosity). Low-viscosity fractions are used to impart better grease pumpability and good low-temperature performance. Most greases are made from medium-viscosity base stocks equivalent to an ISO 100 or ISO 150 (SAE 30 or 40) grade oil. Heavy-duty greases and high-temperature greases usually require heavier base stocks, approximately ISO 460 (SAE 140) grade.

Higher-quality petroleum-based stocks are used in higher-quality greases. Refining these base stocks can involve solvent extraction, bleaching, clay or carbon treating, hydrogenation, and redistillation. Water white-colored base stocks are referred to as white mineral oil, and are used in food grade, USDA-H1 greases that are suitable for incidental food contact.

Figure 3 shows the chemical structures of the three basic types of petroleum: paraffinic, naphthenic, and aromatic. Each type is described below, as well as in Table 1.

Table 1 Properties of three petroleum types that influence grease preparation and grease applications

Properties	Paraffinic	Naphthenic	Aromatic
Molecular form	Saturated	Saturated	Unsaturated
Oxidation stability	Best	Moderate	Poor
Thermal stability	Best	Moderate	Poor
Additive solubility	Poorest	Moderate	Best
Higher grease yields (use of less soap)	Poorest	Moderate	Best
Viscosity index	Highest	Low	Lowest
Low temperature	Fair	Good	Best
Flash points	Highest	Lower	Lowest
Boiling range	Highest	Lower	Lowest
Evaporation	Low	Moderate	Highest
Carbonization due to oxidation	Normally hard[a]	Soft	Soft
Toxicity	Minimal	Minimal	High
Elastomer seal swell[b]	Minimal	More swell	Most swell

(a) Can be corrected by better compounding.

(b) Oils do affect elastomers or rubber seals. Choice of seals with various greases must be considered. Selection of rubber-grease compatibility is beyond the scope of this article.

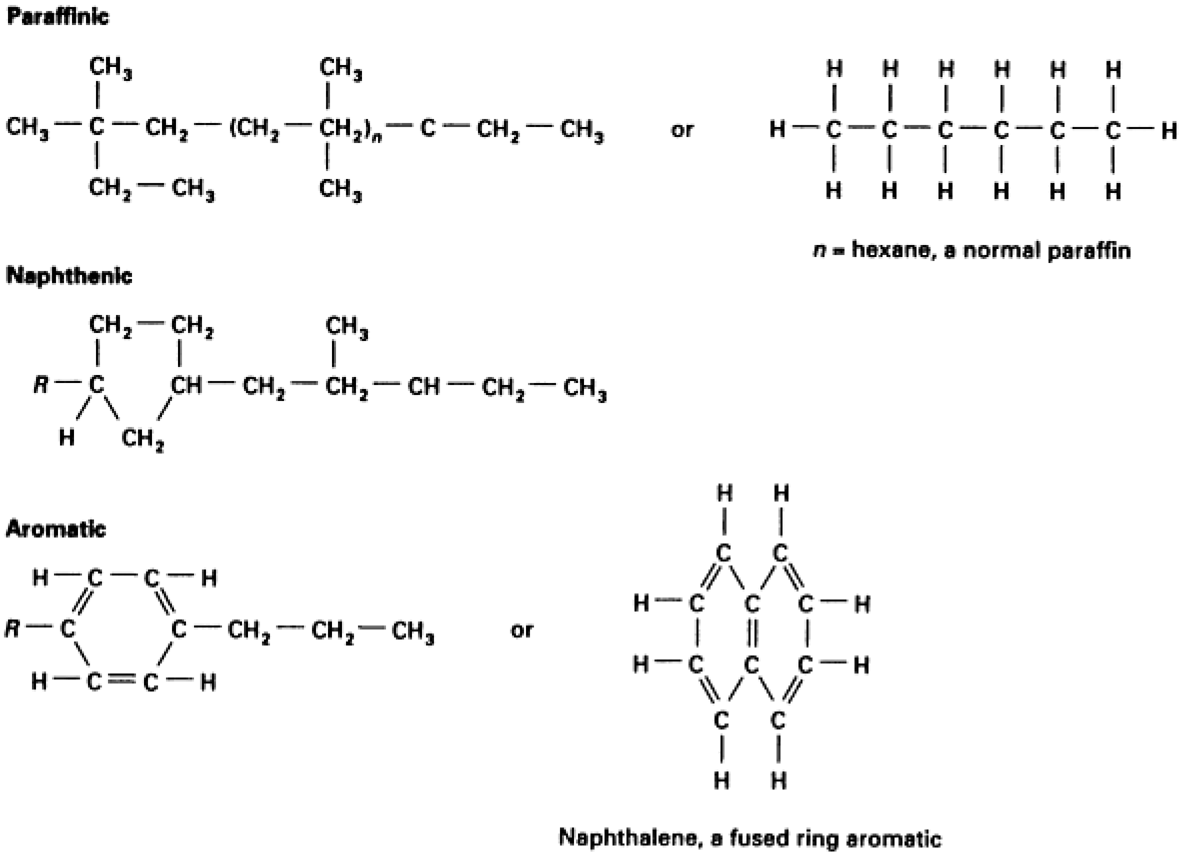

Fig. 3 Chemical structures of three basic types of petroleum: paraffinic, naphthenic, and aromatic

Paraffinic. The distinguishing feature of a paraffin is that the molecule is fully saturated; that is, no unsaturated, olefinic, double bonds exist. The carbons may be arranged in a straight line or branched.

Naphthenic stocks are similar to paraffinics, except that some carbon atoms are joined in saturated or cyclic ring structures.

Aromatic. Carbons in aromatic petroleum stocks are joined in hexagonal geometric structures with alternating double bonds between pairs of carbons. Often, two "aromatic" rings may be fused together. Use of aromatics are falling into disfavor, because of their toxicity. Aromatics can be thin oil (100-second), medium oil (30 weight), or heavy oil (bright stock, 140 weight).

Synthetics. A trend toward the use of synthetic lubricants began during the period from 1920 to 1945. The need arose for various reasons (Ref 6, 7). One reason was the increasing shortages of petroleum supplies in countries such as Germany, France, and Japan. Another reason was the demand for lubricants for new machines that required operability over greater temperature ranges than could be satisfied by petroleum. An early example was the liquid lubricant required for the jet engine. Both low- and high-temperature synthetic greases are used by industry and the military.

The major types of synthetic lubricant base stocks are:

- Esters
- Synthetic hydrocarbon (SHC) or polyalphaolefin (PAO)
- Polyglycols
- Silicones
- Chlorofluorocarbon
- Alkylated benzene
- Phosphate esters
- Polyphenyl ethers

Chemical structures are shown in Fig. 4, whereas Table 2 summarizes temperature ranges and typical uses of synthetic greases.

Table 2 Synthetic greases showing approximate temperature ranges and typical uses

Synthetic base fluid	Approximate temperature range[(a)]	Typical uses
Diesters	-68 to 176 °C (-90 to 350 °F)	Low temperature for aircraft and land-based vehicles (mostly military) and freezers. Also high temperatures
Polyolesters	-59 to 232 °C (-75 to 450 °F)	Low temperature for aircraft and land-based vehicles (mostly military) and freezers. Also, high temperatures
SHC synthetic hydrocarbon (PAO, polyalpha olefin)	-73 to 149 °C (-100 to 300 °F)	Industrial and automotive use, low temperature, high temperature to 150 °C (300 °F), freezers, can be food grade (USDA-H1)
Polyglycol	-34 to 176 °C (-30 to 350 °F)	Lubrication of rubber or plastic on steel. Resistance to chlorine
Silicones	-73 to 260 °C (-100 to 500 °F)	Lubrication of rubber or plastic on steel. Good temperature extremes. Poor lubricant for steel on steel. High-vacuum grease
Chlorofluorocarbon	-51 to 315 °C (-60 to 600 °F)	Chemically inert to oxygen, chlorine, acids, nonflammable. Good for rubber and plastics
Alkylated benzene	-26 to 176 °C (-15 to 350 °F)	Low-temperature applications. Radiation resistant
Phosphate esters	-26 to 260 °C (-15 to 500 °F)	Fire resistance
Polyphenyl ethers	10 to 315 °C (50 to 600 °F)	Very high vacuum diffusion pumps. High temperatures. Radiation resistant

(a) Temperature range of base fluid, which can be maintained in grease form by proper selection of thickener

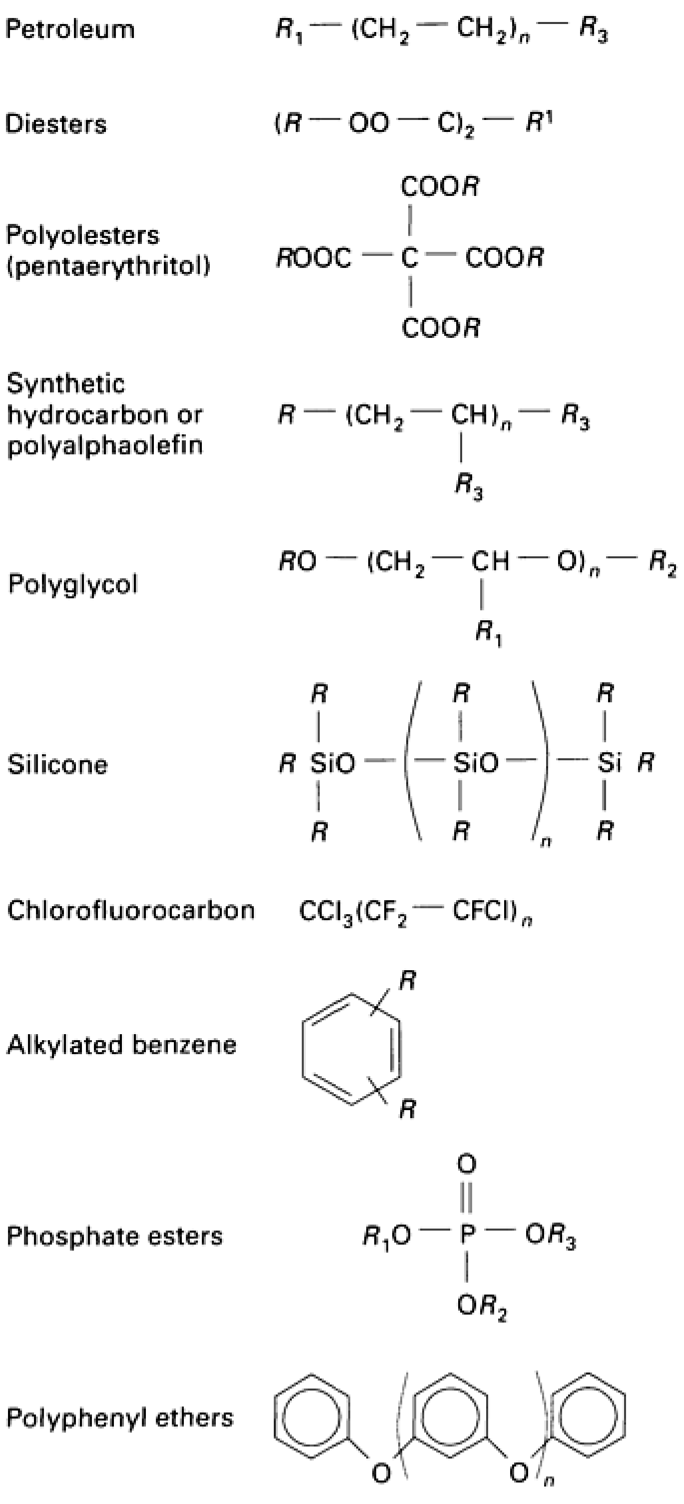

Fig. 4 Chemical structures of synthetic lubricant base stocks versus petroleum

Synthetic lubricants are manmade products that are used when petroleum-based oils can no longer perform. Conditions for use include high temperatures (95 to 315 °C, or 200 to 600 °F) and low temperatures (-40 to -75 °C, or -40 to -100 °F), and when there is a need for longer lubricant life or clean operation with less carbon, sludge, and varnish.

Additives (Ref 8)

The basic additives for making grease are:

- Antioxidants, for longer grease life because of better resistance to oxidation from air at high temperatures
- Anticorrosion agents, to provide resistance to chemical attack on alloy bearings
- Rust inhibitors, to protect against rust formation under wet conditions
- Extreme-pressure agents, for high film strength under shock loads, such as gears reversing direction rapidly, worm gears, or hypoid gears
- Solid additives, such as molybdenum disulfide (moly) and graphite, are *sometimes* used for back-up lubrication in high-temperature applications over 315 °C (600 °F). Solid additives also have some application in greases that need extreme high-pressure properties, such as roll neck bearings in a steel mill. Without adherence to proper greasing cycles, these solids can accumulate in bearings, causing wear. Either heat or too-infrequent greasing can cause oil evaporation or bleed, concentrating thickener and solids
- Polymers or viscosity index improves, which are used to prevent both leakage of grease out of bearings and the entrance of contaminants into the bearing. Polymers improve lubrication properties, control the rate of oil bleed to allow the grease to last longer, and improve water resistance

Types of Grease-Thickener Systems

Lubricating grease is a solid to semifluid mixture of a fluid lubricating oil and a thickening agent. A typical grease consists of 90% oil and 10% thickening agent. Table 3 (Ref 8) shows thickener types, normal percent thickener, melting (dropping) point, and typical uses. The National Lubricating Grease Institute (NLGI) grade is defined in specification IID, grease classifications.

Table 3 Effect of the thickener type on melting point and typical grease use

Total U.S. grease market, %	Thickener type	Thickener for NLGI grade 2, %	Dropping point[(a)]	Typical uses based on properties of thickener[(b)]
50.12	Lithium soap	7.25	188 °C (370 °F)	Most widely used grease; can be pumped in central grease systems
15.28	Lithium complex soap	12	>260 °C (>500 °F)	Multipurpose; high-temperature; central systems
2.97	Sodium soap	12	182 °C (360 °F)	Water soluble grease; low-cost "old" wheel bearing grease; fibrous
4.58	Calcium soap, hydrated	14	88 °C (190 °F)	Low-cost cup and water pump grease
3.99	Calcium soap, anhydrous	7.25	143 °C (290 °F)	Multipurpose; central systems; good water resistance
3.02	Calcium complex soap	16	>260 °C (>500 °F)	Multipurpose; good water resistance; good high temperature; NLGI 0 grade needed to pump in central systems
New	Calcium sulfonate	20	>260 °C (>500 °F)	Heavy-duty high extreme pressure; high temperature
6.07	Aluminum complex soap	6	249 °C (480 °F)	Best water resistance; best chemical resistance
0.88	Other soaps	9-30	Variable	. . .
1.3	Other thickeners, nonsoap, organic, inorganic	9	. . .	. . .
5.03	Polyurea	9	>260 °C (>500 °F)	Multipurpose; central systems; wide temperature range; long life; good low temperature
6.34	Benton (clay)	7	>260 °C (>500 °F)	Multipurpose; excellent high temperature (does not melt)

Source: Ref 8, p 26

(a) Dropping point of grease is that temperature where it melts and becomes liquid.

(b) Consider that base stock selection also has some effect on use. See Table 2 for synthetics. Refer to text on petroleum base stocks.

The manufacture of a grease is still an art. There are a limited number of grease manufacturing plants in the United States and throughout the world. Scientific understanding of grease manufacturing is increasing, but has not replaced the art that is necessary.

The thickening agent can be thought of as a sponge. This sponge is usually soap, which is crystalline or micellular in nature. The oil portion saturates the sponge. Typical chemical structures of soaps are shown in Fig. 5. The simple soaps have a lower dropping point. Complex soaps are larger molecules that allow the grease to have a higher dropping point.

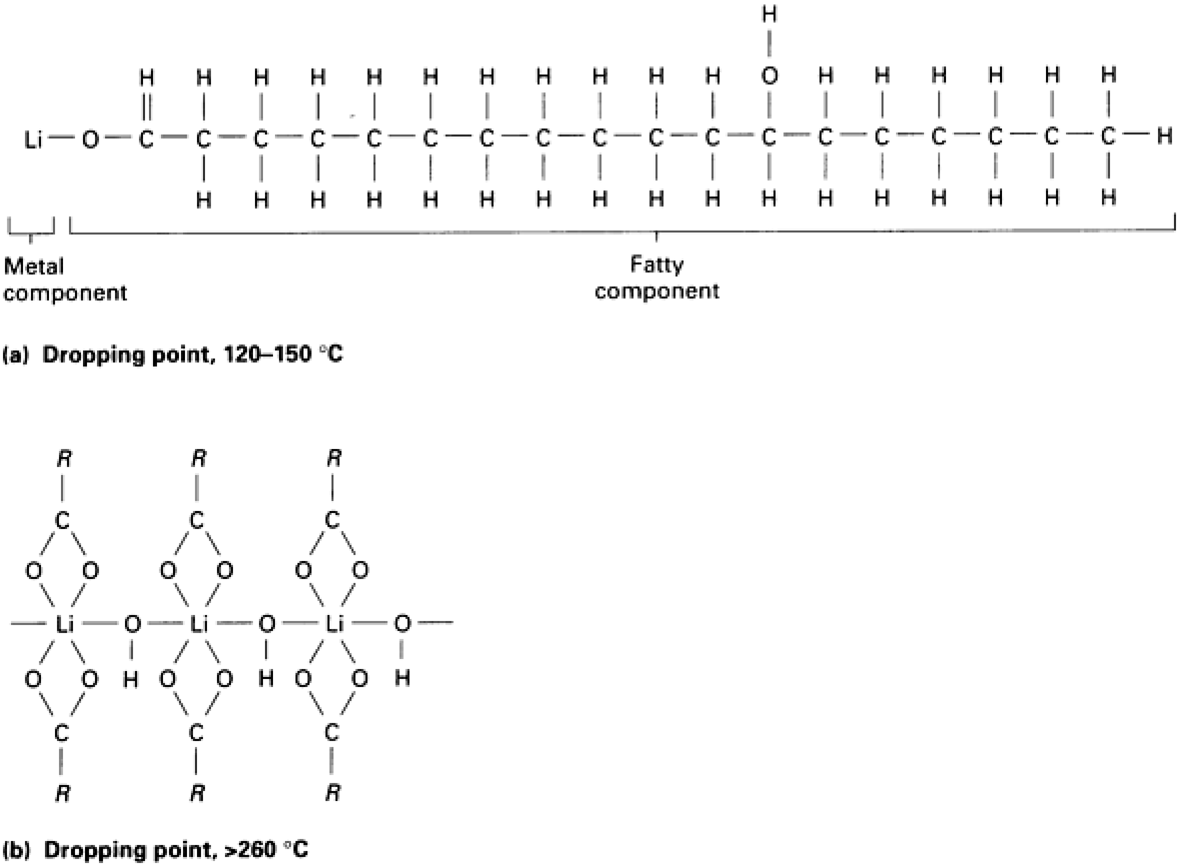

Fig. 5 Typical chemical structures of soap thickeners. (a) Simple soap. (b) Complex soap, proposed structure (lithium 12-hydroxystearate). Source: Ref 3

Table 4 summarizes thickener types and provides reasons for their use. Most thickeners are soaps that have a metal component, which affects grease performance. The fatty component of each soap type is usually 12-hydroxystearic acid.

Table 4 Thickener types and reasons for use

Thickener	Reasons for use
Soaps (metal component)	
Lithium	Most common grease in the world; easy to manufacture; easy to store; good pumpability; resistance to dust and coal; its flowability allows contaminants to flow out
Calcium	Requires less regreasing; good water resistance; the soap itself aids lubrication
Aluminum	Highest resistance to water, chemicals, acids, bases
Barium	High water resistance; somewhat toxic
Sodium	Fibrous; water soluble
Inorganics, clays, silica	No dropping point; does not melt
Polyurea (organic)	High water resistance; pumpable, long life, good at low temperature

Grease Classifications

The NLGI has classified the consistency of greases on the basis of ASTM D 217, Cone Penetration Test (refer to NLGI specification IIE, grease testing). Penetration is the consistency, or hardness, of a grease measured by the distance that a standard cone will penetrate the surface after a free fall at a standard temperature. Table 5 identifies NLGI grades and penetration measurements.

Table 5 NLGI grease classifications and consistency grades

NLGI grade	ASTM penetration at 25 °C (77 °F), 10^{-1}mm	Consistency
000	445-475	Semifluid
00	400-430	Semifluid
0	355-385	Semifluid
1	310-340	Soft
2	265-295	Common grease
3	200-250	Semihard
4	175-205	Semihard
5	130-160	Semihard
6	85-115	Hard

Common grease is NLGI grade 2. It is normally sold in cartridges for ordinary grease guns.

Thin greases, which are less than NLGI grade 2, pump more easily in central lubricating systems and generally allow operation at lower temperatures. They are sometimes used in cases of high (above 5000) rev/min.

Heavier greases, which are greater than NLGI grade 2, have limited use. A classic use of grade 6 block grease is in a feed box for journal bearings in old paper mills. Block, or sock, greases were once used for railroad journal wheel bearings. The new American Association of Railroads specification 942-88 has switched to large, tapered roller bearings for railroad cars, for which NLGI grade $1\frac{1}{2}$ nonextreme-pressure grease is used. Locomotives use the extreme-pressure version.

Heavy greases are sometimes used for high-speed bearings above 5000 rev/min. The high-speed theory is that the heavy grease channels allow the bearing to rotate at a high rev/min rate, but a trace amount of grease contacts the bearing, keeping it lubricated.

Grease Testing

The most frequently used grease laboratory testing procedures are those of ASTM (Ref 9, 10), which are summarized in Table 6.

Table 6 Summary of grease laboratory tests

Test name	ASTM No.	Test description	Results
Penetration	D 217	Consistency or hardness of a grease	Range from semifluid to brick-hard grease
Shear stability	D 217A	Ability of grease to withstand repeated working with minimum change in consistency	Results after 10,000 strokes: 5% excellent; 5-15%, good; 15-30%, fair; >30%, poor
Dropping point	D 566	Temperature at which grease melts or turns liquid	Typical drop points: simple soaps, 120-175 °C (250-350 °F); complex soaps, 205-290 °C (400-550 °F); nonsoap, no melting point
Shell roller test	D 1831	Simulates conditions of roller bearing greases	Penetration change after 4 h of rolling: 0-10% excellent; 10-25%, good; 25-60%, fair; >60%, poor
Bleeding and evaporation	U.S. Steel	Measures oil bleed of greases in storage	Held at 100 °C (212 °F) for 50 h
Wheel bearing test	D 1263	Measures leakage and varnish deposits	Held at 113 °C (235 °F) for 6 h; target is zero

			loss and no varnish
Extreme pressure (Timken)	D 2509	To determine maximum load the bearing or gear will carry	Greater than 155-180 N (35-40 lbf) "OK load" is usually considered an extreme-pressure grease
Cloud and pour points of base stock	D 97	"Cloud" temperature at which solids begin to crystallize; "pour," temperature when there is no movement for 5 s	Low-temperature performance

Applications

This section describes the parameters that should be considered when selecting a grease, and discusses the incompatibility of greases.

Grease Selection

Although the applications described in this article are industrial in nature, the same rules apply when selecting grease for automotive service. Interested readers are referred to ASTM D 4950, "Classification of and Specifications for Automotive Service Greases." Consideration of the parameters described below is necessary for engineers or maintenance personnel who must select the best grease for a particular job.

Bearing Temperature. The grease dropping point should be about 27 °C (50 °F) above the bearing temperature so that the grease does not liquify. The evaporation rate of the base stock at various high temperatures can be used as a parameter for choosing a grease. If the evaporation rate is high, then the grease may be unsuitable or may require many applications.

A laboratory test for evaporation is ASTM D 2595, "Evaporation Loss of Grease," which measures evaporation loss of lubricating greases at temperatures between 95 and 315 °C (200 and 600 °F). Evaporation should be low (5 to 10%, maximum) at the use temperature. The higher the evaporation loss, the more frequently grease will need to be replaced. Evaporation that is too fast will cause grease hardening because of lack of oil and increased concentration of thickener.

Low Temperature. As an indicator for low-temperature applications, the pour point of the grease base stock is used as the minimum temperature at which the grease will not be frozen. Thinner greases, such as NLGI grades 0 or 00, pump more easily at low temperatures than does a normal NLGI grade 2 grease.

Several low-temperature grease tests are available to help define low-temperature grease behavior:

- U.S. Steel, grease mobility testing, usually run at -18 °C (0 °F)
- ASTM D 4693 (1987), "Low Temperature Torque of Grease Lubricated Wheel Bearings"
- ASTM D 1478, "Low Temperature Torque of Ball Bearing Greases," which was developed specifically for greases with low torque at -54 °C (-65 °F) for aerospace activities
- ASTM D 1092, "Apparent Viscosity of Lubricating Greases," in which viscosity is measured from -54 to 38 °C (-65 to 100 °F)

Speed. Using conventional greases, the speed (rev/min) of a bearing or gear is usually not a problem. Most greases can easily handle 3500 rev/min. The normal speed of electric motors is 1750 rev/min. Normal industrial equipment runs at less than 1750 rev/min. Some large grease manufacturing companies (Ref 11) use ASTM D 3336 to test their greases on lab equipment that operates as high as 10,000 rev/min. At these higher speeds, most greases still perform, but the equipment can get noisy.

The choice of grease can also be aided by using a DN value. This value, also called the speed factor, is the product obtained by multiplying the diameter of a bearing by the number of rev/min, that is, DN = diameter (in mm) × N (rev/min). The shaft diameter should be used for journal (sleeve) bearings, and the pitch diameter, for antifriction bearings. For a diameter given in inches, multiplying by 25.4 will yield mm. Table 7 identifies grease selection bases on DN values.

Table 7 Selection of NLGI grade grease at various *DN* values

For *DN* values of:	NLGI grade No.
0-50,000	3
50,000-125,000	2
125,000-250,000	1
250,000-350,000	0

Note: This general *DN* guide holds for multipurpose greases whose oil viscosity is below 250 mm^2/s at 40 °C (1200 Saybolt universal seconds at 100 °F.) Lower *DN* values may have to be used with greases having either tacky properties or higher oil viscosities.

Pressure. Although most industrial equipment does not require extreme-pressure greases, it is advisable to use greases that contain these additives. They will protect the bearings or gears when either extreme-pressure or shock-loading conditions arise.

Standard laboratory tests that are used to measure extreme-pressure greases are:

- ASTM D 2509, "Standard Method for Measurement of Extreme-Pressure Properties of Lubricating Grease (Timken Method)," where the minimum load for extreme-pressure greases should be 178 to 223 N (40 to 50 lbf)
- ASTM D 2596, "Standard Method for Extreme-Pressure Properties of Lubricating Grease (Four-Ball Method)," where the minimum weld point for extreme-pressure greases should be about 1.96 kN (200 kgf)

The weld point, under the conditions of the test described above, is the lowest applied load in kgf at which the one rotating ball seizes and then welds to the three stationary balls, which indicates that the extreme-pressure level of the grease has been exceeded.

Viscosity, Speed, and Pressure (Ref 12). The relationship of these parameters is of interest as a point of reference. The base oil viscosity of a grease is the primary determining factor in its ability to provide a proper lubrication film. The relationship that exists for the oil portion of the grease is: coefficient of friction = ZN/P, where Z is the viscosity of the oil, N is the speed in rev/min, and P is the pressure. To understand this formula, consider that most high-speed operations are associated with low-viscosity oil and light loads, and that most low-speed operations are associated with high-viscosity oil and heavy loads.

Viscosity as Function of Bearing Diameter and Speed. A method for choosing the minimum viscosity base oil required in a grease to adequately lubricate the bearing at the operating temperature has been devised (Fig. 6 and 7).

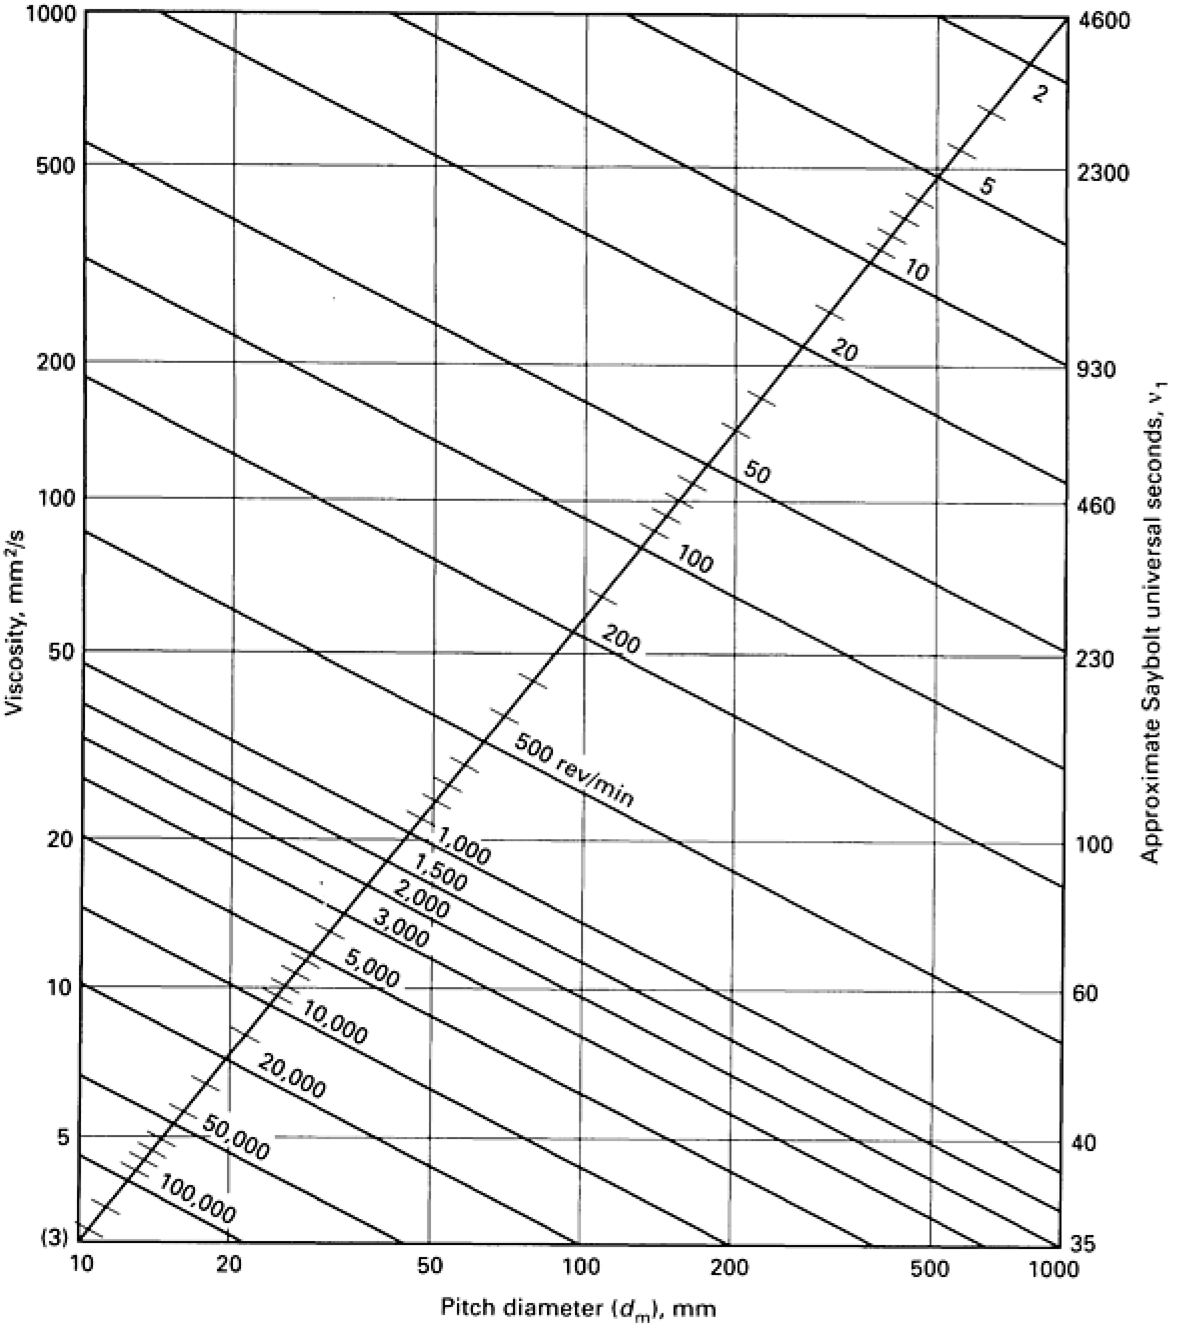

Fig. 6 Minimum required lubricant viscosity as function of pitch diameter and speed. d_m = (bearing bore + OD) ÷ 2; v_1 = required lubricant viscosity for adequate lubrication at operating temperature

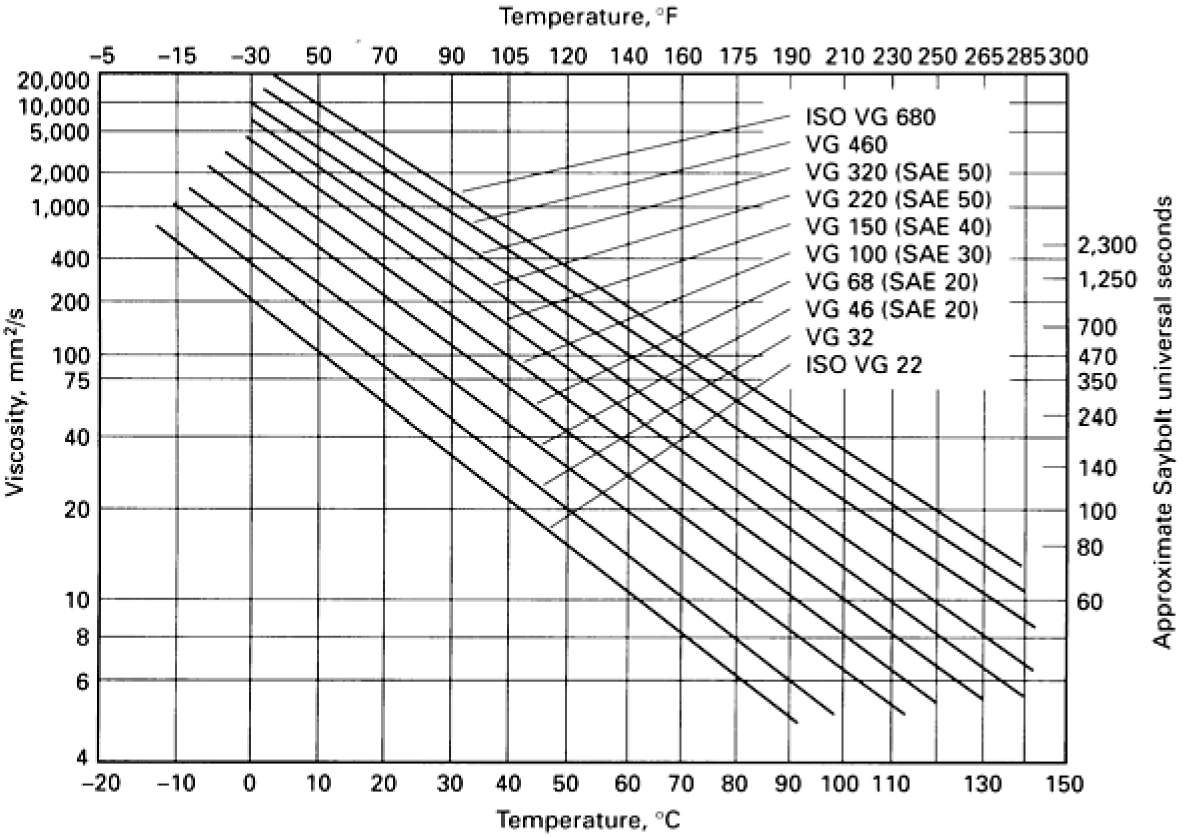

Fig. 7 Viscosity-temperature chart. Viscosity classification numbers per ISO 3448-1975 for oils having viscosity index of 95; approximate equivalent SAE viscosity grades shown in parentheses

Conditions, Environment, and Contamination. Most industrial greases are not subjected to unusual environmental conditions, because they are used inside plants with clean, controlled conditions. Grease selection can thus be made with more freedom, based on other parameters. However, Table 8 identifies unusual or extreme environmental conditions and chemicals, and recommends the use of specific greases. The requirements associated with hot and cold temperatures were discussed in the sections "Bearing Temperature" and "Low Temperature" in this article.

Table 8 Grease selection under adverse conditions

Unusual condition	Suggested grease
Water, rolling oil, cutting fluid	Aluminum-complex grease should be used where large quantities of water run over the bearing or gear; calcium-complex grease is effective for more incidental water contact
Coal dust, paper particles, dust, foundry atmosphere	Lithium-complex grease or grease with good flow characteristics and low-viscosity base stock to allow dust to work out; NLGI grades 1 or 2
Presence of acids, bases	Calcium sulfonate [over-based[a]] is particularly good in the presence of acids; petrolatum (vaseline); aluminum complex
Harsh chemicals, such as chlorine and oxygen	Grease made from chlorofluorocarbon base stock. *Caution: Do not use grease made from petroleum, because it will burn*
Rubber on steel lubrication	Greases from polyglycol or silicone base stock

(a) Overbased sulfonate detergents were used in the early 1950s in automotive engine oils. It was found that fully oil soluble sulfonates could be prepared using 3 to 15 times as much metal, calcium in this case, as the normal sulfonates. Highly based sulfonates were found to possess a great capacity to neutralize acidic contaminants.

Pumpability is an important property because grease must reach the bearing or gear that needs lubrication. Because grease guns develop extremely high pressures, they can pump almost any grease directly into a bearing. Small-diameter lines between the grease gun and a bearing can be a problem. The grease must be carefully selected when small lines and

centralized grease systems are used. Three tests (Table 9) can aid in this selection. Factors involved in the pumpability of grease are described below.

Table 9 Tests to evaluate grease pumpability in central systems and small grease lines

Test	Description
Apparent viscosity of lubricating grease, ASTM D 1092	Greases are nonNewtonian in nature and may be said to have an "apparent viscosity" (not the true viscosity). The apparent viscosity holds only for the shear rate (and temperature) at which the viscosity is determined. The test involves forcing the grease through a capillary with a piston
Lincoln ventmeter	Apparatus consists of a 7.5 m (25 ft) coil of $\frac{1}{4}$ in. copper tubing. Grease is pumped into the coil and pressurized at 12.4 MPa (1.8 ksi). The grease is released and the pressure measured at the end of 30 s. The test can predict grease line diameter and length
Trabon or Lubriquip Houdaille grease test	Lubriquip runs a grease in its commercial central lubricating systems and selects the appropriate system to pump grease

Fluid Viscosity. Greases made with high-viscosity base stocks are harder to pump than those made with thin base stocks.

Temperature. Warm greases pump easier. Low temperature has been discussed previously.

Thickener type was described in Tables 3 and 4. The classical central lubricating greases are lithium thickened. Although greases that use other thickeners can be pumped in central systems, grease composition may have to be adjusted by using either thinner base stocks or less thickener.

Amount of thickener. Grease with an NLGI grade 0 rating can be pumped easier than an NLGI grade 2 grease of the same type. In any family of greases, the NLGI grade is dependent on the amount of thickener.

A centralized grease system, described below in "Dispensing Methods," is the best method for supplying grease to a large number of bearings on a machine. A bearing constantly uses grease in small quantities, and a central system can supply small quantities as often as desired. A centralized grease system is also designed for operation within a definite pressure range. Exceeding this pressure can cause the separation of thickener and base stocks, which then plug the system. Therefore, grease pumpability is crucial.

Seals are important to the grease system because they keep the grease in and contaminants out. Parameters that need to be considered are described below.

Composition. Normal seals used in industry include Buna-N, neoprene, viton, and silicone rubbers.

Compatibility of the seal with the grease being used is important. The rubber can be tested for changes in volume, appearance, cracking, Durometer hardness, elongation, and tensile strength. Test methods include ASTM D 4289, "Compatibility of Lubricating Grease with Elastomers," established in 1983, and the older federal test methods (FTM) 791e, 3603.4, and 3604.1, run at temperatures from 70 to 205 °C (158 to 400 °F).

Temperature. It is important to determine the maximum and minimum temperatures that the seal will encounter, and to select the seal accordingly.

Paints. If paints are encountered either inside or outside the grease system, they should be tested for compatibility with the grease. Because there are so many paints and surface coatings, it would be most expedient to contact the paint company for general guidelines and/or tests.

Incompatibility of Greases

The compatibility of greases is largely controlled by the thickener type (Table 10). If the thickeners of two greases are the same, then they will probably be compatible. Greases made from different thickeners are generally incompatible, because of the chemical reaction between the thickeners. Compatibility problems arise primarily when grease is supplied through a gun into a zerk fitting, and then into the bearing. To avoid problems, the grease gun should be slowly pumped until the grease being exhausted from the bearing is the same color as the grease being pumped. This purging procedure normally

replaces about 90% of the old grease. If only about 50% of the grease is replaced, then the grease mix usually liquifies and runs out of the bearing in 5 or 10 min. Grease compatibility problems do not seem to arise if dissimilar greases are fed to bearings through central systems. The exact reason is not known.

Table 10 Grease incompatibilities

	Aluminum complex	Barium	Calcium	Calcium 12-hydroxystearate	Calcium complex	Clay	Lithium	Lithium 12-hydroxystearate	Lithium complex	Polyurea
Aluminum complex	. . .	I	I	C	I	I	I	I	C	I
Barium	I	. . .	I	C	I	I	I	I	I	I
Calcium	I	I	. . .	C	I	C	C	B	C	I

Practices

The practices described in this section include the methods and frequency of grease application, as well as the problems associated with either overgreasing or undergreasing. The storage and handling of greases are also discussed.

Dispensing Methods (Ref 10)

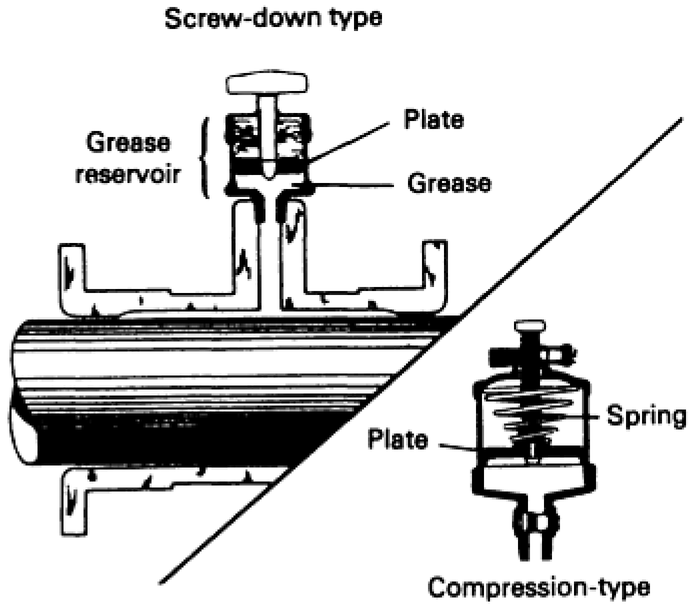
There are basically three methods of applying grease: by hand; by hand- or air-operated mechanical devices, which deliver grease to one point of use at a time; and by centralized grease systems, which supply a number of points of use from one central reservoir.

Hand application involves the direct application of grease to the part. This method is frequently used during the assembly of a machine. Grease is spread over bearings and gears to protect them from rust and to ensure lubrication when the machine is started for the first time. Balls and roller bearings require that grease be worked by the fingers into the spaces between the balls or rollers, in addition to requiring an overall coating. However, dirt is a predominating threat in hand greasing.

Another hand method involves pouring melted grease from a suitable container onto gears or open guide bearings. In any hand method, care should be taken not to apply too much grease, because the excess is squeezed out and wasted.

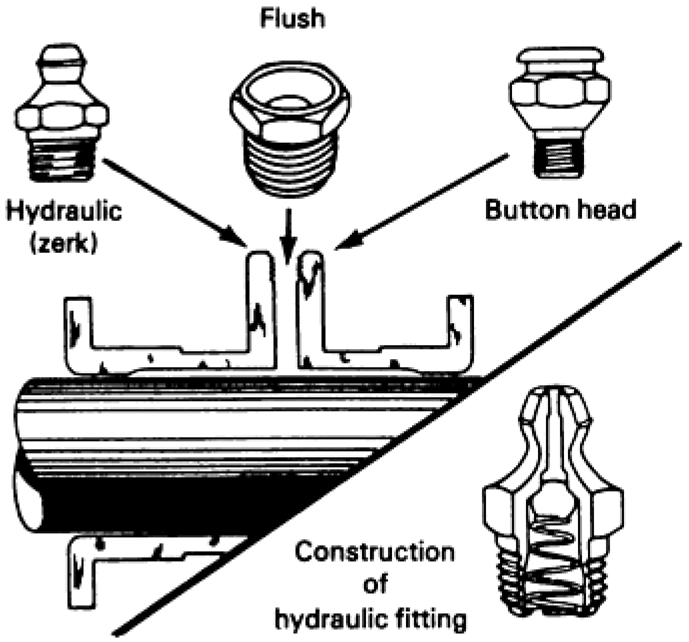
Hand- or air-operated mechanical devices deliver grease to one point of use at a time. A variety of devices are described below.

Grease cups are used to apply grease to bearings. The ordinary screw-down type consists of a small reservoir for holding the grease and a plate that screws down into the reservoir, exerting pressure on the grease and forcing it into the bearing. It is filled by unscrewing the plate, filling the reservoir with grease, and replacing the plate.



The compression type of cup has a spring-loaded plate, which maintains pressure on the grease and forces it slowly into the bearing. Compression types with a spring are now available with a zerk grease fitting for refilling.

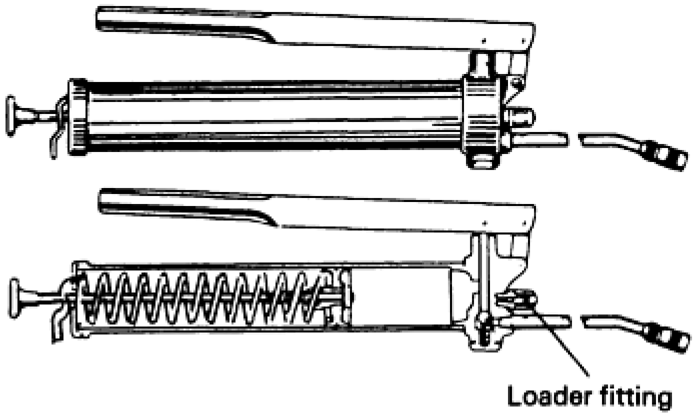
Grease fittings, which make possible the use of pressure grease guns, have replaced grease cups on most steel-mill equipment, because they reduce the time needed for greasing. Of the several types available, the hydraulic fitting is most frequently used on smaller and lighter machinery. A "flush" fitting is used when clearance or other design considerations warrant it. Although it is not actually flush, it extends very little above the surface of the bearing housing. Button-head fittings are used on heavier mill equipment, where severe conditions prevail and large volumes of grease must be forced through the fitting.



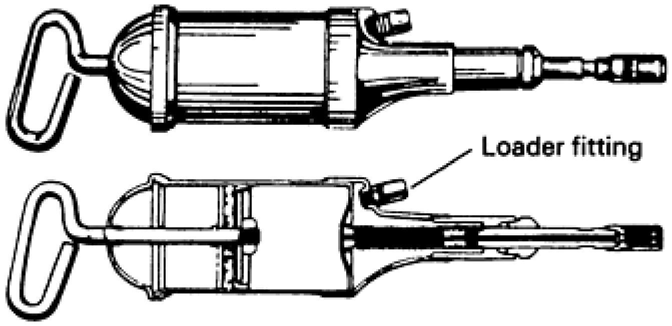
The inner construction of all hydraulic fittings includes a spring holding a steel ball against the grease-entrance hole. Grease that enters under pressure forces the ball back against the spring, but, when the pressure is stopped, the spring forces the ball back into place, effectively sealing the hole against the escape of grease or entrance of dirt.

Grease fittings must be wiped clean with a cloth (not waste, which shreds) before applying a grease gun. Otherwise, dirt might be forced into the fitting and carried onto the bearing. If a fitting is damaged or will not take grease when pressure is applied, it must be replaced.

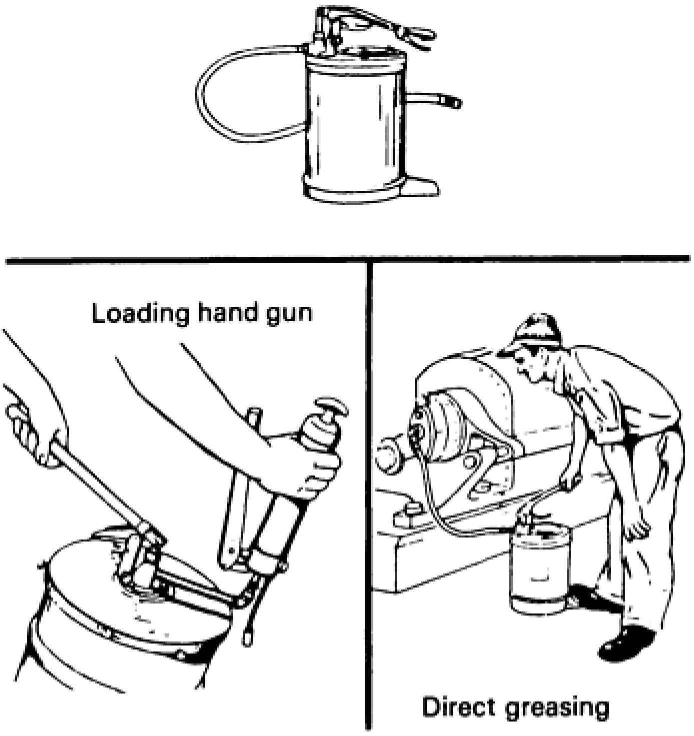
Grease Guns. Two types of hand-operated grease guns that hold from 0.5 to 1.5 kg (1 to 3 lb) of grease are commonly used. The lever gun is used primarily to grease large pieces of machinery where a large volume of grease is needed and pressure up to 70 MPa (10 ksi) is desirable. The gun is filled through the loader fitting at the front. Grease is then forced into the fitting by pumping the lever. As the grease is ejected, the spring pushes the plate forward, which keeps the remaining grease packed and in position for use.



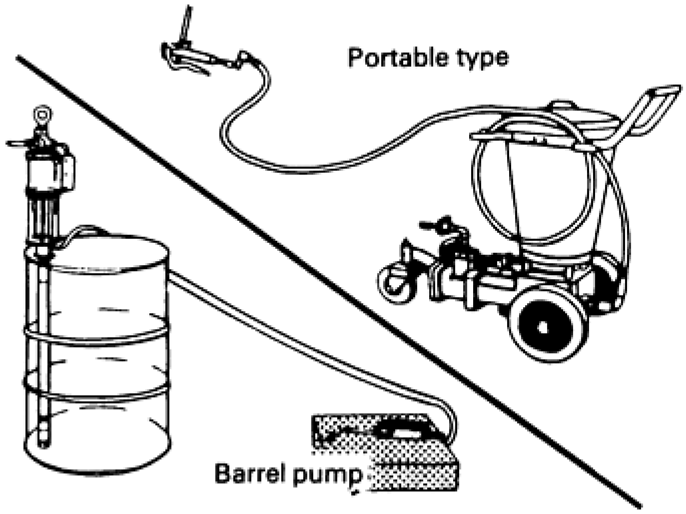
The push gun is generally used for delivering smaller quantities of grease at lower pressures to electric motor bearings and smaller machinery in the steel plant. It is filled through a loader fitting in the front. To force grease into the bearing, the nozzle is placed against the grease fitting and the handle is pushed, causing a pumping unit in the front of the gun to force grease into the bearing.



A bucket pump, which can hold about 16 kg (35 lb) of grease, is used when a greater grease-holding capacity is desired. It can be used to either fill hand guns through loader fittings or to pump grease directly into bearings through grease fittings. The bucket pump is placed on the floor and the handle is worked to deliver grease through a hose to the bearing. The bearing is usually equipped with a buttonhead fitting if it is to be lubricated with a bucket pump. The figure below illustrates a grease gun being filled by a portable loaded pump placed in a drum of grease.



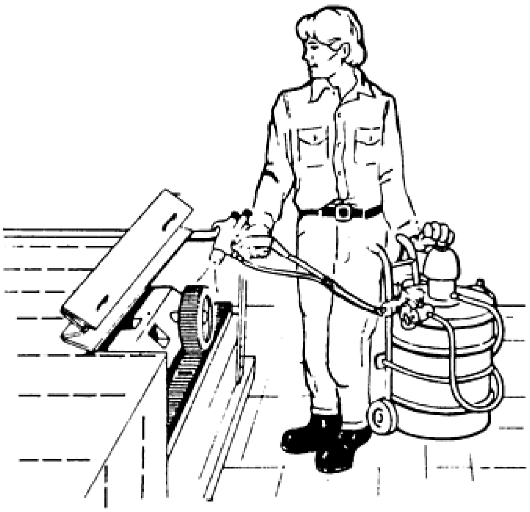
Air-operated grease pumps can be used to advantage when large numbers of bearings require a considerable volume of grease. A typical air-operated grease pump has an 18 kg (40 lb) grease reservoir mounted on wheels. Before the pump can be operated, it must be connected by hose to a compressed-air supply. Grease is delivered through a hose and hand-control valve to the bearings being lubricated.



Another type of power pump is the air-operated barrel pump, which is inserted directly into a grease drum. Barrel pumps can be used to pump grease directly to bearings, portable grease pumps and buckets, or through centralized grease systems.

It should be mentioned at this point that mobile-power grease guns, operated by electricity, are convenient to use at points beyond the range of the plant compressed-air lines.

Spray guns represent another grease application method. The guns, which are similar to those that deliver paint, use compressed air to spray gear teeth with a film of grease sufficient for lubrication. Grease is delivered to the spray gun through a hose from an air-operated barrel pump inserted in the grease drum. This method is not as wasteful as hand application, which tends to apply an excess of grease that is eventually squeezed out and lost.



Centralized grease systems supply a number of points of use from one central reservoir. If properly serviced and maintained, this system is the best method for supplying grease to a large number of bearings on a machine. Such a system consists of a centrally located grease reservoir with a pump and permanently installed piping with grease distribution valves, through which grease is conveyed from the reservoir to the various bearings. When the pump is operated, each bearing receives a definite quantity of grease, thereby eliminating the need to grease each bearing individually by hand. The pump can be operated by hand, by compressed air, or by an electric motor. If it is air or motor operated, the system can be equipped with a timer, which automatically starts and stops the pump at predetermined intervals.

Frequency (Ref 14)

The period during which a grease-lubricated bearing will function satisfactorily without relubrication is dependent on the bearing type, size, speed, operating temperature, and the grease used. The relubrication intervals (hours of operation) obtained from Fig. 8 are valid for bearings in stationary machines where loading conditions are normal. The diagram is based on the use of an age-resistant, average-quality grease and is only valid for bearing operating temperatures up to 70 °C (158 °F), measured at the outer ring. The intervals should be halved for every 15 °C (27 °F) increase in temperature above 70 °C (158 °F), but the maximum permissible operating temperature for the grease must not be exceeded. However, it should be noted that relubrication intervals can vary significantly even where apparently similar greases are used.

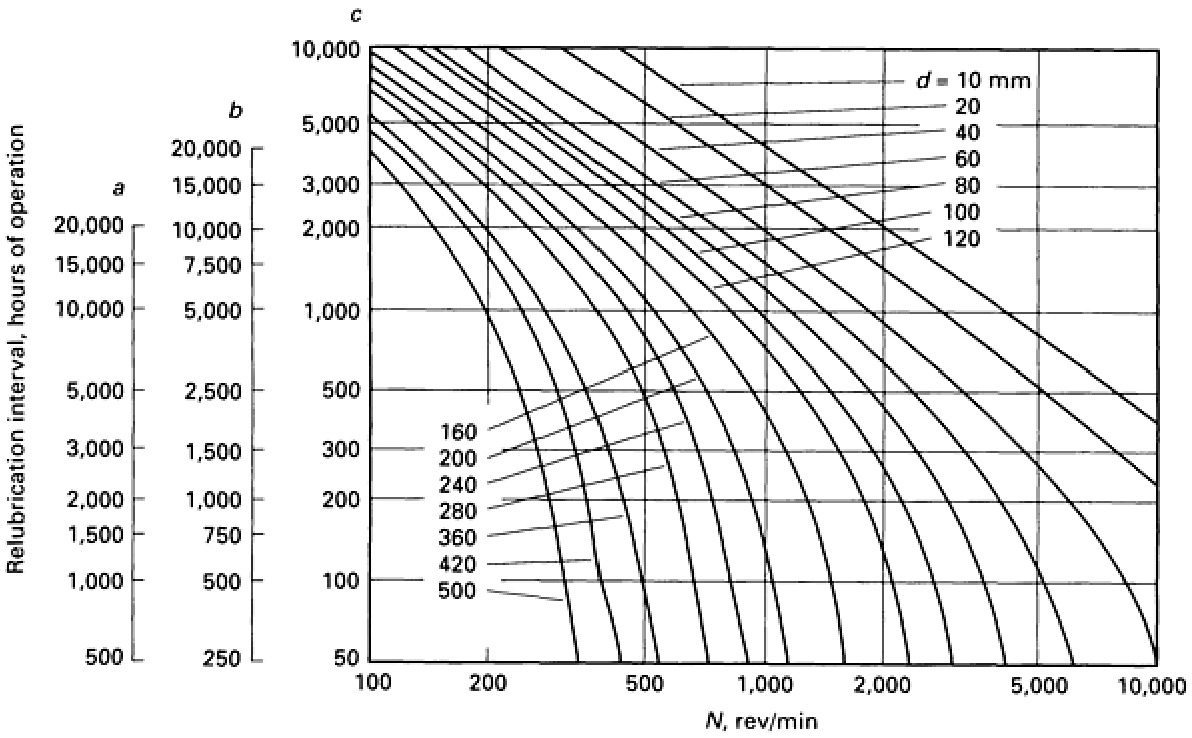


Fig. 8 Grease relubrication intervals. *a,* radial ball bearings; *b,* cylindrical or needle roller bearings; *c,* spherical or taper roller bearings and thrust ball bearings; *d,* bearing bore diameter. Courtesy of SKF-USA, Inc.

For small bearings, particularly deep-groove ball bearings, the relubrication interval is often longer than the life of the bearing application and relubrication is not normally required. Ball bearings fitted with shields or seals that are "lubricated for life" are a viable alternative in such cases.

Where there is a definite risk of the grease becoming contaminated, the relubrication intervals should be reduced. This reduction also applies to applications where the grease is required to seal against moisture. For example, bearings in paper-making machines (where water runs over the bearing housings) should be relubricated once a week.

Overgreasing/Undergreasing

Overgreasing is one of the biggest reasons for bearing failures. Undergreasing is rare. Heat is the principal enemy of a bearing, and overgreasing causes the bearings to run at higher temperatures, sometimes to the point of smoking. The reason for the high temperature is the inability of the balls or rollers to move if packed full with grease. Normally, a bearing should be from one-quarter to one-third full. The bearing manufacturer can advise on the proper amount of grease to lubricate a specific bearing. This amount of grease can be translated into so many shots of grease from a grease gun or other grease application method. In critical bearing areas, a grease-quantity apparatus can be purchased.

Storage and Handling

Storage and handling of grease is important from the standpoints of product quality assurance, housekeeping, safety, and cost. Multipurpose greases should be considered wherever possible to reduce the number of greases in inventory. A multipurpose grease should have properties such as wide operating use temperature, extreme-pressure resistance, shock-loading resistance, pumpability, and resistance to any contaminants it may encounter.

Storage in bulk containers is desirable if justified by the usage rate. Reusable bulk containers are available, eliminating the need for handling drums and drum disposal. Disposable bulk containers are also gaining popularity. Portable bulk tanks can be placed either close to the area requiring lubrication or in a central storage area. If the latter is desired, it should be neat, clean, well organized, and, preferably, inside at either room or ambient temperature.

If outside storage in drums or other containers is essential, the drums are best stored on their sides under a roof, because most grease drums have bung holes on the lid or top. Any water that stands on top of the bungs is likely to get sucked into the drum, no matter how tight the drum is sealed or capped.

Lubricants for Rolling-Element Bearings

John Rumierz, SKF USA, Inc.

Introduction

PROPER LUBRICATION of ball and roller bearings is essential to their successful performance. Guidelines for the lubrication of rolling-element bearings differ markedly from the practices established for plain or sleeve-type bearings. The science behind their lubrication is fundamental for the correct design of bearing installations and for the institution of maintenance procedures necessary to meet full service lifetimes.

Lubricants perform several functions in their role to prevent premature failure of rolling element bearings. These functions include:

- Lubrication of the sliding contact between the retainer and other bearing components
- Elastohydrodynamic lubrication of all true rolling contacts
- Lubrication in that part of the contact between the raceways and the rolling elements not represented by true rolling

Other functions of the lubricant, especially under harsh environmental conditions, are also significant. It is often required to minimize functional power losses in a bearing, and it must protect the internal surfaces of the bearing from chemical attack and corrosion. Internally, a flushing function is important, serving to remove wear debris from the rolling contact path; externally, a sealing function is significant, preventing extraneous dirt from entering the roller contact paths. The

lubricant has a strong influence on frictional noise level performance and can provide a damping medium for vibration. It will effect the thermal dynamics of a bearing, acting as a heat transfer medium to cool the bearing and to redistribute the internal heat in order to minimize differential thermal expansions.

Obviously, no specific product or class of lubricating products can meet the wide variety of rolling bearing application requirements. Operating conditions that range from cryogenic to ultrahigh temperature, or from partial rotation to very high speeds, and involve a variety of hostile chemical environments all must be accommodated. A compromise is often necessary between performance levels and cost considerations. The latter involves not only initial lubricant costs and application system expense, but also the effect of bearing lifetime and replacement on the cost of the entire mechanical system.

Liquid Lubricants

Liquid lubricants for rolling bearing applications are usually refined mineral oils. However, the wide variation in petroleum-base stocks, with respect to molecular species and refining techniques, gives rise to oils of differing physical and chemical properties. Essentially all oils are additive-enhanced for both viscosity retention and performance improvement.

Synthetic hydrocarbon fluids (SHC) are manufactured from petroleum-base stocks. These products are synthesized with specifically chosen molecular compounds to provide favorable physical properties for lubrication. Because of their chemical similarity, SHC fluids are miscible and compatible with refined mineral oils.

Other synthetic fluids are manufactured from nonpetroleum-base chemicals. Included in this class are dibasic acid esters, phosphate esters, silicones, silicate esters, and fluorinated polyalkylethers, none of which are compatible with petroleum-base lubricants.

The advantages of fluid lubrication, versus other types of lubrication, are:

- In applications with high contamination levels, fluids are easier to remove and refill
- Lubricant quantity is more easily and accurately controlled, depending on the application
- Fluids may be more suitable for lubricating the multicomponent system
- When used with a cooler, a circulating fluid system permits the lubrication of bearings at temperatures well beyond the oxidative capacity of the bulk fluid

Fluid Lubrication for Rolling Bearings

For most applications that do not involve operating conditions of extremely high temperatures, good-quality refined mineral oils are satisfactory. Under extreme operating conditions, one of the synthetic fluids may be preferred. In either case, the lubricant must be free of contamination that can cause wear or corrosion in the bearing. Furthermore, the fluid should resist evaporation, oxidation, and viscosity change under the conditions of operation.

Internal heat generation, friction torque, and, eventually, bearing lifetime are all affected by two main factors. One is dependent on the bearing design and loading particulars and the other is a function of lubricant quantity, viscosity, and the bearing speed. Only enough lubricant is required to permit formation of a thin film between contacting surfaces. Both too much lubricant and too high a fluid viscosity will adversely affect friction and torque.

Heat generation in a bearing is dependent on torque and speed. Lubricant temperature rise will always result in decreased fluid viscosity and a decrease in frictional torque. The overall heat balance of the bearing and surrounding structure will determine the steady-state condition.

No one lubricant is suitable for all bearing applications. When operation calls for a wide temperature range, a fluid with a high viscosity index, that is, the least change in viscosity versus temperature, should be chosen. Applications with very low starting temperatures require fluids with a sufficiently low pour point for free bearing rotation upon low-temperature start-up. The bearing manufacturer should be contacted for specific recommendations when unusual conditions exist.

Methods. Proper enclosures and supply systems must be provided to contain fluid lubricants and thereby prevent leakage and deterioration of fluid and the bearing. Several of the most widely used containment systems are described below.

Oil bath or sump lubrication provides a minimum amount of fluid in constant contact with the bearing, as shown in Fig. 1. This configuration is useful in vertical, horizontal, and inclined axis applications. In the static condition, the lubricant level just reaches the center of the lowest rolling element. Higher levels will result in churning losses, which can cause fluid oxidation and early failure. Too low a lubricant level leads to windage, lubricant starvation, and early failure. A gage must be provided to maintain the proper fluid level.

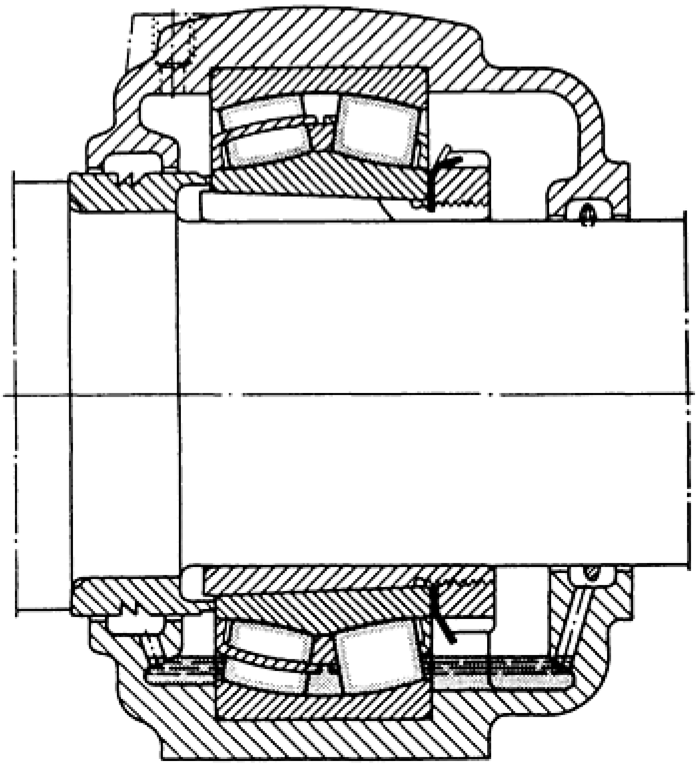

Fig. 1 Oil bath method of bearing lubrication

Oil bath systems are widely employed in hot applications where grease purging cannot be tolerated. Fluid circulation provides better heat dissipation and cooler running temperatures. This aspect is important under conditions of heavy load, where contact friction losses dominate viscous churning losses. The use of a heat pipe or cooling coils with an oil bath system can greatly extend the application temperature of the fluid.

Shaft motion can be used to drive a viscous pump for fluid supply, reducing the sensitivity of the system to the fluid level. A disk drags oil from the sump up a housing groove to a scraper blade that deflects the oil to a drilled passage leading to the bearing. A limitation of sump systems is the lack of effective filtration. Such systems are only suitable for inherently clean-running applications.

Circulating Fluid Systems. Operation at higher speeds will cause the temperature to increase and will accelerate oxidation of the lubricant. In such situations, a circulating system provides significant advantages over static systems. Pumping a fluid lubricant through the bearing into a reservoir increases the amount of heat dissipation. A pressure feed arrangement allows the use of heat exchangers to either remove or add heat as the operating conditions dictate, as shown in Fig. 2.

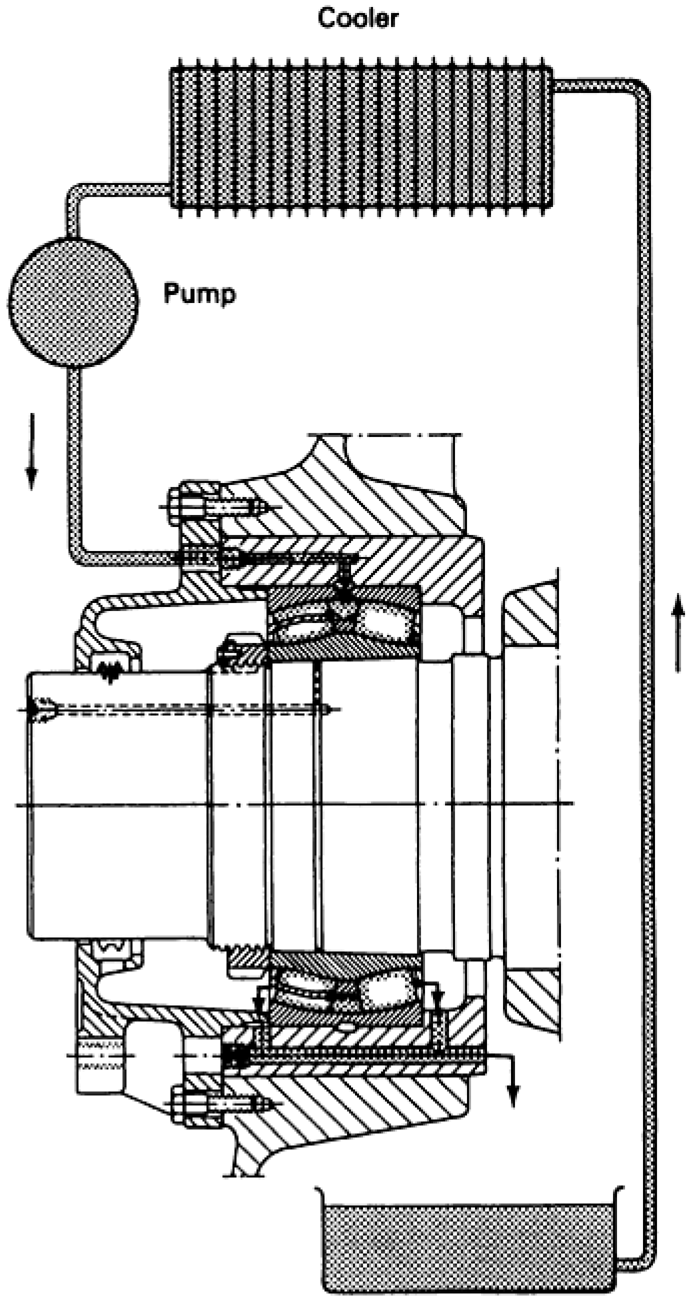

Fig. 2 Circulating oil lubrication system

Circulating systems are usually fitted with filtration systems to remove bearing wear and environmental contamination from the lubricant. The use and maintenance of clean oil is of utmost significance in obtaining extended bearing life. Generally, increased filtration is beneficial to bearing lifetime if the filter is properly chosen and maintained. A 10 μm (0.4 mil) filter is a good choice. The sump should be of adequate capacity to contain oil for at least 30 min in order to provide settling of contaminants.

Oil Jet. The amount of oil for very high speed operation should be minimized to limit bearing temperature rise. A useful method for this case is oil jet lubrication. As shown in Fig. 3, a jet of oil under pressure is directed at the side of the bearing, between the inner ring outside diameter and cage inside diameter. The oil jet velocity must be high enough (>15 m/s, or 50 ft/s) to penetrate the turbulence generated by the bearing rotation.

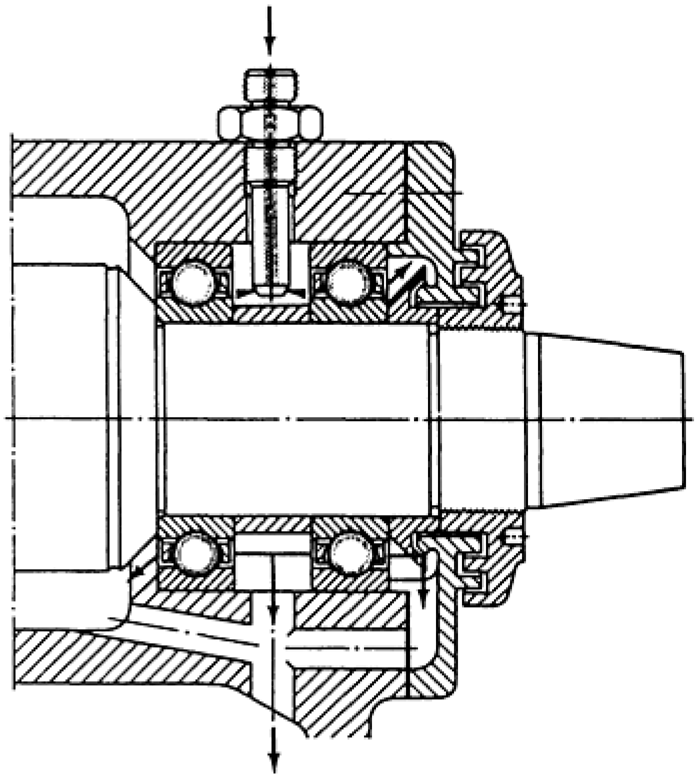

Fig. 3 Oil jet lubrication of rolling bearings

Oil mist lubrication has been found to be useful in either high-speed applications or those in which the bearing housing is surrounded by water and grit. Mist lubrication is suitable for both horizontal and vertical shafts. Very small, accurately metered amounts of oil are directed at the rolling element by compressed air. By minimizing oil quantity, operation can occur at a lower temperature and higher speed than is possible using any other method of lubrication. Oil consumption is consequently low, and the air flow prevents the entrance of grit and subsequent wear. Several atomizer designs are available from a variety of manufacturers.

Single-pass lubrication systems can be effective when minimum bearing friction is essential, loads are low, and speeds are moderate. A minimum spray of fluid mist is delivered to the bearing contacts. Churning and resultant losses are eliminated, and low usage permits discarding the lubricant after a single pass. One-time exposure to the contact environment relaxes the oxidation and property requirements of the lubricant. Tests have shown that trace quantities of injected lubricant at 1 h intervals are sufficient to keep precision spindle assemblies running at friction torque levels that are unobtainable by any other method. A disadvantage is that the generation of oil mists outside the bearing enclosure must be strictly limited to meet health and safety regulations.

Mineral Oils

The predominant chemistry for rolling bearing lubricants is refined mineral oil, which generically refers to a product of petroleum crude. Chemically, these oils are composed of a large number of paraffinic, naphthenic, and aromatic groups, combined into many distinct molecules. Also present are trace amounts of molecules containing sulfur, oxygen, or nitrogen. On an elemental basis, the composition of petroleum oils is consistent: carbon, 83 to 87%; hydrogen, 11 to 14%; and a remainder composed primarily of sulfur, nitrogen, and oxygen. The exact molecular makeup of a petroleum-base stock is very complex and is dependent on its specific origin.

With regards to lubrication, petroleum-base stocks are characterized by the chemistry of the distillates obtained. Therefore, it is common to speak of paraffinic, naphthenic, and mixed crude oils. Aromatics seldom predominate in lubricant oils. Modern distillation, refining, and blending techniques allow the production of many oil products from a given base stock. However, because of subtle variations, some base stocks are more desirable for lubricant formulation, as discussed below.

Paraffinic-base stocks have a favorable viscosity-temperature relation for lubrication. Such fluids are generally low in undesirable trace components. Naphthenic-base stocks do not contain paraffinic waxes and are better suited for certain low-temperature uses. These base stocks also have lower flash points and are more volatile, compared with paraffinic oils.

Two common industrial lubricants are the rust and oxidation (R&O) inhibited and the extreme-pressure (EP) oils. R&O inhibited oils are often formulated with additional additives, such as antifoam and antiwear agents. These products are generally suitable for use between -20 and 120 °C (-4 and 248 °F). They are often employed in applications where bearings and gears share a common lubricant reservoir.

Extreme-pressure oils are usually R&O inhibited products with an EP additive to generate a lubricating surface that can prevent metal-to-metal contact when the fluid film fails. Two main strategies exist in formulating EP oils. One is to use active sulfur, chlorine, or phosphorus compounds to generate sacrificial surfaces at the contacts. These surfaces will then shear, rather than weld, upon contact. The second approach employs a planar solid to impose between the contact surfaces. Of course, both contacting situations occur only when there is insufficient fluid film to separate them.

EP oils are used either when bearing loading is high or where shock loading exists. Normally, EP oils are used between -20 and 120 °C (-4 and 248 °F). Some cautions are necessary when such products are used. EP solids can reduce internal bearing clearances, causing wear and, possibly, failure in certain bearing types. These additives can also be lost upon filtration. Some sulfur-chlorine-phosphorus additives are corrosive to bronze and nylon cages and accessory items.

Synthetic hydrocarbon fluids are manufactured from chemical precursors, rather than the petroleum-base stocks that constitute mineral oils. Whereas a large number of molecules exist in mineral oils, the number and type of molecules in synthetic hydrocarbons are strictly controlled by the manufacturing process involved. The ability to pick and choose components allows the production of a petroleum fluid with optimum properties for lubrication. One commercially important type is the polyalphaolefin (PAO) fluids that are widely used in turbine lubricants, hydraulic fluids, and grease formulations.

PAO fluids show very high viscosity indexes, compared with refined mineral oils, which means better viscosity retention at elevated temperatures. Synthetic hydrocarbon lubricants exhibit superior thermal and oxidation stability over conventional lubricants, permitting higher operating temperatures. Other improved properties include flash point, pour point, and volatility characteristics. Although synthetic, the materials are compatible with refined petroleum lubricants because of the similar chemistry involved.

Viscosity of Lubricants

The most important property of a lubricant under normal conditions is viscosity. This applies both to fluid lubricants and to the base fluids in grease formulations. By definition, viscosity is the resistance to flow. For the purposes of this article, viscosity is the factor of proportionality between shearing stress and the rate of shear. Very simply, increased viscosity relates to an increased ability of the lubricant to separate contacting microsurfaces under pressure. This separation is at the heart of lubrication for rolling bearings.

Viscosity is usually measured kinematically per ASTM D 445. This test measures the time required for a measured volume of fluid to pass through a standard length of capillary tube under the force of gravity. Standardized test temperatures for rolling bearing lubricants are between 40 and 100 °C (104 and 212 °F). Many alternative viscosity determinations exist and are of utility when either very viscous fluids or low temperatures are involved.

The ISO VG classification is universally used to designate lubricant viscosity grade. This classification is based on the ISO 3448-1975(E) standard. Simply put, an ISO VG 32 lubricant has an approximate viscosity of 32 mm^2/s (32 cSt) at 40 °C (104 °F). A range of viscosities is defined for each grade in the ISO standard. ISO grades run from VG 2 to VG 1500.

The derived quantity, viscosity index (VI), is often encountered. This dimensionless number reflects the effect of temperature on kinematic viscosity. The higher the VI for a fluid, the smaller the viscosity loss with increased temperature. A typical paraffinic mineral oil base lubricant will have a VI from 85 to 95. Polymers can be added to mineral oil base stocks to obtain a VI of 190 or more. The shear stability of these additions, as well as the actual effect in the microcontact, is open to question, and the VI of such fluids generally deteriorates with time. Many of the synthetic fluids have VIs that far exceed those of mineral oils. ASTM D 567 describes the method of calculating VI from kinematic viscosities at two temperatures.

Selection of Proper Viscosity for Petroleum Oil Lubricants. Figures 4 and 5 can be used to obtain a minimum acceptable viscosity for a bearing application. With known values for the pitch diameter, d_m, and the rotational speed, Fig. 4 can indicate the minimum suitable viscosity at the bearing operating temperature. Figure 5 can then be used to relate this viscosity to the standard reference viscosities for ease of selection. Figure 5 can also be used to determine the actual viscosity of a petroleum oil with a VI of 85 at a given temperature if its standard viscosity data are known.

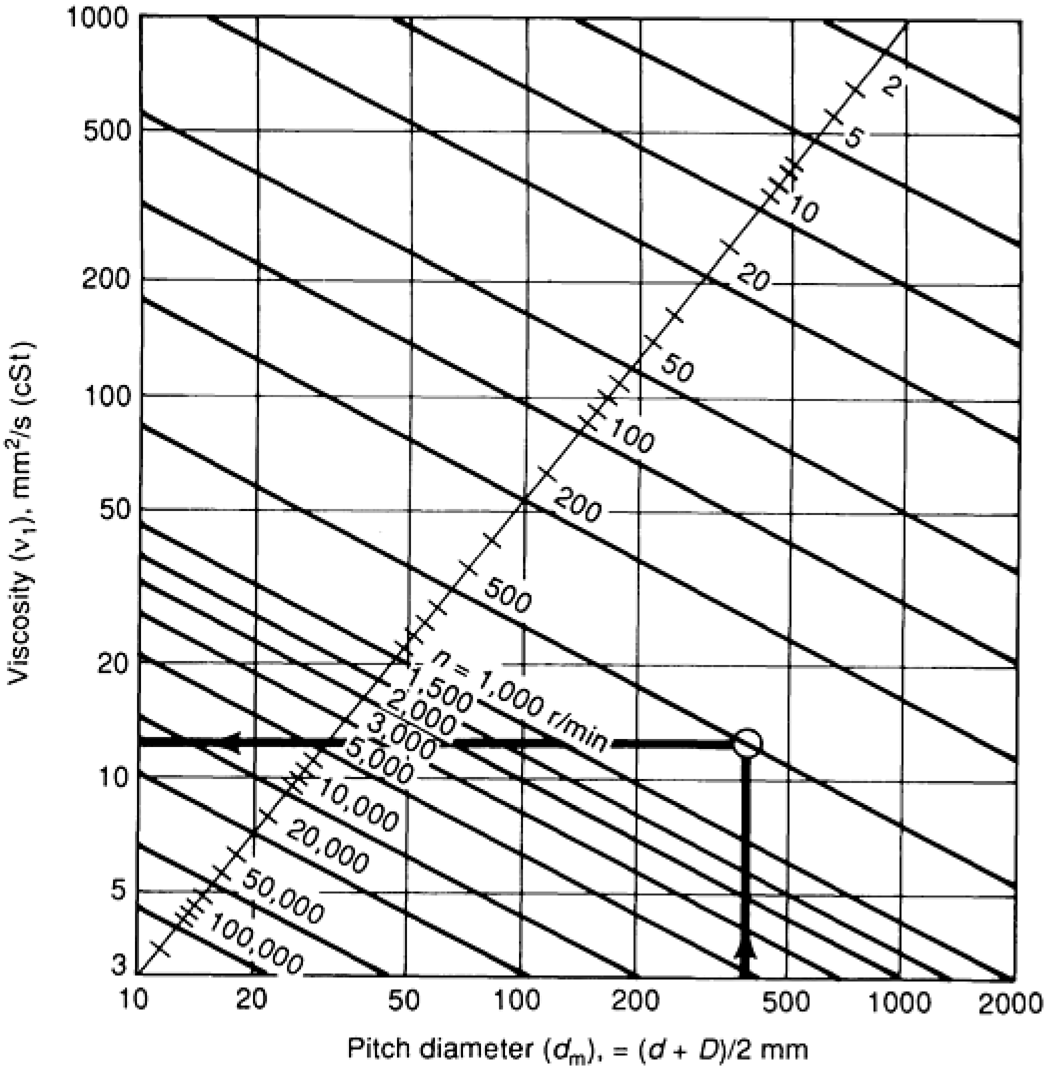

Fig. 4 Calculation of minimum required viscosity

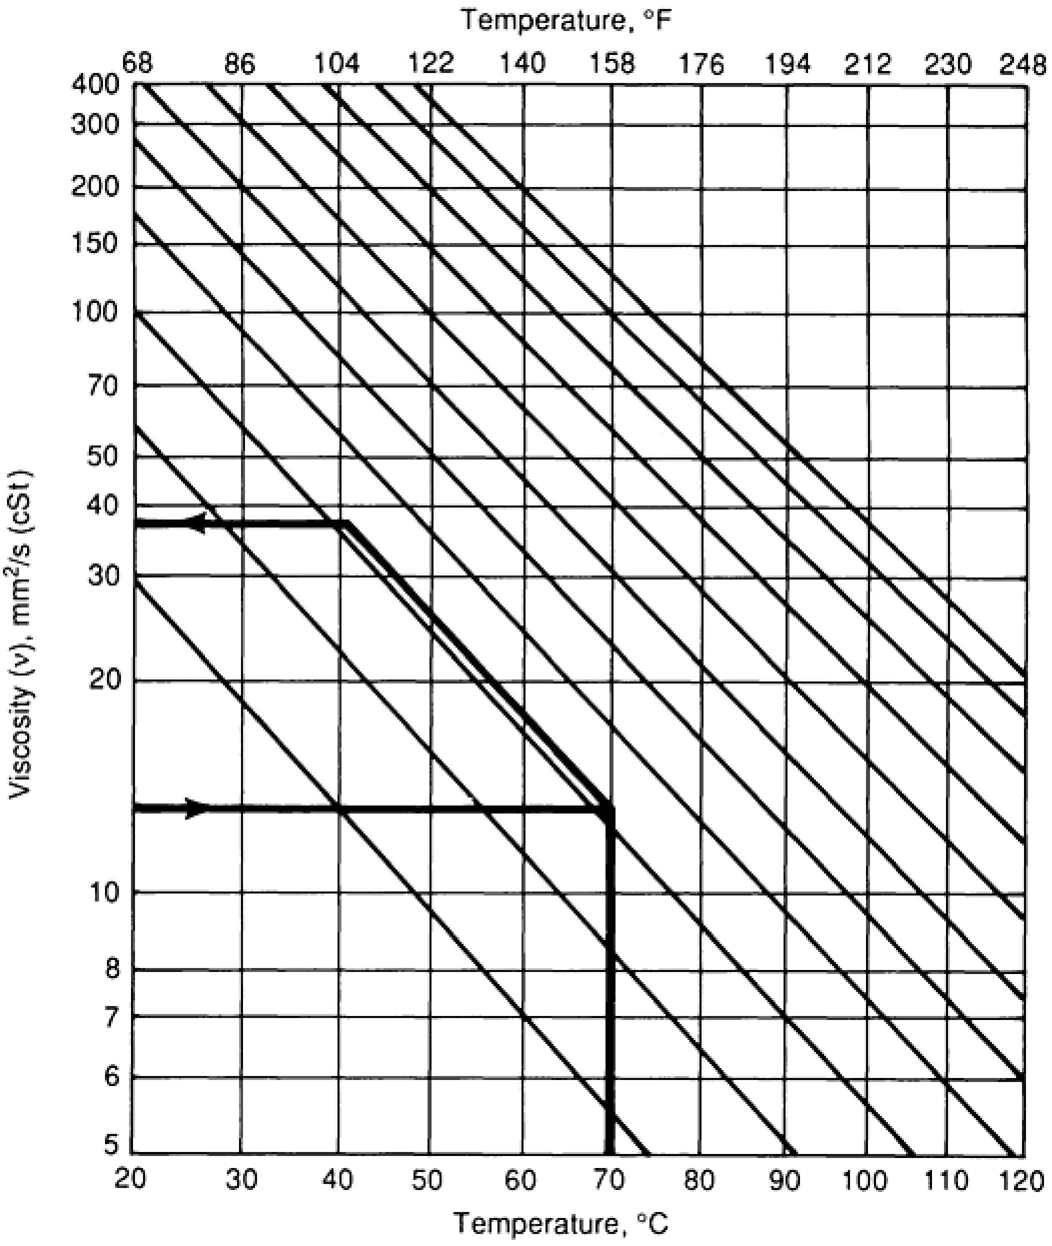

Fig. 5 Viscosity-temperature relation for mineral oil base lubricants with a VI of 85

Example of Viscosity Calculation. A bearing has a bore diameter, *d,* of 340 mm (13.6 in.) and an outside diameter, *D,* of 420 mm (16.8 in.). Thus, its pitch diameter is 380 mm (15.2 in.). It is operating at 70 °C (160 °F) and at 500 rev/min. What is the minimum acceptable viscosity under these conditions? As shown in Fig. 4, the required kinematic viscosity is at least 13 mm^2/s (13 sSt). Remembering that the operating temperature is 70 °C (160 °F), it can be seen, in Fig. 5, that the required viscosity of an oil at 40 °C (104 °F) is at least 39 mm^2/s (39 cSt).

When estimating operating temperature, it is useful to remember that the oil temperature is from 3 to 11 °C (5 to 20 °F) higher than the bearing housing temperature. If a lubricant with a higher than required viscosity is used, an improvement in bearing fatigue life is expected. However, because increased viscosity will raise the operational temperature, there is a practical limit to the lubrication improvement that can be obtained by these means. When unusually high or low speeds, or heavily loaded conditions, or unusual lubrication circumstances are encountered, the bearing manufacturer should be consulted.

Types and Properties of Nonpetroleum Oils

Many types of "synthetic" fluids have been developed in response to lubrication requirements that are not adequately met by petroleum oils. These requirements include extreme temperature, fire resistance, low viscosity, and high viscosity index.

Table 1 lists typical properties of various lubricant base stocks and indicates application areas for finished products of each type. As is the case for petroleum oils, many additive chemistries have been developed to enhance the properties of these fluids.

Table 1 Typical properties of lubricant base fluids

Base fluid	Density, g/cm^3	Viscosity at 40 °C (104 °F), mm^2/s	Viscosity index	Flash point		Pour point		Volatility(a)	Oxidation resistance(a)	Lubricity(a)	Thermal stability(a)	Application range

(a) The value 5 characterizes highly refined mineral oil. Values of <5 reflect superior performance, whereas values >5 reflect inferior performance to mineral oil with respect to lubrication properties.

Before discussing the general synthetic classes, it should be noted that the use of such lubricants requires a thorough understanding of the application requirements. The favorable properties of some synthetics are obtained only with unsuitable performance characteristics in areas such as load-carrying ability and high-speed operation. Similarly, many very high temperature fluids developed for military applications have very short service lifetimes, compared with commercial requirements.

Polyglycols are often used as a synthetic lubricant base in water emulsion fluids. This class of fluids includes glycols, polyethers, and polyalkylene glycols. Properties of the class include excellent hydrolytic stability, high viscosity index, and low volatility. The most prevalent usage is as a component of fire-resistant hydraulic fluids.

Phosphate esters have poor hydraulic stability and a low viscosity index. Because an outstanding characteristic of these fluids is fire resistance, they are often used as hydraulic fluids in high-temperature applications, such as aerospace.

Dibasic acid esters are a family of synthetic base stocks that are widely used in aircraft turbine applications and as a basis for low-volatility lubricants. They are synthesized by reacting aliphatic dicarboxylic acids (adepic to sebacic) with primary branched alcohols (butyl to octyl). Some are available from natural sources, such as castor beans and animal tallow. Characteristic properties of these fluids are low volatility and high viscosity index. Polyol esters that are formed by linking dibasic acids through a polyglycol center are suitable as high film strength lubricants.

Blends of dibasic esters, complex esters with suitable antiwear additives, VI improves, and antioxidants are used to form the current generation of jet engine lubricants. Generally, these products show excellent viscosity-temperature relationships, good low-temperature properties, and acceptable hydrolysis resistance. Elastomeric seals used with these materials must be chosen carefully, because many standard rubbers will suffer attack.

Silicone fluids (organosiloxanes) exhibit outstanding viscosity retention with elevated temperature and are functional under conditions of extreme heat and cold. These fluids are the basis for many high-temperature (200 °C, or 392 °F) lubricants.

In addition to favorable viscosity-temperature characteristics, volatility is low and both thermal and oxidation resistance characteristics are excellent. As a family, these fluids exhibit good hydrolytic stability. If very high temperatures are avoided, these fluids are inert with most elastomers and polymers. However, oxygen exposure with high temperature can result in gelation and loss of fluidity.

The lubrication properties of these fluids are not impressive when compared with other classes of lubricating fluids. Typical applications are in electric motors, brake fluids, oven preheater fans, plastic bearings, and electrical insulation.

Silicate esters represent a mating of the previous two lubricant fluid types. As a class, these fluids possess good thermal stability and low volatility. They are used in high-temperature hydraulic fluids and low-volatility greases.

Fluorinated polyethers are the highest-temperature lubricating fluids commercially available. Although distinct chemical versions are marketed, all of these fluids are fully fluorinated and completely free of hydrogen. This structural characteristic makes them inert to most chemical reactions, nonflammable, and extremely oxidation resistant. Products from these oils show very low volatility and excellent resistance to radiation-induced polymerization. The products are essentially insoluble to common solvents, acids, and bases. The density of these oils is approximately double that of conventional petroleum oils.

Products of this chemical family are used to lubricate rolling bearings at extremely high temperatures from 200 to 260 °C (392 to 500 °F). Other application areas include high-vacuum operations, corrosive environments, and oxygen-handling systems. As would be expected, the cost of these oils is very high.

Grease Lubrication

Greases consist of two major components: a fluid phase and a thickener system that determines the consistency of the product. Although thickeners can comprise a variety of materials, all provide a large specific surface area to retain oil. Mineral oils predominate, but the fluids used in grease formulations encompass the spectrum of lubricating fluids. The resulting product behaves like a semisolid, releasing oil at a controlled rate to meet the requirements of the rolling bearing. The fluid phase of the grease is either gradually degraded by oxidation or lost by evaporation, centrifugal force, and other factors. In time, the grease at the contacting bearing surfaces becomes depleted.

For many applications, greases have several advantages that are not offered by fluid lubricants:

- Fluid level is no longer a consideration, which reduces maintenance
- Enclosures around the bearing can be simplified, because grease is confined to the bearing interior
- Leakage is better controlled, which minimizes contamination of foodstuffs, textiles, and chemical products
- Grease usage can provide improved bearing sealing in conjunction with properly designed seals
- After start-up, friction torque and the associated temperature rise are usually more favorable

Excess grease will cause the bearing temperature to rise, especially at high speeds. Recommended grease quantity should be determined by the bearing vendor and followed. A fuller bearing is not necessarily a better bearing, where grease is concerned. For a typical application, a grease fill that ranges from 33 to 50% of the internal bearing volume will ensure adequate lubrication. Greater amounts will be purged past the seals and wasted.

Grease Speed Limits. A maximum operating speed based on type and design specifics is set by bearing manufacturers for their products. Speed limits for grease lubrication are lower than for fluid lubrication because of the initial temperature peak that occurs at bearing start-up. Operating temperatures will drop to lower levels once the grease has been distributed through the bearing. Certain bearing designs, such as angular-contact ball bearings, full-complement cylindrical rolling bearings, and taper rolling bearings, accentuate grease churning and make even lower speed limits necessary.

Operating speed is influenced by the shear strength of the grease, which is primarily determined by thickener type. A speed factor, nd_m, is often quoted by grease manufactures to indicate the speed capability, where n is the operating speed and d_m is the mean bearing diameter in millimeters. Among various grease compositions, these values ranges from 5×10^4 to 1.5×10^6. Greases that run above their nd_m value will cause temperature excursions in the bearing.

Lubricating Grease Composition. Rolling bearing greases are either thickened mineral oils or synthetic fluids. The thickeners are often metallic soaps. Additives are used to enhance certain properties of the grease. The maximum operating temperature is dependent on the chemistry of the constituents. Grease consistency is determined by the type and concentration of the thickener. When selecting a grease for a rolling bearing application, the viscosity of the base fluid, the operating temperature range, the rust-inhibiting properties, and the load-carrying capability are usually the most significant factors.

Base Fluid Viscosity. The efficiency of lubrication is primarily determined by the degree of separation at the microcontacts of the bearing. If an adequate load-carrying fluid film is to be formed, the lubricant must have a given minimum viscosity at the operating temperature. Base fluid viscosity for rolling bearings normally falls between 15 and 500 mm^2/s at 40 °C (104 °F). Grease that are based on heavier fluids may bleed oil so slowly that the bearing surfaces will not be adequately lubricated. Greases with very high viscosity fluids are recommended in only very special circumstances. Generally, oil lubrication is more reliable for high-viscosity requirements. Base fluid viscosity also governs the maximum operation speed of a grease in a given application. For very high speeds, the most suitable greases will have base fluids of very low viscosity.

Consistency of Lubricating Greases. Consistency refers to how stiff or soft a grease is. Stiffer products offer better sealing, whereas softer greases show less resistance to flow. Greases are categorized by consistency classes according to the National Lubricating Grease Institute (NLGI) scale (Table 2). ASTM D 217 is used to generate the penetration values upon which the greases are classified.

Table 2 NLGI penetration grades

NLGI grade	Penetration (60 strokes)[(a)]
000	445-475
00	400-430
0	355-385
1	310-340
2	265-295
3	220-250
4	175-205

5	130-160
6	65-115

(a) Per ASTM D 217

The consistency of rolling bearing greases should not dramatically change with temperature or with mechanical working. Greases that soften excessively, either with temperature or with working, may leak from the bearing, whereas those that stiffen at low temperature may restrict bearing rotation. Greases of NLGI grade 1, 2, or 3 are generally used for rolling bearing applications. NLGI grade 3 greases are often used for vertical shaft arrangements to prevent grease leakage.

Some greases that are thickened with polyurea can soften and harden reversibly, depending on shear rate, being relatively soft under low shear and stiff under high shear. The use of such greases should be restricted to ball bearings in horizontal applications.

Temperature Range. The operating temperature range of a rolling bearing grease depends on the chemical type of base fluid and thickener used. The lower temperature limit is dependent on the base fluid type and viscosity. Good low-temperature performance is important for applications below -20 °C (-4 °F), where lubricant stiffness results in increased starting resistance and running power requirements. The maximum temperature is determined by the thickener type and the oxidative stability of the base fluid. The upper operational temperature limit should not be confused with the dropping point value quoted by lubricant manufacturers. Dropping point indicates the temperature at which the grease loses its consistency and becomes fluid. The temperature can be well in excess of the maximum serviceable temperature of the grease. Greases based on synthetic oils, ester oils, synthetic hydrocarbons, or silicones can be used at temperatures above or below the operating temperatures of greases based on mineral oil.

Table 3 gives the operating temperature ranges for the most commonly used rolling bearing greases based on thickener type. The ranges are valid for greases that have a mineral oil base but no EP additives. Of the grease types listed, lithium 12-hydroxystearate soap thickened greases are the most commonly used for rolling bearing lubrication.

Table 3 Properties of mineral oil base grease with various thickeners

Thickener	Dropping point		Maximum temperature				Low-temperature limit		Water resistance(a)	Load-carrying capability(a)	Corrosion protection(a)
			Continuous		**Peak**

(a) P, poor, F, fair, G, good; E, excellent

Relubrication intervals for rolling bearings depend not only on the lubricant type and environmental conditions, but on specific design features, which vary among bearing manufacturers. Although the manufacturer should be consulted for relubrication interval recommendations for their products, some general considerations can be given. As conditions become more severe in terms of operating temperature and/or frictional heat generated, the bearing must be relubricated more frequently.

As a rule of thumb, temperatures above 70 °C (158 °F) will shorten the relubrication interval of good-quality, lithium soap greases. Beyond 70 °C (158 °F), increments of 15 °C (27 °F) will halve the interval. This is useful in estimating the performance of a grease at elevated temperature, given a fixed reference point. For example, knowing that a certain grease

gave 500 h of bearing life at 150 °C (300 °F) allows estimation of its lifetimes at 165 °C (330 °F) (250 h) and 135 °C (275 °F) (1000 h).

Bearings that operate under 70 °C (158 °F) will probably require relubrication less often. However, a doubling phenomena with 15 °C (27 °F) temperature reductions has not been shown. Bearings that operate on a vertical shaft require relubrication approximately twice as often as horizontal shaft applications.

Relubrication interval requirements will vary according to the types of grease used and may also vary among greases of similar types. For small ball bearings, the relubrication interval is often longer than the life of the bearing application and therefore relubrication is not required. Where marked contamination occurs, the recommended relubrication intervals should be reduced. This is also true in applications where moisture intrusion in significant.

Corrosion Prevention Behavior. The rust-inhibiting properties of greases are generally determined by additives to the grease formulation. A grease must provide protection against corrosion and should not be easily washed out in cases of water intrusion.

Load-Carrying Ability. Under very high loads, the lubricant film that separates the contacting surfaces may become discontinuous, causing high bearing wear and premature failure. For heavily loaded bearings, it has been customary to recommend the use of grease containing EP additives, because these additives increase the load-carrying ability of the lubricant film. Previously, lead-based compounds dominated the EP additive field, often to the benefit of greases formulated with them. Because of health and environmental concerns, lead-base additives have been superseded by other compounds, some of which have proven aggressive to bearing steels at high temperatures. Reductions in bearing lifetimes have been recorded in some instances. EP additives should be used only with the utmost care to prevent reduced bearing life.

Grease Compatibility. Mixing greases of chemically different thickeners and/or base fluids can produce an incompatibility, resulting in a loss of lubrication and bearing failure. Mixing greases of differing base fluids can result in a two-component fluid phase that will not provide a continuous lubrication film. In some cases, mixing different thickeners can result in a grease mix that is either too stiff to lubricate properly or too fluid to remain in the bearing cavity. Early failure can be expected in either situation. Lubricants of differing chemical makeup should not be mixed. If there is doubt, then new lubricant should be used to purge the bearing cavities and supply lines until all traces of the prior product are removed before starting operation.

Regreasing Procedures. If the relubrication interval specified by the manufacturer is less than approximately six months, an additional grease charge can be made directly to the bearing, in accord with the manufacturer's recommendation. For intervals greater than six months, all of the used grease should be removed from the grease cavities and replaced with fresh grease.

Polymeric Lubricants

A polymeric lubricant uses a matrix, or sponge-like material, that retains its physical shape and location in the bearing. Lubrication is provided by the oil alone after it has bled from the polymeric sponge. Although ultrahigh molecular weight polyethylene forms a pack with generally good performance properties, it is temperature limited to about 100 °C (212 °F), precluding its use in some applications within the temperature capability of standard rolling bearings. Other higher-temperature materials, such as polymethylpentene, form excellent porous structures, but are relatively expensive and suffer higher torque. Fillers and blowing agents, which are standard tools of the plastics industry, interfere with the oil flow behavior and therefore contribute little in this situation.

Despite its temperature limitations, a polyethylene-base material, designated W64 by SKF, has achieved success in the solution of everyday bearing lubrication problems. Perhaps the most notable success occurs where a bearing must operate under severe acceleration conditions, typical of those found in planetary systems. Although the bearing rotational speed about its own axis may be moderate, the centrifuging action that is due to planetary motion is strong enough to throw conventional greases out of the bearing, despite the presence of seals. When polymerically lubricated bearings are substituted, life improvements of two orders of magnitude are not uncommon. Such situations occur in cable making, tire winding, and textile mill applications.

Another major market for polymer lubricants is food processing, where machinery must be cleaned frequently, often daily, using steam, caustic, or sulfamic acid solutions. Because these degreasing fluids tend to remove lubricant from the

bearings, it is standard practice to follow every cleaning procedure with a relubrication sequence. Polymer lubricants have proven to be highly resistant to washout by such cleansing methods, which reduces the need for regreasing. After washing down, the bearings should be rotated to prevent static corrosion.

The reservior effect of polymeric lubricants has been exploited in bearings that are normally lubricated by a circulating oil system, where there can be a delay in the arrival of the oil at a critical location. The same effect has been used to provide a backup, should the oil supply system fail.

The high occupancy ratio of the void space by the polymer minimize the opportunity for the bearing to "breathe" as temperature change, thereby reducing corrosion caused by internal moisture condensation. Because all ferrous surfaces are very close to the pack, conditions are favorable for using vapor-phase corrosion control additives in the formulations.

Despite these advantages, polymeric lubricants have some specific drawbacks. There tends to be considerable physical contact between the pack and the moving surfaces of the bearing. This leads to increased frictional torque, which produces more heat in the bearing. In conjunction with thermal insulating properties of the polymer and its inherently limited temperature tolerance, the speed capability is reduced. Moreover, the solid polymer is relatively incapable of entrapping wear debris and dirt particles, as compared with grease.

Solid Lubricants

Solid lubricants are used whenever conventional lubricants are not suitable. Extreme environment conditions frequently favor solid lubricants, which can survive temperatures well above the decomposition temperatures of oils. They can also be used in chemically reactive environments. The disadvantages of solid lubricants are their high coefficient of friction, inability to act as a coolant, finite wear life, difficult replenishment, and small damping effect for controlling vibrational instabilities of rolling elements and separator components.

Many common solid lubricants, such as graphite and molybdenum disulfide are layered lattice compounds that shear easily along preferred planes of their structure. Molybdenum disulfide has weak van der Waals forces between sulfur bonds, giving the material a characteristic relatively low coefficient of friction. It also oxidizes at approximately 399 °C (750 °F) in air, and the oxides can be abrasive.

The low friction associated with graphite depends on intercalation with gases, liquids, or other substances. For example, the presence of absorbed water in graphite imparts good lubricating qualities. Thus, pure graphite has deficiencies as a lubricant except when used in an environment containing contaminants such as gases and water vapor. With proper additives, graphite can be effective up to 649 °C (1200 °F). Tungsten disulfide is similar to molybdenum disulfide in that it is a type of layered lattice solid lubricant. It does not need absorbable vapors to develop low shear strength characteristics.

Other "solid" lubricating materials are solid at bulk temperatures of the bearing, but melt from frictional heating at points of local contact, giving rise to a low shear strength film. This melting can be very localized and of very short duration. Soft oxides, such as lead monoxide, are relatively nonabrasive and have a relatively low friction coefficient, especially at high temperatures where their shear strengths are reduced. At these temperatures, deformation occurs by plastic flow rather than by brittle fracture. Melted oxides can form a glaze on the surface, which can either increase or decrease friction, depending on the "viscosity" of the glaze within the contact region. Stable fluorides, such as lithium fluoride, calcium fluoride, and barium fluoride, also lubricate well at high temperatures, but over a broader range than lead oxides.

Metalworking Lubricants

Joseph T. Laemmle, Aluminum Company of American, Alcoa Technical Center

Introduction

DURING METALWORKING OPERATIONS, tool and workpiece surfaces are brought together in the presence of a lubricant. The tool is used to change the shape of the workpiece. Typical examples of tools used in metalworking operations are a drill bit in a drilling operation, a work roll in a rolling operation, and a forging die in a forging operation. In the drilling operation, the workpiece is the object being drilled. In the rolling operation, the workpiece is the strip being reduced, and in the forging operation, the workpiece is the billet being shaped.

Metalworking lubricants have some functions that are common to all metalworking operations, such as

- Controlling friction
- Reducing tool wear
- Improving surface quality of the workpiece

Common functions and special requirements that a metalworking lubricant must meet when used, for example, to roll aluminum that is to be used for food packaging include:

- Control friction
- Reduce roll wear
- Cool roll and strip
- Minimize transfer of aluminum from the strip to the work roll and produce a uniform and stable work roll coating
- Produce an appropriately bright, smudge-free surface
- Produce a surface free of defects caused by lubricant failure
- Protect the sheet surface from water stains and handling marks in downstream operations
- Resist oxidative degradation and bacteriological attack
- Withstand plant environments and resist performance changes due to contamination
- Be compatible with lubricants used in downstream operations
- Prevent corrosion
- Be easily filtered
- Leave residues that do not produce stains upon sitting or annealing
- Ease of maintenance
- No production of objectional odors
- Cost effectiveness
- Easy waste disposal
- Satisfy regulatory requirements, such as those mandated by the Food and Drug Administration (FDA)
- Satisfy hygiene and environmental criteria

The formulation or selection of a modern metalworking lubricant that meets all process and product requirements is often a sophisticated task.

One of the two generally recognized categories of metalworking lubricants is represented by lubricants that are used in operations where metal is removed from the workpiece in order to obtain a desired shape. Examples of metal removal operations include drilling, broaching, turning, grinding, milling, threading, reaming, boring, and sawing. The other category is represented by metal forming lubricants, which are used in operations where metal is plastically deformed to obtain the desired shape of the workpiece. Examples of metal forming operations are hot rolling, cold rolling, foil rolling,

forging, wire drawing, tube drawing, deep drawing, ironing, extrusion, and spinning. Because metalworking lubricants can generally cool, as well as lubricate, they are often called metalworking fluids, metalworking coolants, or lubricant-coolants.

Ferrous metals, such as carbon steel, low-alloy steel, and stainless steel, constitute the majority of fabricated metal products. Large quantities of aluminum are subjected to metalworking operations, with lesser amounts of copper, brass, and titanium also being processed. Other metals subjected to either removal or forming processes include nickel-based alloys, cobalt-based alloys, magnesium, zinc, tin, beryllium, zirconium, tungsten, molybdenum, tantalum, uranium, and vanadium.

Considering the various types of metalworking operations involving various alloys with different sets of requirements, it should be evident that lubricant formulation, selection, and use is a complex process. This article presents an overview of lubricant properties common to metalworking operations, followed by discussions involving lubricant issues that are especially important to metal removal operations and metal forming operations.

The author would like to thank both Mr. John Bohaychick, who aided in the preparation of this article, as well as the Aluminum Company of America for permission to publish.

Formulations

Metalworking lubricant formulations commonly consist of a petroleum oil compounded with additives of various types. The oil-additive combination is often emulsified in water. Lubricants that are based on synthetic oils, rather than petroleum oils, are also used. Some metalworking lubricants contain no oil at all, but consist of friction-modifying additives and corrosion inhibitors dispersed or solubilized in water.

Petroleum oils are naturally occurring materials that are refined by processes such as distillation, hydrotreating, solvent extraction, molecular sieving, and dewaxing to give desired properties. Properties include physical attributes, such as viscosity, color, and odor, as well as chemical attributes, such as degree of saturation and freedom from undesirable elements such as sulfur.

Petroleum oils are commonly called mineral oils and are referred to as either bases or base oils in terms of metalworking lubricants. Petroleum oils are generally classified as paraffinic, naphthenic, or aromatic. Paraffinic oils are further classified as either linear paraffins or isoparaffins. The molecular species associated with each classification is illustrated in Fig. 1. Linear paraffins consist of straight-chain hydrocarbons, whereas isoparaffins consist of branched-chain hydrocarbons. Naphthenic oils consist of hydrocarbons that contain five- or six-member ring structures that may be unsaturated, but not aromatic. Aromatic oils consist of hydrocarbons that contain totally unsaturated six-member rings known as either benzene or aromatic rings. Petroleum oils generally consist of a mixture of paraffinic, naphthenic, and aromatic molecules and are classified by the species that predominates. For example, a petroleum oil consisting of 70% naphthenic molecules is called naphthenic. The different classes of oils have different properties. Linear paraffins, for example, have high resistance to oxidative degradation, whereas naphthenic oils are more easily emulsified.

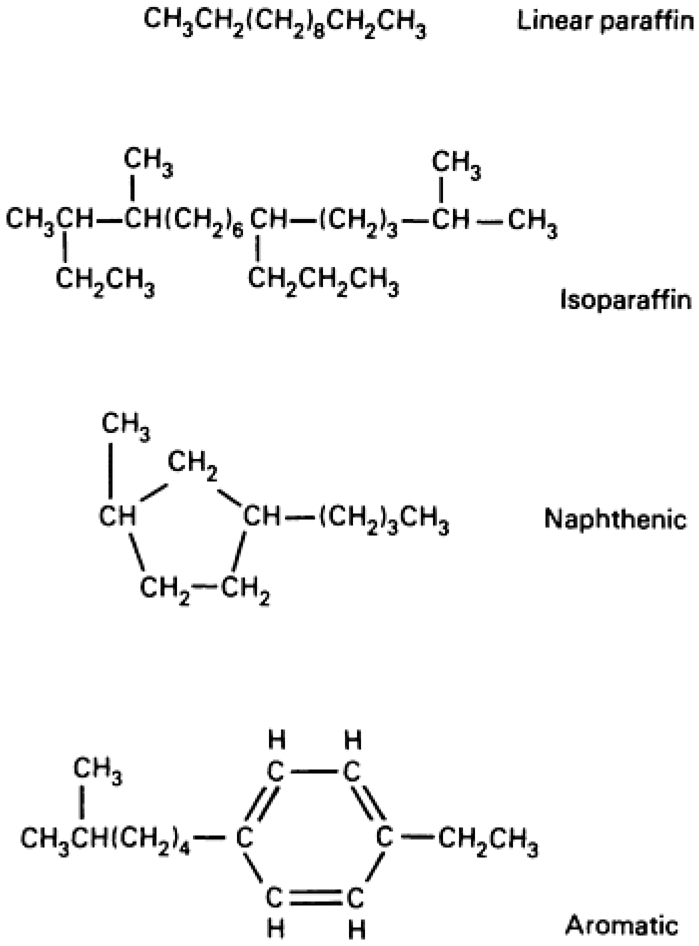

Fig. 1 Examples of molecular species contained in petroleum oils

Synthetic Fluids. Although less commonly used than petroleum oils, synthetic fluids are becoming increasingly popular as bases for metalworking lubricants in cases where their tailored properties can more than make up for their higher cost. Examples of some synthetic fluids are illustrated in Fig. 2. Synthetic hydrocarbons, such as polyisobutylenes and poly-α-olefins, are often referred to as synthetic oils.

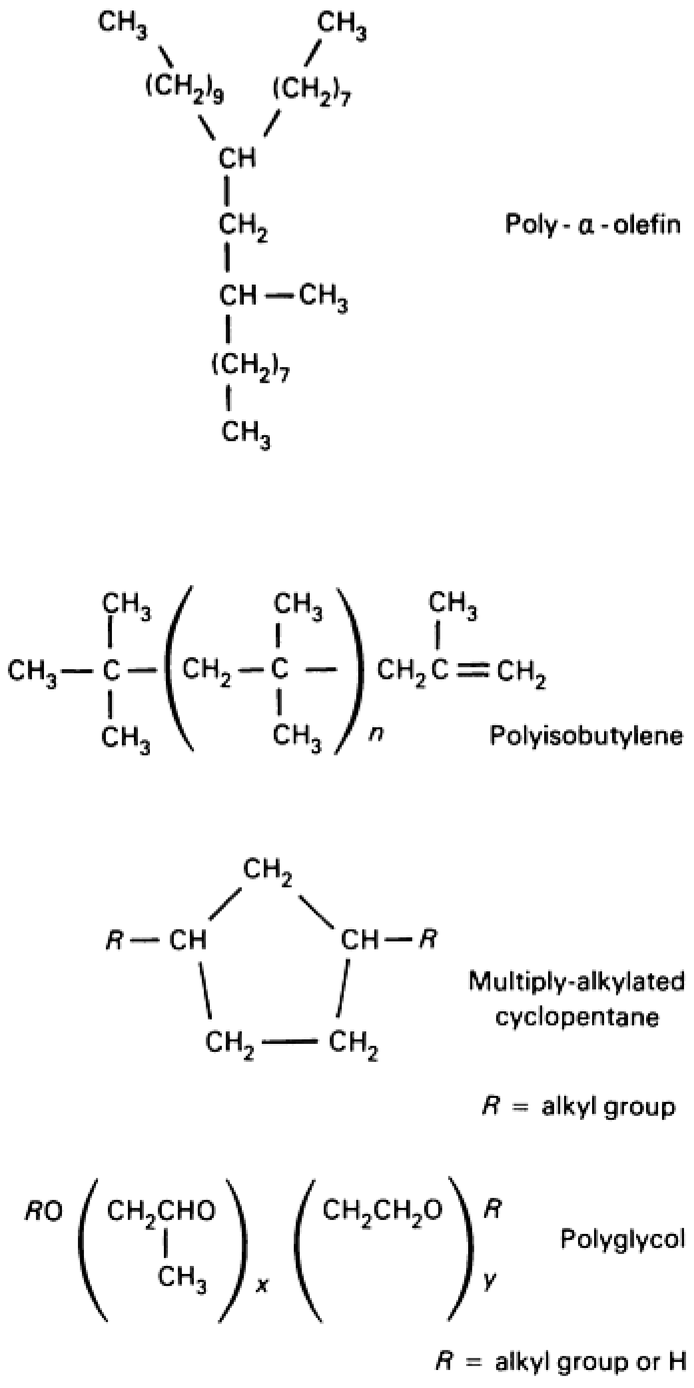

Fig. 2 Examples of molecular structure of four classes of synthetic fluids

Polyglycols are often used in metal removal lubricant formulations. These materials are prepared through polymerization of ethylene oxide and propylene oxide in either random or block fashion. The terminal groups can be either alkyl groups or hydrogen. Properties are controlled by molecular weight, nature of terminal groups, and the ratio of ethylene oxide to propylene oxide. For example, high molecular weight versions have high viscosities. Polyglycols with high ratios of ethylene oxide to propylene oxide tend to be water soluble, whereas those with low ratios tend to be water insoluble. The ratio can be adjusted such that the polyglycol is water soluble at room temperature, but water insoluble at elevated temperatures. This property can be very useful in formulating solutions that are clear in the circulating system, but will separate polyglycol and the additive package from solution at the hot tool-workpiece interface.

Polyisobutylenes can be made in a wide range of viscosities by controlling molecular weight. They have a unique property of depolymerizing at high temperatures. This makes them useful as rolling and drawing oils for ferrous and

nonferrous forming operations where subsequent annealing would produce staining if petroleum oil forming lubricants were used.

Poly-α-olefins, while not as commonly employed in metalworking operations as polyglycols and polyisobutylenes, have properties that make them useful for some operations. They can be used over a wide temperature range, and they produce less hydrocarbon emissions than petroleum oils at similar viscosities. They also are very resistant to oxidative and thermal degradation.

Multiply-alkylated cyclopentanes are a new class of synthetic hydrocarbons that are promising in terms of future formulations. Their properties can be varied over a wide range by varying the number and nature of alkyl groups. They have excellent pour points and viscosity indexes, as well as exceptionally low volatility. A number of synthetic fluid categories beyond those discussed above also exist, but have very limited use as base oils in metalworking operations.

Viscosity

Viscosity is a measure of the resistance of a fluid to flow and is a very important lubricant property. Kinematic viscosity, which represents the resistance of a fluid to flow under gravity, as measured by the ASTM D 445 test, is the preferred method for describing the viscosity of lubricants. In ASTM D 445, a fixed volume of lubricant is allowed to flow through a calibrated orifice that is held at constant temperature. The kinematic viscosity is calculated by multiplying the flow time in seconds by the calibration constant of the viscometer. The correct SI unit of kinematic viscosity is mm^2/s. A centistoke, which is equivalent to 1 mm^2/s, is also commonly used. The standard temperatures for measuring viscosity are 40 °C (104 °F) and 100 °C (212 °F). The viscosity of fluids decreases as temperature increases. Viscosity index is an empirical, dimensionless number that indicates the rate at which lubricants change kinematic viscosity with temperature. The higher the viscosity index of a lubricant, the less rapidly its viscosity changes with temperature.

In metal forming operations, viscosity is a major factor in determining the lubricant film that separates the tool from the workpiece and thus is critical in controlling friction and wear. In metal removal operations, optimum lubricant viscosity must be estimated for a particular operation. Factors to be considered in estimating the optimum viscosity of a metal removal fluid include the capability of the lubricant to penetrate and remain in the contact zone, the durability of the lubricant film, the desired rate of spreading, and the cooling capability.

Additives

In most metalworking operations, the base oil does not totally separate the tool from the workpiece, nor is it desirable to do so. In rolling operations, for example, complete separation of the work roll and strip leads to very low friction and loss of mill control. In metal removal operations, the tool surface must contact the workpiece surface in order for chip formation to occur. In both cases, additives to the base oil are required to modify friction, control tool wear, and protect workpiece surfaces in those areas where tool-workpiece surface contact occurs. Additives that preserve the life of the formulated coolant and that prevent corrosion of the tool, workpiece, and lubricant handling system are also commonly used. In water-based metalworking lubricants, special materials are employed to disperse or solubilize the oil-additive package in water. Additives commonly used in metalworking formulations are described below.

Film-strength additives adsorb on tool-workpiece surfaces and prevent direct metal-to-metal contact and the subsequent welding of asperities and destruction of the workpiece surface. These additives are often called boundary additives, load-bearing additives, oiliness additives, or friction modifiers. Film-strength additives consist of materials with a polar head and a hydrocarbon tail generally containing 10 or more carbon atoms. Compounds that function as film-strength additives include fatty acids, esters, alcohols, amides, amines, and alkyl acid phosphates.

Figure 3, which illustrates how film-strength additives work, shows the results of a crossed-cylinders test in which a stationary aluminum specimen 6.35 mm (0.25 in.) in diameter transversed a circular path on a rotating steel specimen 19 mm (0.8 in.) in diameter at a velocity of 411.5 mm/s (16.2 in./s) and a total load of 8.895 N (2 lbf). Three lubricants were used to lubricate the steel-aluminum contact: two linear paraffins of different viscosities and a linear paraffin of lower viscosity formulated with 5% methyl ester film-strength additive. Higher-viscosity lubricants give thicker lubricant films and, therefore, less tool-workpiece surface contact and lower friction in metalworking operations. This is clearly seen in Fig. 3. Even the higher-viscosity linear paraffin, however, shows much spiking in the frictional force trace, indicating tool-work-piece surface contact with localized asperity welding and associated friction spikes. The addition of the film-strength additive eliminates friction spikes and gives an overall low and smooth frictional force trace.

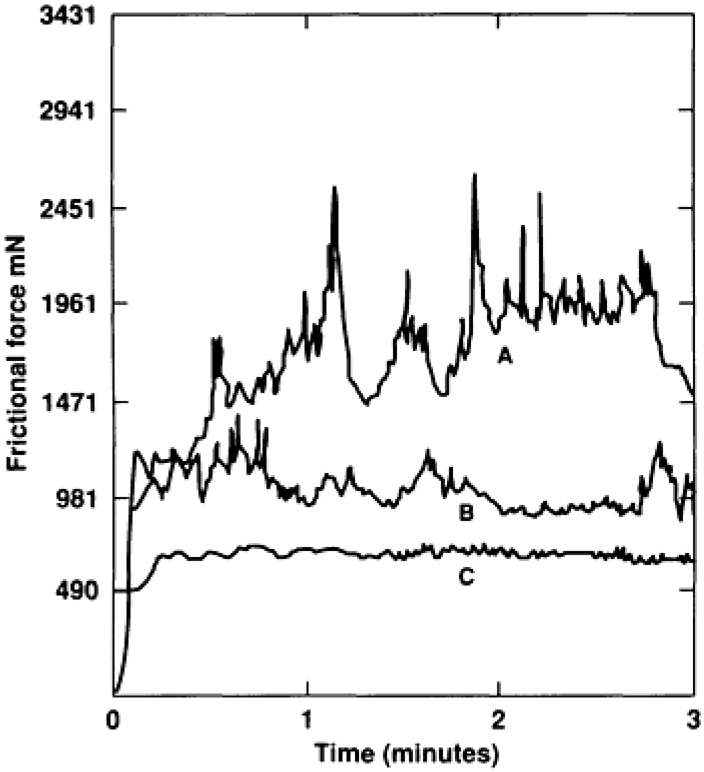

Fig. 3 Crossed-cylinders frictional force showing 1.18 mm^2/s (1.8 × 10^{-3} $in.^2/s$) linear paraffin (curve A), 2.49 mm^2/s (3.9 × 10^{-3} $in.^2/s$) linear paraffin (curve B), and 5% methyl ester in 1.18 mm^2/s (1.8 $in.^2/s$) linear paraffin

Extreme pressure (EP) additives are generally useful in relatively severe metalworking operations involving ferrous metals. The most commonly employed EP additives are compounds containing sulfur, chlorine, phosphorus, or some combination of two or more of these elements. Closely associated with EP additives are so-called "antiwear" additives containing the same elements. Extreme pressure additives function by forming a reaction layer triggered by the high temperatures reached at the tool-work-piece interface in ferrous metalworking operations. These reaction layers reduce friction and wear. Phosphorus-containing compounds produce iron phosphates, iron pyrophosphates, or iron phosphides, depending on the nature of the compound. Sulfur-containing compounds produce iron sulfide, whereas chlorine-containing compounds produce iron chloride. Examples of EP additives include sulfurized triglycerides, chlorinated hydrocarbons, chlorinated esters, phosphate esters, and alkyl acid phosphates. A commonly used class of antiwear additives are the zinc dialkyl dithiophosphates.

A new class of EP additives, called passive extreme pressure (PEP) additives, has been recently introduced. They function by adsorbing a film of carbonate particles at the tool-workpiece interface in metalworking operations. These films have low shear strengths and high melting points. They reduce friction and minimize metal transfer from the workpiece to the tool. Passive extreme pressure additives do not contain phosphorus, sulfur, or chlorine, but are synergistic with sulfur-containing EP additives. They offer advantages over conventional EP additives in that they are less corrosive, are more easily disposed of after use, are low foaming, and are easily cleaned from the workpiece surface. They can be used with both ferrous and nonferrous metals.

Suspended Solids. Solids such as graphite, molybdenum disulfide, metal powders, metal oxides, metal halides, mica, and polytetrafluoroethylene are used as lubricants suspended in either oil or water carriers for certain metal forming operations, such as extrusion and forging. The solids are generally in the form of very finely divided powders held in suspension by either mechanical agitation or emulsifiers, or a combination of both. The oil or water carrier often functions solely to coat the die and work-piece in a uniform fashion, and the solid itself functions as a lubricant. Solids employed as lubricants have the general property of being easily sheared at the tool-workpiece interface. Suspended solids are not generally used in metal removal lubricants, although some types of PEP agents are colloidal suspensions.

Emulsifiers, often called surfactants, are materials that have portions within the same molecule that are hydrophilic, or compatible with water, and lipophilic, or compatible with oil. The hydrophile-lipophile balance (HLB) of an emulsifier is a measure of its tendency to be more compatible with water or oil. The HLB scale runs from 0 to more than 30, with oil compatibility decreasing and water compatibility increasing at higher numbers. Emulsifiers with HLB values higher than 13 form clear solutions in water.

Because emulsifiers have portions of their molecules compatible with water and other portions compatible with oil, they tend to concentrate at the oil-water interface in oil-water mixtures, reduce oil-water interfacial tension, and thereby promote emulsification. The emulsification process is that technique in which oil globules that are larger than colloidal size are dispersed in water. Petroleum oils, animal and vegetable oils, synthetic oils, and waxes each have an HLB value at which they form the most stable emulsion. This is known as the "required HLB" of the material to be emulsified. Required HLB values are different for different materials. For example, the required HLB to emulsify a paraffinic petroleum oil is 10, whereas the required HLB to emulsify castor oil is 14. An emulsifier or emulsifier combination that has the same HLB as that required of the material to be emulsified is chosen if the most stable emulsion is desired.

Emulsifiers are classified as cationic, anionic, amphoteric, and non-ionic. The most common cationic emulsifiers are long carbon chain quaternary ammonium halides. Anionic emulsifiers include alkali metal and amine soaps of long carbon chain fatty acids, and long carbon chain sulfates or sulfonates. Examples of amphoteric emulsifiers include long-chain amino acids and alkyl betaines. Examples of non-ionic emulsifiers include ethoxylated alcohols, ethoxylated fatty acids, and ethoxylated sorbitol. The most commonly employed emulsifiers in metalworking lubricants are the non-ionic and anionic types.

Corrosion inhibitors for ferrous metals are often contained in metalworking lubricant formulations, particularly those that are water based, in order to protect the tool, machine parts, and lubricant system. In some instances, they also protect the workpiece during and after processing. Prior to the 1980s, a commonly used and very effective corrosion inhibitor was sodium nitrite. In the mid-1970s, it was discovered that nitrosamines, which are carcinogenic, were contained in many commercial metalworking formulations. The nitrosamines were found to arise through a reaction between sodium nitrite and secondary amines, particularly diethanolamine. Much work has been one in recent years to find suitable replacements for sodium nitrite.

A number of types of compounds have been developed for the prevention of ferrous metal corrosion in modern metalworking lubricants. These include amine-borates, amine carboxylates, amine alkyl acid phosphates, and sulfonates. None of these materials forms nitrosamines and are therefore more acceptable.

Corrosion inhibitors for nonferrous metals are important in some metalworking operations. Benzotriazole is an effective corrosion inhibitor for copper or brass. Cobalt corrosion inhibitors, such as tolyltriazole, are used to prevent cobalt leaching in those operations employing cobalt-cemented tungsten carbide tools.

Oxidation inhibitors, also called antioxidants, are formulated into metalworking lubricants to minimize oxidative degradation of the lubricant into acidic products that tend to form sludge and corrode metal surfaces. Oxidative degradation involves molecules containing unpaired electrons called free radicals. These radicals are transformed into degradation products while transforming other lubricant molecules into more free radicals in a chain reaction. Small concentrations of oxidation inhibitors functioning as free radical scavengers intercept the unpaired electrons and break the chain. Oxidation inhibitors are not normally used at levels above 0.5%. Commonly used oxidation inhibitors include hindered phenols, such as butylated hydroxytoluene and butylated hydroxy anisole, and secondary aromatic amines, such as phenyl naphthyl amine. Because the rate of oxidation occurs much more rapidly at elevated temperatures, oxidation inhibitors are especially useful for hot metalworking operations, such as the hot rolling of either ferrous or nonferrous metals.

Defoamers. Lubricant foaming can have a deleterious effect on metalworking operations. Foam inhibits tool-workpiece interface cooling, creates a mess if it overflows sumps and tanks, and can even lead to lubricant starvation if excessive amounts of the lubricant mass are in the form of foam. Nearly all water-based metal-working lubricants contain emulsifiers, which not only lower oil-water interfacial tension, but also lower the surface tension of the lubricant compared to water. The surfactants concentrate at the air-fluid interface and form an elastic film that expands, but does not rupture, as air is introduced. Foam is created when air is injected into the lubricant either through spraying at the metalworking operation or through circulation of the lubricant through the lubricant handling system. Small additions of chemical agents, called anti-foams or defoamers, can drastically reduce or eliminate foams. A good defoamer must have the right combination of dispersibility and surface tension. It should spread throughout the system without dissolving in it, and it should spread over the foam surfaces. When this happens, the defoamer acts at the gas-fluid interface to collapse

the elastic film of the fluid, thereby allowing it to release the air and drain. Silicones are very effective defoamers. Their major drawback is that if the workpiece is to be coated or painted in a subsequent operation, adhesion may be adversely affected. Nonsilicone defoamers include long-chain alcohols, certain triglycerides, and water-insoluble polyglycols.

Antimicrobial agents are materials designed to inhibit the growth of bacteria, fungi, and yeast in metalworking lubricants. All water-based metalworking lubricants are vulnerable to attack by one or more of these agents; even oil-based lubricants containing small amounts of water as a contaminant can be degraded by microbes. Attack of metalworking lubricants by bacteria leads to one or more of the following: buildup of acidic materials, corrosion of machinery and tools, destruction of additives, objectionable odors, and loss of stability in emulsions. Growth of fungi can lead to slimy material coating the machinery and tools, as well as the clogging of pumps and filters. Bacteria, fungi, and yeast are often monitored on a regular basis through commercially available simple culture techniques, and when counts reach a certain level, there is cause for alarm.

Microbes can generally be controlled at acceptable levels through use of antimicrobial agents known as biocides and fungicides. Standard practice often calls for the addition of two different biocides to the metalworking lubricant at regular intervals in an alternating fashion, in order to guard against microbes developing an immunity to one of them, resulting in an uncontrolled infestation.

Although many types of biocides exist, two of the most common are phenolic materials and formaldehyde-release agents. Phenolic materials, such as 2,4,5-trichlorophenol, destroy bacteria directly. Materials such as 1,3-di(hydroxy-methyl)-5,5-dimethyl-2,4-dioxoimidazole, upon being added to water-based metalworking lubricants, release formaldehyde slowly to keep bacteria in check. Materials such as 2,2-dibromo-3-nitrilopropionamide are useful for controlling bacteria, fungi, and yeast.

There are over 50 commercially available antimicrobial agents. In choosing the proper one, parameters such as the required concentration, effect on emulsion stability, and regulations concerning discharge into waste streams must be taken into account. Finally, antimicrobial agents are designed to destroy living organisms. They all display some degree of toxicity toward humans and should be handled with caution.

Metalworking Lubricant Types

Four commonly used types of metalworking lubricants are illustrated in Fig. 4. Straight metalworking oils, often simply called straight oils, are given this term because they are not mixed with water prior to use. Emulsions are mixtures of either simple or compounded oils with water, stabilized by the use of emulsifiers. Emulsion droplets are similar in size to, or larger than, the wavelength of visible light; hence, emulsions appear milky white. Microemulsions can be similar to emulsions in composition, but, through emulsifier choice, have oil droplet diameters that are much smaller than the wavelength of visible light and therefore appear transparent. Micellar solutions are similar to microemulsions, except that they contain no oil.

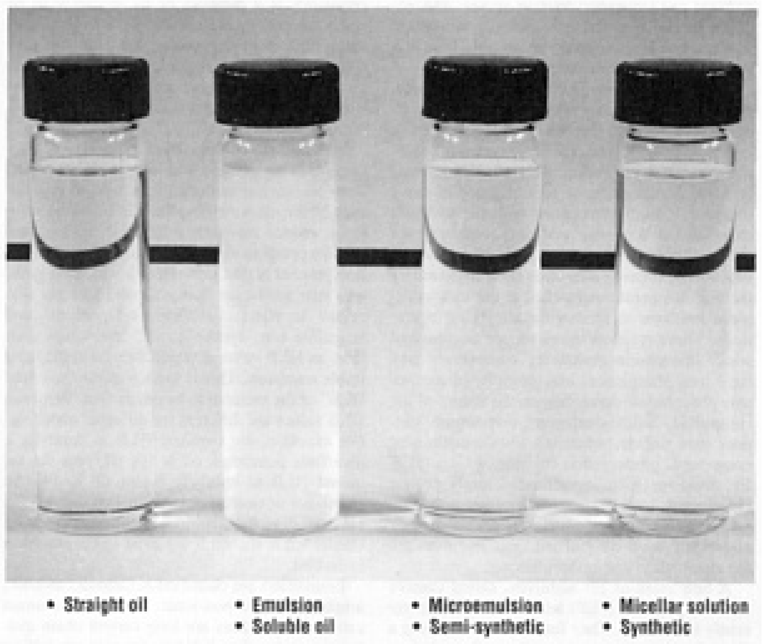

Fig. 4 Commonly used metalworking lubricants

Petroleum oils, as previously defined, are naturally occurring materials that are refined through processes that separate the crude substances into various molecular fractions and remove impurities. In some cases, they are hydrogenated or subjected to reforming catalysts, but are not otherwise chemically altered. The chemical reaction of smaller molecules produces the larger molecules of synthetic fluids, such as poly-α-olefins and polyisobutylenes. In metalworking lubricants, the term synthetic is often used to describe either transparent micellar solutions (Fig. 4) or true solutions containing no petroleum oils. Unfortunately, this dual definition for synthetic lubricant has led to confusion. It should be obvious that if the definition of synthetic lubricant is one that contains a preponderance of man-made materials, then the straight oil, emulsion, or microemulsion of Fig. 4 is, strictly speaking, synthetic, if the base oil is a synthetic fluid such as poly-α-olefin, rather than a petroleum oil.

Straight oils are generally petroleum oil fractions that are normally formulated with either film-strength additives or EP additives or a combination of both. They generally provide excellent friction reduction and workpiece surface finish, good corrosion protection, and a long service life. Straight oils containing certain EP additives will stain nonferrous metals, such as copper, and are commonly referred to as staining oils. The major disadvantage of straight oils is their poor capability for heat removal, compared to water. In addition, straight oils with low flash points, coupled with the high temperatures often encountered in metalworking operations, can create fire hazards. Straight oils are commonly used in metalworking operations where lubrication is a major factor and cooling is a minor factor. Examples of such operations include low to moderate speed metal removal operations where accuracy, tolerance, and workpiece finish are important, and metal forming operations such as aluminum foil rolling where strip surface quality is highly important.

Emulsions. In commonly used metalworking emulsions, oil globules are finely dispersed in water, and this oil-water combination is employed as a lubricant-coolant. In these types of emulsions, oil is said to be the dispersed phase, and water, the continuous phase. Oil-in-water mixtures are thermodynamically unstable; that is, their state of lowest free energy is total separation. Because of this, oil tends to separate, and emulsifiers are added to stabilize the emulsion. Emulsifiers concentrate at the oil-water interface and inhibit coalescence of oil globules. This is illustrated in Fig. 5. The structural formula of sodium oleate, an anionic emulsifier, is shown in Fig. 5(a). A simplified "straight pin" is depicted in Fig. 5(b). An oil-in-water emulsion stabilized by sodium oleate is shown in Fig. 5(c). The hydrocarbon chain of sodium oleate is compatible with the oil globules and penetrates them. The carboxylate head of sodium oleate is compatible with water and lies at the surface of the oil droplet penetrating into the water phase. Because the carboxylate head carries a negative charge, the surface of each oil droplet is negatively charged, and since like charges repel, the oil droplets tend to stay dispersed. Because the state of lowest free energy of the emulsion is still total separation, the emulsion is said to be kinetically stabilized.

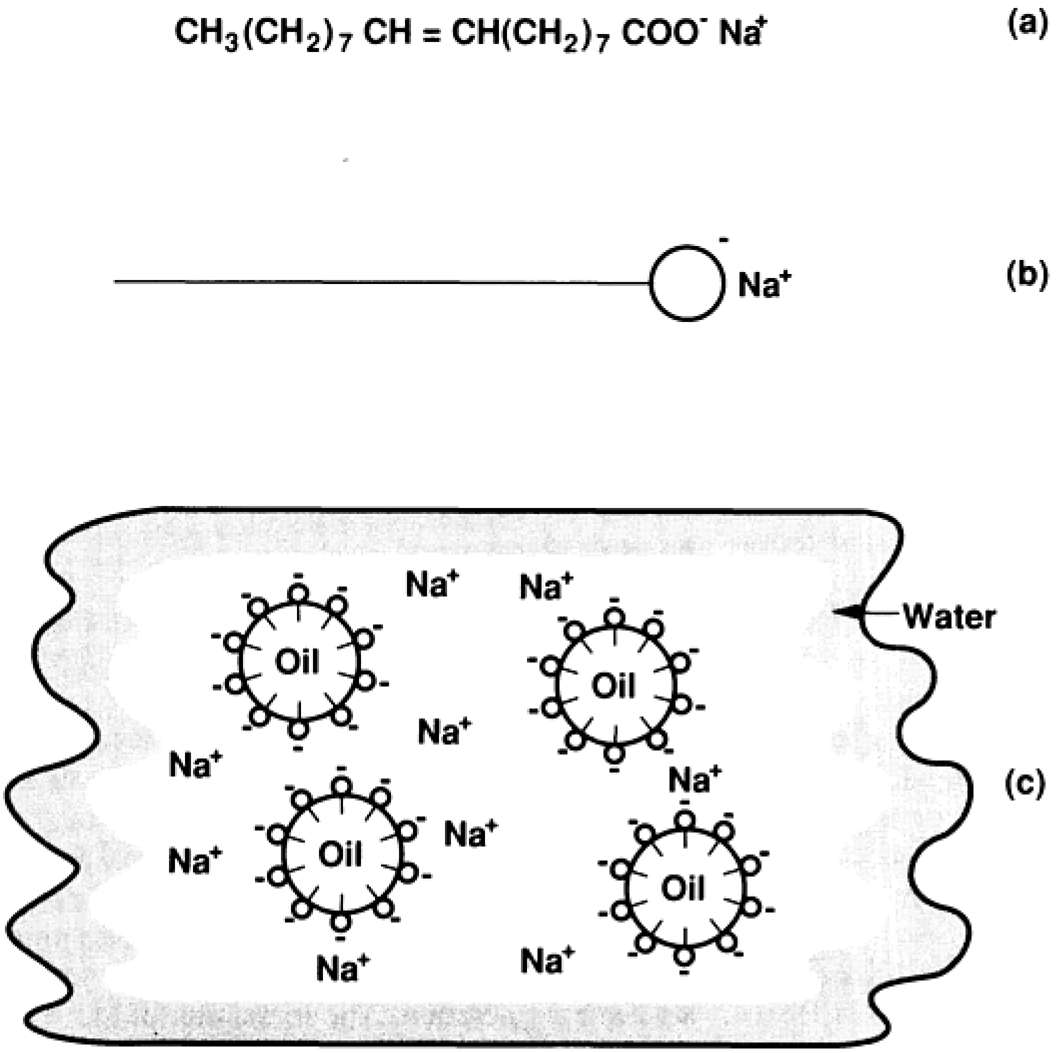

Fig. 5 (a) Sodium oleate. (b) "Straight pin" depiction of sodium oleate. (c) Oil-in-water emulsion stabilized by sodium oleate emulsifier

Emulsions can vary in stability over a wide range, depending on the nature of the oil phase and the nature and concentration of the emulsifier package. Emulsion oil globule size can vary between about 0.2 μm (8 μin.) to as high as 10 μm (400 μin.) or more. Therefore, emulsions appear as off-white to white opaque solutions. The globule sizes within a given emulsion are polydispersed; that is, they vary over some distribution. Stable emulsions have smaller average globule size distributions than unstable ones.

A major factor in lubricating with emulsions is the availability of the oil phase to lubricate. Two factors control oil availability: the emulsion stability and the concentration of oil in the emulsion, which is often called "percent oil." In general, the less stable the emulsion and the higher the percent oil, the greater is the availability of oil for lubrication. Unfortunately, the less stable an emulsion is, the higher is the tendency for stability to change, sometimes rapidly, over time. This can lead to undesirable instability in some metalworking operations, such as rolling. Also, as the percent oil in an emulsion increases, cooling capability decreases. Therefore, the stability and percent oil in an emulsion must be carefully balanced to satisfy the lubrication and heat removal needs of a particular metalworking operation.

The fact that emulsions are kinetically, rather than thermodynamically, stable leads to other factors in their behavior. One of these is called the emulsion "batch life." New emulsions are generally the most stable and have the least oil available for lubrication. Metalworking operations are often not optimal when a new emulsion batch is introduced. Over time, as debris is generated in the emulsion, providing nucleation sites for oil globule coalescence, and as emulsifiers are depleted, the emulsion becomes less stable and performs at its best. At yet a later time, the emulsion becomes so degraded and unstable as to be rendered useless and is discarded. A new batch is introduced, and the process repeats itself. In general,

emulsions that are initially less stable have shorter batch lives. A second factor is the care that must be taken upon introducing foreign substances into the emulsion. For example, introduction of a biocide to combat a microbial infestation or contamination by acids or bases can greatly affect emulsion stability and therefore the consistency of the metalworking operation.

Metalworking lubricant emulsions are often complex mixtures of emulsifiers, film-strength additives, oxidation inhibitors, corrosion inhibitors, and coupling agents. Coupling agents are generally lower molecular weight diols and triols that aid in the initial emulsification. Emulsions can also contain various mixtures of EP additives. The formulated oil mixture is called the concentrate and is added to water with agitation to form the emulsion. The quality of the water is extremely important. Distilled or deionized water should be used whenever possible. Metalworking emulsions generally operate at levels between 5 and 10% oil.

Metalworking emulsions are maintained in a variety of ways. The percent oil is determined by breaking the emulsion in a graduated bottle with an acid or salt solution, and it is maintained by adding new concentrate during the life of the batch. Nonemulsifiable tramp oils (those that have leaked into the metalworking lubricant) are skimmed off, and the emulsion is subjected to continuous filtration to remove fine debris. In the case of metal removal fluids, chips are often removed by mechanical means. Microbe levels are monitored and controlled by the addition of appropriate antimicrobial agents at prescribed intervals. Emulsions have good lubricating and heat removal qualities and are widely used in most metal removal operations and many metal forming operations.

Microemulsions are clear-to-translucent solutions containing water; a hydrophobic liquid, that is, an oil phase; and one or more emulsifiers, which are often referred to as surfactants and co-surfactants. Microemulsions in which water is the continuous phase and oil is the dispersed phase are called oil-in-water microemulsions and are the type generally used as metal-working lubricants. Microemulsions employed as lubricants are commonly called semisynthetic fluids.

Several parameters differentiate microemulsions from emulsions. Most importantly, microemulsions are thermodynamically stable; that is, the state of lowest free energy is dispersed rather than separated. Therefore, the stability problems associated with emulsions are nonexistent. Microemulsions remain stable indefinitely, as long as they are maintained in appropriate ranges of pH, oil-to-water ratio, and temperature. These ranges may be very narrow to very broad, depending of the nature of the microemulsion. The diameters of the dispersed oil globules in microemulsions range from about 0.01 to about 0.2 μm (0.4 to 8 μin.), depending on the nature of the oil and the types and concentrations of emulsifiers. This small oil globule size is the feature that makes them appear clear to translucent. Additionally, the oil globule diameters are much more uniform in microemulsions than they are in emulsions.

Microemulsions are generally produced in the metalworking environment by adding a concentrate to water with agitation. The concentrate generally contains oil, the emulsifier package, film-strength additives, corrosion inhibitors, biocides, and in some cases, EP additives. Dilutions range from about a 10:1 ratio of water to concentrate to as high as 60:1. Lower dilutions are used in operations were lubrication is more important, whereas higher dilutions are used where cooling is more important. Concentration is commonly determined with a hand-held refractometer and a calibration chart that relates the instrument reading to concentration.

Microemulsions offer good resistance to corrosion and to microbial attack, as well as excellent stability and cooling. They suffer from higher initial cost, difficulty of disposal, and a stronger tendency to foam. Microemulsions formulated with fatty acid soap-type emulsifiers tend to degrade rapidly in hard water, because of the formation of insoluble calcium and magnesium carboxylates.

Micellar Solutions. When emulsifier molecules are dissolved in water, they tend to aggregate into larger units called micelles. Micelles are spontaneously formed because of the fact that the lipophilic portion of the emulsifier molecule tends to aggregate in the interior of the micelle, whereas the hydrophilic portion tends to penetrate into the water phase. Figure 6 illustrates, in two dimensions, the relation between a molecule of a typical anionic emulsifier, sodium dodecyl sulfate, and the spherical micelle that it forms in water. Micellar solutions used as metal-working lubricants contain neither petroleum oils nor synthetic hydrocarbons. They contain film-strength additives, EP additives as appropriate, and corrosion inhibitors solubilized within the interior of the micelles. Because micelles have diameters typically between about 0.005 and 0.015 μm (0.2 and 0.6 μin.), micellar solutions are transparent to the eye and, like microemulsions, are thermodynamically stable. Because virtually all of the components of micellar solutions are obtained by chemical synthesis, they are often referred to as either synthetic lubricants or chemical coolants.

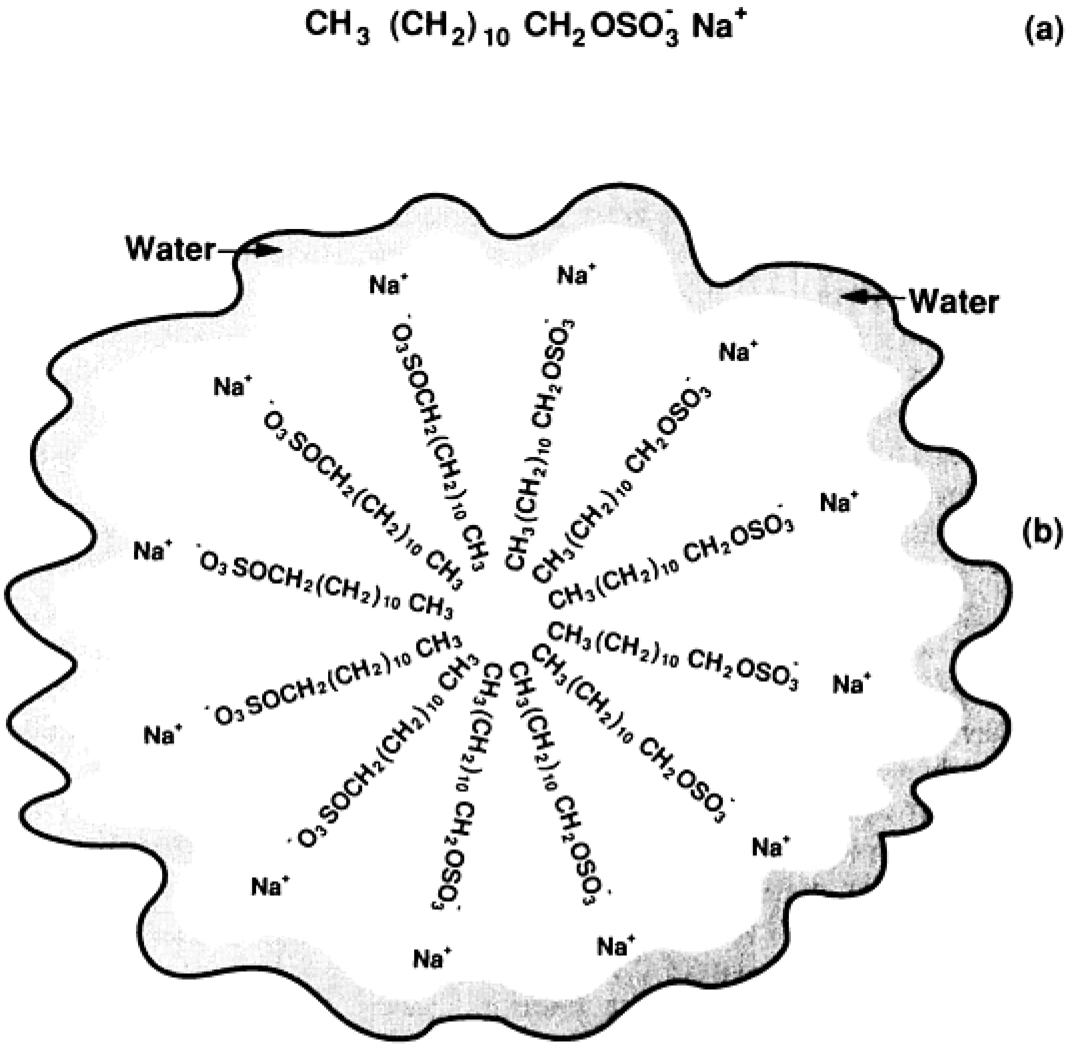

Fig. 6 (a) Molecule of sodium dodecyl sulfate. (b) Sodium dodecyl sulfate micelle in water

Like emulsions and microemulsions, micellar solutions for metalworking are generally formed by the addition of a concentrate to water with agitation. Dilutions typically range from a water-to-concentrate ratio of 10:1 to about 50:1, depending on the application. As in the case of microemulsions, concentration is determined by refractive index.

Micellar solutions that contain no alkali metal soaps or amine fatty acid soaps show good stability in hard water. They are more resistant to microbial attack than either emulsions or microemulsions. They can be formulated to reject tramp oils, which can then be skimmed and collected for disposal or recycling. They have excellent cooling capability, provide excellent corrosion control, and have a long useful life.

On the downside, because micellar solutions tend to cost more initially, a total cost-benefit analysis should be performed. Additionally, because they are highly fortified with emulsifiers, foam can be a real problem. Antifoaming agents can be added to control foam. Micellar solutions, in general, have lower lubricating capability than other types of metalworking lubricants. This limits their applications to those metal removal operations with low tool pressures and high tool speeds where cooling is of paramount importance. In such operations, tool life can be extended as much as 250 ° by using micellar solutions, compared to straight oils. One final drawback is waste disposal. It is often very difficult to separate the organic materials from water, because of their nature. The organic materials tend to remain soluble over wide ranges of pH, temperature, and salt concentration. It is often necessary to resort to sophisticated techniques, such as reverse osmosis, for disposal.

True solutions differ from micellar solutions in that the molecules of active substances do not form micelles when dissolved in water. Rather, each ion is solvated by water molecules. Because essentially all film-strength additives and EP

additives either form micelles or require micelles to dissolve them, true solutions offer lubricating qualities that are little better than those of water.

True solutions are used in cases where cooling is the only consideration. In these cases, their advantages are low cost, very high cooling, stability, low foam, and a very long life. Typical true solutions often contain nothing more than a corrosion inhibitor, such as sodium nitrite, in water.

Solid-Lubricant Suspensions. Lubricants for specialized uses often contain solids in the form of finely divided powders suspended in a liquid carrier, such as oil or water. The liquid carriers may also contain soluble additives of the classes previously mentioned. One of the most common suspended substances is colloidal graphite, with specific surface areas that often exceed 100 m^2/g (3×10^4 ft^2/oz). It is used extensively in hot forging and extrusion of both ferrous and non-ferrous metals. Molybdenum disulfide is another commonly used suspended solid. Both graphite and molybdenum disulfide are compounds that possess layered crystal structures with weak forces bonding the layers together so that they are easily sheared. They function by plating onto tools and workpieces such that the weak shear direction is parallel to the surfaces. As the tool and workpiece surfaces are brought together, they form a solid film, preventing tool-work-piece contact and shear along the weak shear plane, thereby reducing friction.

Other types of solids that are suspended as fine powders in some metalworking lubricants include mica, polymers such as Teflon, certain metal oxides, and glasses. Mica has a layered structure and functions in a way similar to graphite. Polymers mechanically separate metal surfaces, lower friction, and reduce metal transfer. Hard metal oxides, such as aluminum oxide, have good wear resistance but high friction coefficients. Soft oxides, such as lead II oxide, give relatively low friction coefficients that decrease at higher temperatures, where the mechanism of deformation changes from fracture to plastic flow. Glasses are suspended in lubricants for use in metalworking operations at high temperatures, where they soften on hot die and work-piece surfaces and function as parting agents of low shear strength.

Solids can be kept in suspension by using surface active agents, mechanical agitation, or both. Problems can arise if not enough care is taken and the solid is allowed to "settle out." Also, metalworking lubricants containing suspended solids tend to produce buildup on tools and workpieces that are difficult to clean. These problems can be minimized by the appropriate formulation.

Metal Removal Lubricants

A metal removal operation is shown in Fig. 7. In some cases, such as turning, the workpiece is moved against a stationary tool. In other cases, such as drilling, the tool is moved against a stationary workpiece. Either operation results in essentially the same type of metal removal mechanism. The tool cuts into the workpiece, resulting in the formation of a chip. Workpiece metal is deformed in the metal deformation zone, resulting in about 65% of the heat generated in the operation. The remainder of the heat is generated by friction between the tool and the chip, and the tool and the workpiece. The lubricant penetrates the shear zone and reduces heat by reducing friction and carrying heat away from the tool and workpiece. Heat can also be reduced by increasing the shear angle, thereby reducing the amount of metal deformation that occurs.

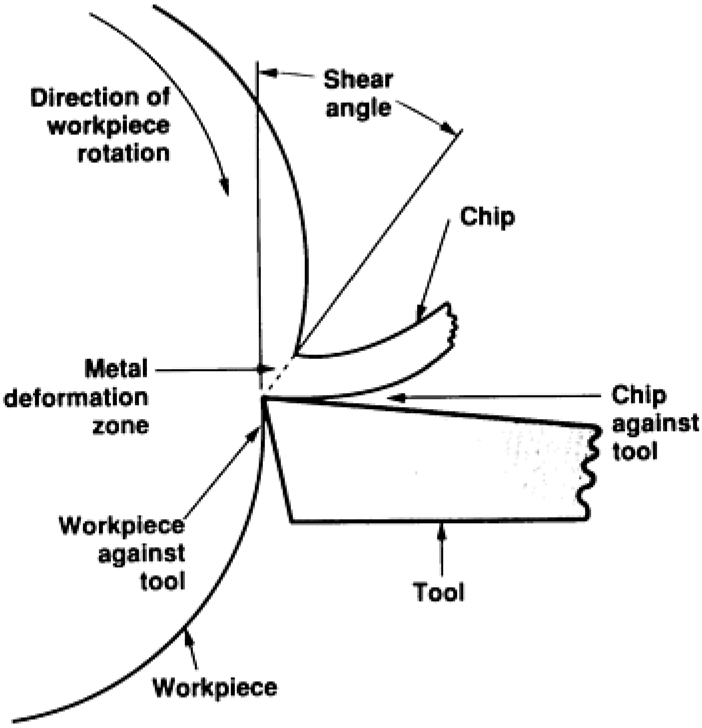

Fig. 7 Metal removal process

One problem that occurs in metal removal, especially with ductile metals, is known as "built-up edge." This problem results when some of the workpiece welds to that part of the tool that is in contact with the chip. Portions of the built-up edge eventually detach, come between the tool and the workpiece, and blemish the workpiece finish. Built-up edge is controlled through film strength and EP additives, which react at the interface to prevent welding, and by choosing an appropriate cutting speed.

In addition to reducing friction and removing heat, the metal removal fluid must flush away chips and debris from the metalworking interface. Unremoved chips can retard the progress of the tool and damage the workpiece. Because a significant amount of the heat generated is located in the chip, removal of the chip is a major factor in reducing heat buildup. An important function in prolonging tool life is reducing and removing heat from the operation.

Selection of metal removal lubricants depends on the operation and on the type of metal composing the workpiece. In operations where low speeds and relatively deep cuts are used, or where workpiece finish and tolerances are important, straight oils are often used. In these cases, lubrication plays a more important role than cooling. Conversely, in high-speed operations with relatively shallow cuts, cooling is most important, and microemulsions or micellar solutions are often employed. Many producers of commercial metal removal fluids provide a fluid selection table with their product literature, such as that shown in Table 1. The table is a matrix with metal removal operations listed in order of decreasing severity on one axis, and various workpiece materials listed on the other axis. The matrix is then filled in with the lubricants recommended for a particular operation and workpiece material. In those cases where the lubricant is dispersed or solubilized in water prior to use, the table often gives the recommended oil:water dilution ratio. In general, straight oils would be more commonly recommended for operations at the top of the table, microemulsions and micellar solutions more commonly recommended for operations toward the bottom, and emulsions recommended over a wide range of operations. However, the recommendations are general, and instances can be found where almost every type of lubricant has been employed satisfactorily in almost every type of operation.

Table 1 Organization of typical metal removal fluid selection chart

Operation severity	Cutting speed	Operation	Ferrous metals	Nonferrous metals
HIGH		Broaching: internal		
		Broaching: surface		
		Threading: pipe		
		Tapping: plain		
		Threading: plain		
		Gear shaving		
		Reaming: plain	Recommended lubricants	
		Gear shaping	and	
		Drilling: deep	recommended dilutions	
		Milling: plain		
		Milling: multiple cutter, hobbing		
		Boring: multiple head		
		Drilling		
		Turning: single-point tools, form tools		
		Sawing: circular, hack		
		Grinding: thread and form		
	HIGH	Grinding: plain		

In addition to this type of table, commercial suppliers furnish information about each lubricant in specification sheets. These sheets customarily contain: recommended uses; physical properties, such as viscosity and specific gravity; staining tendencies on nonferrous metals; and chemical data, such as percent sulfur, chlorine, and fat. Information on materials that are not contained is also provided, such as "contains no nitrites, phosphorus, chromates, or heavy-metal salts." For those materials that are diluted with water prior to use, waste disposal information, such as chemical oxygen demand, biological oxygen demand, oil and grease, and alkalinity, is often given for a particular ratio of water to oil. In addition, commercial suppliers provide material safety data sheets for each lubricant in their product line. These describe potential hazards associated with the use of the lubricant and safe handling procedures, such as required protective clothing like safety glasses and gloves.

Lubricant Application. In most metal removal operations, the lubricant floods both the tool and the workpiece. The lubricant is supplied through high-volume low-pressure spray nozzles to maximize cooling and minimize splashing and foam. The lubricant is customarily directed into the contact zone between the tool and the workpiece. The lubricant is also directed at other positions on the workpiece, where appropriate, to enhance cooling. In Fig. 7, for example, lubricant would be directed into the contact zone to reduce friction, prevent metal transfer, and facilitate cooling. Lubricant would also be sprayed over the back of the chip to further enhance cooling.

Lubricant Maintenance. Lubricants can be maintained through a variety of practices. In water-based coolants, tests for percent oil, pH, tramp oil contamination, suspended solids, microbes, and corrosion are made on a regular basis, and corrective action is taken as required. For example, an increase in pH beyond a specified range might signal contamination by a very basic substance. On the other hand, a decrease in pH might be due to oxidation, microbial infestation, or contamination by an acidic substance. Corrective action could involve adding an oxidation inhibitor, adding a biocide, or finding and eliminating sources of contamination.

During their use, metal removal fluids become contaminated with metal chips and fine debris, such as metal particles and insoluble metal oxides. If not removed, these contaminants can accelerate degradation of the coolant by promoting oxidation and, in the case of emulsions, providing nucleation sites to destabilize the coolant. These contaminants can also damage the workpiece when circulated back to the contact zone. Metal chips are generally allowed to settle and are then removed. The use of centrifuges can accelerate this process. Fine debris is usually removed by filtration, often in two stages. The first stage involves filtration by paper or cloth to remove coarser debris, followed by filtration through filter aids, such as diatomaceous earth or fine volcanic ash, to remove fine debris.

The leakage of hydraulic oils and other lubricating oils (tramp oils) into a metal removal fluid is very detrimental. In the case of straight oils, tramp oil contamination can change the viscosity and dilute the additive package. In the case of emulsions, tramp oils are often emulsified and increase the oil globule diameters and destabilize the emulsion. Some emulsions and many microemulsions and micellar solutions reject tramp oils. In these cases, the tramp oils are removed by skimming.

Reclamation and Disposal. In metal removal operations, lubricant adheres to the chips and is available for reclamation. The chips are moved to a central location with care to segregate chips that come from operations employing different lubricants. The oil can be collected simply by allowing the lubricant to drain from the chips and collecting it. The use of a centrifuge accelerates the process and results in more complete removal of oil. The oil is then cleaned by filtration, as required, and returned to operation.

Most metal removal fluids in use will reach a point in time at which they can no longer be maintained and must be disposed of. No metal removal fluids should be released into the environment without prior treatment. Petroleum oils, natural fats, and greases, as well as synthetic organic materials, are contained in most metal removal fluids. These materials, when released into streams and rivers, float on the water and thereby slow the adsorption of oxygen from the air into the water. In addition, they consume oxygen in the water through direct oxidation and by promoting the growth of bacteria that consume oxygen as they metabolize. Because aquatic organisms require oxygen for survival, they will die if any substantial amount of that oxygen is depleted by the processes noted. There are strict state and federal laws that regulate disposal of metal removal fluids into streams and rivers, with heavy fines for violators.

Spent straight oils are often added to heavier fuel oils and burned to generate heat or power. Emulsions and some microemulsions, as a first step, are treated with acids or salts to separate the organic phase, which is skimmed off. In a second step, the water is then sent to aerated tanks containing aerobic bacteria, where remaining organic materials are consumed. Most plants using large amounts of metal removal fluids have facilities to carry out at least the first step. The water from first-step treatment is often clean enough to be sent to municipal waste treatment systems, where the second step occurs. Small amounts of microemulsions and micellar solutions that resist breaking in the first step can generally be sent directly into the second step as long as their organic content does not overwhelm the system. A third step is sometimes used when the effluent from the second step does not meet water quality standards for discharge. This third step may include such processes as reverse osmosis, chemical oxidation, or oxidation by ozone. Waste from more concentrated microemulsions and micellar solutions can be effectively treated by these methods.

A complete metal removal fluid program, including fluid selection, maintenance, handling, reclamation, and waste disposal, is a vital part of a metal removal operation. Such a program can increase profitability by reducing lubricant costs, allowing increased feeds and speeds, reducing tool wear, and improving workpiece finish, while being environmentally responsible.

Metal Forming Lubricants

In metal forming operations, the desired shape of the workpiece is obtained through plastic deformation. Most metal forming operations employ liquid lubricants consisting of petroleum oil or synthetic oil fortified with additives. These lubricants form films that partially or completely separate the tool from the workpiece, thereby reducing friction and minimizing metal transfer. In many metal forming operations, cooling is also desirable. Therefore, the use of emulsions, and in certain cases, microemulsions and micellar solutions, is common. Certain metal forming operations also use solid suspensions.

Lubricant films in metal forming operations are either "wedge films" or "squeeze films." Wedge films result when two nonparallel surfaces converge under relative motion in the presence of a lubricant. Both surfaces may be in motion, as in the case of rolling, or just one surface may be in motion, as in the case of wire drawing. Squeeze films result when two parallel surfaces approach each other with a liquid lubricant between them. An example of a metal forming operation that develops a squeeze film is an open die forging method called "upsetting."

Wedge Films. Most metal forming operations that employ liquid lubricants develop wedge films. When surfaces converge under relative motion, the lubricant is swept along the moving surface. As the surfaces approach each other, a gap in the form of a wedge develops. Consequently, the entry of the gap is greater than the exit. As lubricant molecules approach the gap entry, they are slowed because the volume they are permitted to occupy is decreasing. Because the number of lubricant molecules that enter and exit the gap must be the same, the molecules exiting the gap are moving faster than the molecules entering the gap, and indeed are moving faster than those molecules prior to approaching the gap entry. The forces that cause the entry lubricant molecules to decrease in velocity and the exit lubricant molecules to increase in velocity also act to push the surfaces apart.

In metal forming operations, the minimum separation between the tool and workpiece surfaces is referred to as the lubricant film thickness, h. For a given operation, h increases as the velocity of the operation and the viscosity of the lubricant increase, and decreases as the force driving the converging surfaces together increases. In rolling, for example, h

increases with the entry velocity of the strip and with the viscosity of the rolling lubricant, but decreases at a given viscosity and entry velocity as reduction increases. Because the viscosities of lubricants increase dramatically at high pressures and decrease at high temperatures, the viscosity that in part controls *h* is that viscosity in the tool-work-piece inlet zone. The viscosity of naphthenic oils, for example, increases at a greater rate with pressure than does that of linear paraffins. Therefore, in a metal forming operation, a naphthenic oil will produce a larger *h* than a linear paraffin with an identical viscosity at 40 °C (104 °F) and an identical viscosity index.

Squeeze films are formed when two parallel surfaces are brought together at some velocity. In operations such as upsetting, squeeze films increase in thickness as both lubricant viscosity and approach velocity increase. Higher viscosity retards lubricant flow from the contact zone, and high approach velocities seal the tool-workpiece edges more effectively, thereby entrapping the lubricant between the tool and workpiece. As workpiece deformation occurs and the surface expands, the squeeze film becomes thinner. Therefore, the thickness of squeeze films is proportional to viscosity, velocity, and force in the same way as that of wedge films, but for different reasons.

Lubrication regimes are defined by which attribute of the lubricant supports the load, that is, modifies friction and reduces metal transfer. In full fluid film lubrication, there is no contact between the tool and workpiece, and force is transmitted from the tool to the workpiece through the lubricant film. In this case, the lubricant film supports the load. In the thin-film regime, there is partial contact between the tool and the workpiece, and both the lubricant film and the film strength or EP additives support the load. In the boundary regime, contact between the tool and workpiece is essentially the same as if there were no lubricant film at all, and the film strength or extreme pressure additives alone support the load.

Rules of thumb exist that relate the ratio, λ, of film thickness to the combined roughnesses of the surfaces, σ, for rigid surfaces. The combined roughness is defined as the sum of the random roughness amplitudes of the two surfaces measured from their average levels. In general, for $\lambda = h/\sigma \leq 0.5$, operation is in the boundary regime. For $0.5 < \lambda \leq 3$, operation is in the thin-film regime, and for $\lambda > 3$, operation is in the full fluid film regime. In metal forming operations where the workpiece is being plastically deformed and the tool is often elastically deformed at the contact zone, λ for each regime is smaller than the values given above. Friction is highest when operating in the boundary regime and lowest in the full fluid film regime. Many metal forming operations start up in the boundary regime and, as operation velocity and therefore thickness increases, move into the mixed film regime and even into the full fluid film regime. Many operations, such as rolling, operate in the thin-film regime when at operational run speed, and a proper balance of lubricant viscosity and additive package is essential.

Friction. Control of friction is very important in most metal forming operations. Figure 8(a) depicts an upsetting operation where a cylindrical billet (B) is being deformed between two dies (D) with an applied force (F). The arrows on the die denote the direction of applied force, whereas the arrows on the workpiece denote the direction of frictional force. Figure 8(b) shows what the deformed billet would look like if friction were absent. The maximum deformation is obtained for a given force, and the walls of the deformed billet are straight. Figure 8(c) shows what the deformed billet would look like in the presence of friction. Because frictional force opposes the flow of the workpiece, at the same applied die force, less deformation occurs. Additionally, the sides of the deformed billet are bulged, rather than straight.

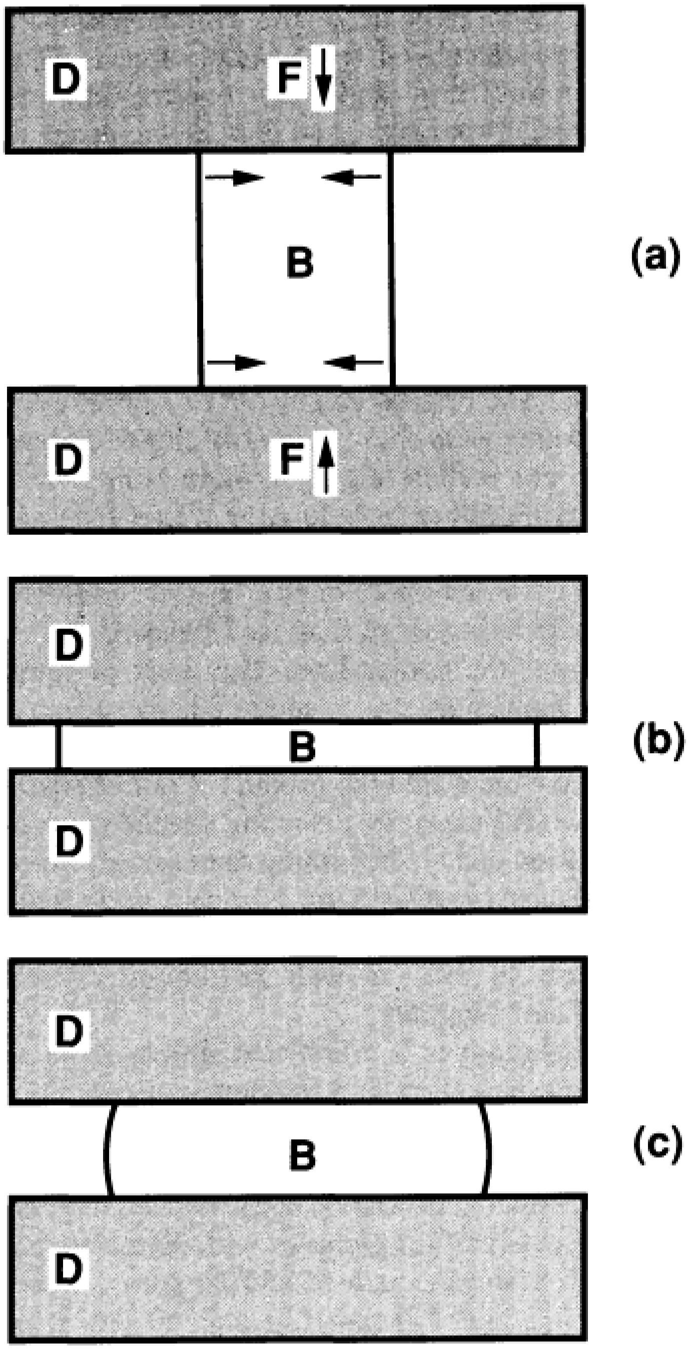

Fig. 8 (a) Billet between two dies. (b) Deformation in the absence of friction. (c) Deformation in the presence of friction. B indicates billet.

Figure 9(a) depicts deformation of strip by a cold rolling process. Metal enters the contact arc at velocity V_1 and exits the contact arc at velocity V_2 and with a reduced thickness. The small arrows along the contact arc denote the direction of frictional force. In rolling, the strip enters the contact arc at a velocity slower than the velocity of the work rolls, and friction is in the direction of metal flow. As strip thickness is reduced in the contact arc, strip velocity increases until it and the work roll velocity are identical. This point is called the neutral point. After the neutral point, further strip reduction occurs, and the velocity of the strip is higher than the velocity of the rolls. Once past the neutral point, frictional force is in the opposite direction of metal flow. Figure 9(b) depicts the pressure distribution within the contact arc in the absence of friction. The area under the curve represents the total pressure required to deform the strip. The pressure generally increases throughout the contact arc, because of strain hardening of the metal, and is therefore higher on the exit side than the entry side. Figure 9(c) illustrates the pressure distribution within the contact arc in the presence of friction.

For the same deformation, the pressure is increased by area A because additional pressure must be exerted to overcome frictional force.

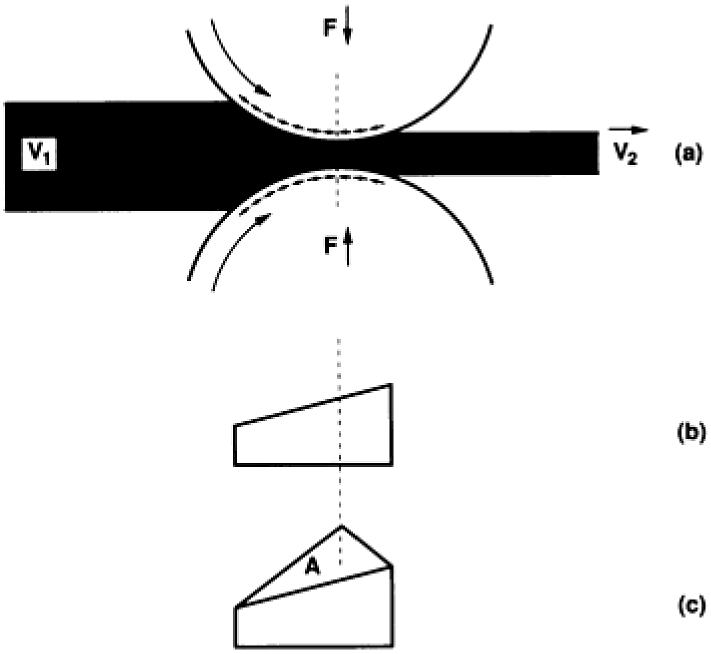

Fig. 9 (a) Deformation of strip by cold rolling. (b) Pressure in contact arc in the absence of friction. (c) Pressure in contact arc in the presence of friction. F is force, A is area.

It should be obvious from these two examples that control of friction in metal forming operations by selection and use of proper lubricants is very important. Friction highly influences power requirements, force requirements, degree of deformation, and operational stability.

Selection of lubricants varies widely depending on the particular metal forming operation and the nature of the workpiece. In the case of ferrous metals, straight oils or emulsions containing fatty materials, as well as extreme pressure additives, are often used. Aluminum metal forming lubricants are commonly straight oils or emulsions compounded with fatty acids, esters, or alcohols. Synergistic blends of these additives are often used. In some cases, such as the body-making operation in the formation of aluminum beverage cans, microemulsions or micellar solutions are successfully used. Lubricants similar to those used for aluminum are successful for copper and copper alloys. Straight oils and emulsions formulated with fatty derived film-strength additives are used. Titanium and its alloys are difficult to form because of the high forces required and a tendency to seize and gall. The surface of titanium is often subjected to surface treatments such as oxidation, nitriding, or cyaniding to lower friction and minimize seizing. Halogenated hydrocarbons, especially fluorocarbons, are effective lubricants for titanium metal forming. Two specific examples of lubricant selection for metal forming are discussed below.

Aluminum Rolling Lubricants. A typical path used to produce commercial aluminum strip begins when a large preheated and scalped ingot enters into a hot reversing mill. The ingot can be several hundred millimeters thick and weigh several thousand kilograms. It is passed back and forth through the reversing mill, often from 15 to 19 times, and its thickness is reduced to about 30 mm (1.2 in.). The sheet is then sent to a hot continuous tandem mill that contains from two to six stands. Here, it is rolled to a gage from 2 to 5 mm (0.08 to 0.2 in.), typically, by employing understand and exit tensions, and then coiled. The coil is typically annealed, allowed to cool, and is then cold rolled on single-stand or multistand mills, under tension, to a gage of about 0.3 to 0.9 mm (12 to 36 mils). Annealing between cold passes to achieve properties is a common practice. The coil is then sent to finishing and prepared for sale.

Because the ingot is not under tension at the reversing mill and large drafts in excess of 30 mm (1.2 in.) per pass are often taken, a major concern is the refusal of the ingot to enter the mill. Reversing mill lubricants are formulated to give high friction to minimize the incidence of refusals, often at the expense of workpiece surface quality. The goal of a reversing mill lubricant formulator is to produce a product that avoids refusals while giving the best possible surface quality.

Typical reversing mill lubricants are very stable emulsions that contain petroleum sulfonate and, often, nonionic emulsifiers with low levels of film-strength additives. The concentrate typically contains oxidation inhibitors, corrosion inhibitors, and antifoaming agents, as well as coupling agents to aid emulsification. Typical concentrate viscosity is about 100 mm^2/s (100 cSt) at 40 °C (104 °F).

At the hot continuous mill, refusals are much less a problem, and surface quality of the workpiece is much more important; therefore, relatively unstable emulsions with more available oil are used. These provide lower friction, but much better surface quality than reversing mill emulsions. Typical lubricants contain petroleum oils and either anionic or non-ionic emulsifiers, and are highly fortified with fatty acid and triglyceride film-strength additives. The concentrate also typically contains the other additives mentioned for reversing mill emulsions and would have a viscosity up to 100 mm^2/s (100 cSt) at 40 °C (104 °F). Because hot continuous mill emulsions are relatively unstable, they have shorter batch lives and are more prone to stability excursions than reversing mill emulsions. Therefore, they must be carefully monitored. The typical percent oil in both hot reversing and continuous mill emulsions is 5%.

Surface quality is of paramount importance in a cold rolling operation. Typical lubricants are straight petroleum oils compounded with small amounts of fatty acids, esters, or alcohols. Typical viscosities range from 3 to 7 mm^2/s (3 to 7 cSt) at 40 °C (104 °F) and are much lower than hot rolling viscosities, because of the lower temperatures.

Rolling oils are maintained through filtration, monitoring of various parameters, and adding components, as required. In the case of the hot mill emulsions, a standard operating procedure for monitoring microbial growth and making biocide additions is also followed.

Steel Warm Forging Lubricants. It is common practice to forge steels over a wide range of temperatures. Cold forging is carried out at ambient temperature, warm forging from about 200 to 700 °C (390 to 1290 °F) and hot forging from about 900 to 1250 °C (1650 to 2280 °F). The choice of temperature employed depends on a balance between sufficient ductility for required formability and the dimensional tolerance required in the forged workpiece. Ductility increases with increasing temperature, whereas dimensional tolerance decreases with increasing temperature. Warm forging often gives an acceptable compromise between ductility and dimensional tolerance.

When forging is performed at room temperature, the billet is commonly subjected to phosphating, in which a zinc phosphate film that aids retention of a soap lubricant is produced. Stainless steels cannot be phosphated, and oxalate films are often used.

At forging temperatures between 400 and 850 °C (750 and 1560 °F), phosphate coatings are ineffective because of oxidation, and are not used. Because molybdenum disulfide begins to oxidize at these temperatures, graphite is the lubricant of choice. Graphite is commonly dispersed in either a water or oil carrier, and is held in suspension by agitation, as well as by either emulsifiers or polymers. Other materials, such as finely divided oxides of tin or lead, can also be present. The lubricant is normally applied to the dies and billet by spraying as a fine mist to ensure complete coating.

Several factors are important for consistent lubrication. The structure, purity, and particle size of the graphite affects results. Large particles have poor film-forming properties, whereas small particles reduce the threshold temperature of graphite oxidation. Particles below about 0.1 μm (4 μin.) become ineffective, because of loss of graphitic structure. Other important factors that require control are the consistency of suspension and the total percent solids.

Handling and Control. It should be evident from the two examples given that lubricant practices are different for dissimilar processes. In the rolling example, the lubricant is reused many times, and issues of handling and control are similar to those already described for metal removal fluids. In the forging example, the lubricant is consumed and destroyed by the process, and the initial composition parameters are controlling factors. The next section in this article briefly addresses modern lubricant practices in terms of quality measures.

Quality

The manufacture of a consistent product requires a consistent process. It should be evident that lubrication is a major factor in metalworking processes, and often plays a dominant role in process consistency. Variability in metalworking lubricants arises from many sources. Incoming lubricant shipments often show batch-to-batch variability in viscosity, additive levels, and interfacial tension, which affects performance. Lubricants in use undergo changes that are due to oxidation, thermal degradation, microbial attack, contamination, and additive depletion.

There are two sources of variation in a process or product. Common sources normally consist of the combined effect of many minor causes and affect the process or product uniformly. Products with variations that are due only to common sources have predictable attributes. Processes with variation that are due to common causes alone produce predictable outputs and are said to be stable. All processes and products have some level of common-source variation.

Special sources of variation affect products and processes in nonuniform ways. They occur in an erratic and unpredictable fashion and are often due to a limited number of significant causes. Products with variations that are due to special causes have unpredictable attributes, whereas variations in processes that are due to special causes yield unpredictable outputs and are therefore unstable, or "out of control."

It has been typical practice to attempt to control metalworking lubricant attributes by setting specifications on incoming supplies and on the lubricants in use and by testing lubricants against these specifications on a regular basis. However, metalworking lubricants can meet all specifications and still be beset by variations that are due to special sources, consequently leading to inconsistent and unstable operations.

Statistical Methods. Statistical process control and statistical quality control use basic statistical tools to detect and reduce special variations in processes and products. Commonly used statistical methods include control charts, histograms, scatter diagrams, and Pareto diagrams. Each is briefly discussed below.

Control charts have many forms, depending on the nature of available data and the parameter to be monitored. A typical control chart, known as an *x*-bar chart (Fig. 10), shows the variation in viscosity of incoming shipments of a rolling oil additive. The chart is based on large samples of measured viscosities for this product. The center line, $\overline{\overline{x}}$, is an estimate of the average viscosity over time calculated from sample means. The upper control limit and lower control limit are calculated statistically such that the incidence of random chance causing the viscosity of a shipment to be outside either limit would occur only 0.3% of the time. When viscosities of shipments lie outside the control limits, the viscosity for individual batches is not predictable, and, by inference, the process used to produce the oil is unstable. The process can be out of control even when points lie within the control limits. Examples would include eight or more consecutive points lying above or below the center line, six or more consecutive points increasing or decreasing in magnitude, or two or three consecutive points lying more than two standard deviations from the center line. The odds of these events happening by random chance are extremely small; therefore, special sources of variation have crept into the product. Control charts are powerful tools for detecting special sources of variation and are becoming increasingly common. Many metalworking lubricant users keep control charts on incoming shipments and on the lubricants in use, as well as request control charts from suppliers.

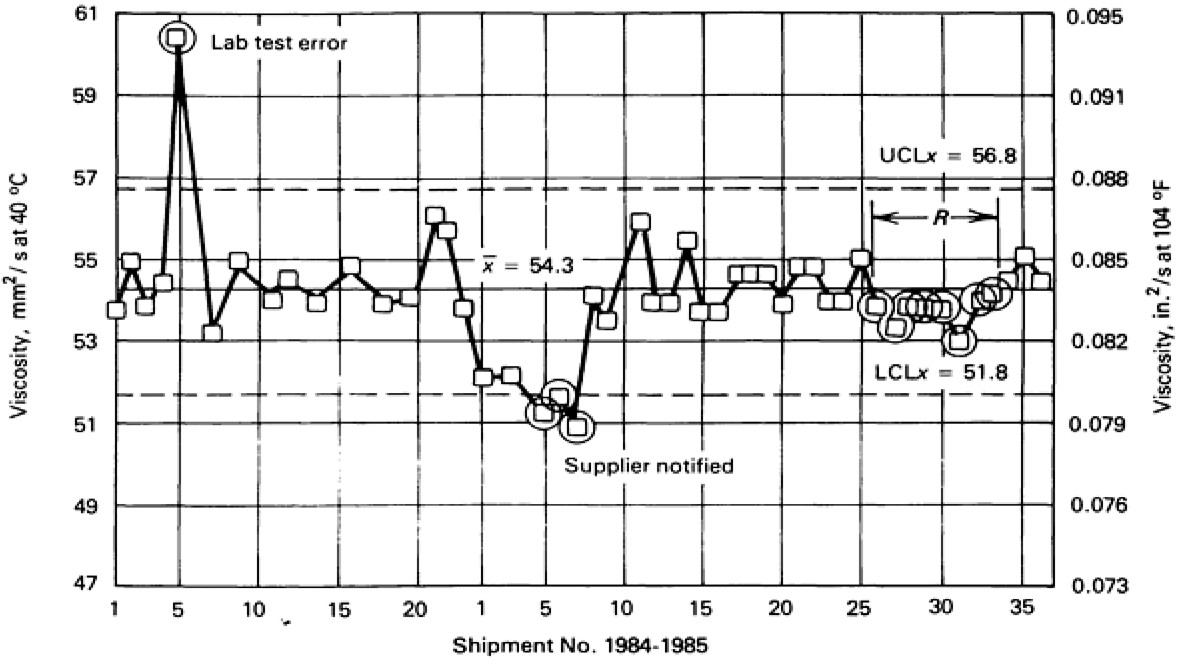

Fig. 10 *x*-bar control chart for viscosity of incoming lubricant shipments

A histogram is a graph that utilizes bars to represent the values in a frequency distribution. In an emulsion, for example, oil globule size can vary between about 0.2 and 10 μm (8 and 400 μin.). A histogram can be constructed that gives the frequency of oil globules with diameters between 0.2 and 0.5 μm (8 and 20 μin.), or between 0.5 and 1.0 μm (20 and 40 μin.), or between 1.0 and 1.5 μm (40 and 60 μin.), for example. With this visual depiction of the frequency of oil globule distribution, a lot of information can be gleaned. It can be determined whether or not the distribution is normal. The average globule size can be determined, along with the spread of the distribution. The difference between the same emulsion under different chemical conditions, pH for example, or at different times also can be determined. Additionally, the variation in oil globule size between emulsions supplied by different sources can be pictured.

A scatter diagram is used to detect the correlation between two variables. If a cause and effect relationship is suspected, then the independent variable is plotted along the abscissa, and the dependent variable is plotted along the ordinate axis. If, for example, observed variation in tool wear in a turning operation was suspected to be due to variation in the concentration of an EP additive, then tool wear would be plotted on the ordinate and EP additive concentration on the abscissa. Often, it is possible to determine if a correlation exists by observing the graph. Statistical methods are available for determining the degree of correlation. Just as control charts are useful in determining whether or not special sources of variation are present, scatter diagrams are useful in determining what those sources are.

Pareto Diagram. In operations where rejections occur, there are generally multiple causes. A Pareto diagram indicates which source of rejections should be solved first. It is really a frequency diagram in the form of a bar chart with the largest source of rejections plotted first, the second largest source plotted second, and so on. Pareto diagrams are made such that the largest source of rejections is plotted on the left, and the smallest, on the right. A lubricant supplier might, for example, want to know the reason for customer complaints and loss of business in a soluble oil line over the past year. Records may show that instability, low viscosity, unacceptable foam, and rust accounted for 100% of the complaints. Further investigation could determine the frequency for each complaint. A Pareto diagram that illustrates that the major cause of complaints was low viscosity, followed by instability, unacceptable foam, and rust in decreasing frequency could be constructed. The diagram visually exposes the relative magnitude of complaints, providing a base of uniform knowledge from which to solve the problem. It also can be used to validate and assess the impact of corrective action.

Total Quality Management. Statistical quality control is one set of tools useful in implementing the larger concept of total quality management or total quality commitment. Other tools include quality function deployment, continuous improvement, statistical experimental design, and problem-solving quality teams. In the future, metalworking lubricant suppliers will have commitment to a continuous and measurable reduction of variation in their processes and products. They also will have a strong focus on all aspects of customer satisfaction. Metalworking lubricant users are beginning to demand these as their customers press them for the same improvements in their products and processes.

Lubricants for High-Vacuum Applications

Michael R. Hilton and Paul D. Fleischauer, Mechanics and Materials Technology Center, The Aerospace Corporation

Introduction

THE SELECTION CRITERIA and performance of lubricants in the vacuum environments that exist in terrestrial equipment and both in and around space vehicles are described in this article, as are the vacuum, mechanical, and thermal conditions of such lubricant use. The tribology issues that should be considered in the initial design of systems used in terrestrial equipment or space vehicles are also defined. The types of vacuum lubricants that are available (dry or solid, liquid, or grease) are reviewed, their properties and applicability to general situations are assessed, and the option of not lubricating is discussed. Examples of specific applications and performance data for lubricants in space and on earth are presented, as well.

Scope of the Problem

The pressures (vacuum) to be considered for lubricant performance range from 1.3×10^{-2} Pa to 1.3×10^{-10} Pa (1×10^{-4} to 1×10^{-12} torr). This range encompasses vacuum systems used for thin-film deposition or materials processing (base pressure of 1.3×10^{-4} Pa, or 1×10^{-6} torr, or higher) and for surface science experiments (1.3×10^{-9} Pa, or 1×10^{-11} torr, or higher). Although deep-space vacuum can reach the 10^{-12} Pa (10^{-14} torr) range, near-earth orbits have higher pressures, perhaps 1.3×10^{-6} Pa (1×10^{-8} torr). Continual outgassing within a space vehicle is estimated to expose any internal mechanism to a pressure of 1.3×10^{-5} Pa (1×10^{-7} torr) or lower (Ref 1). Externally exposed mechanisms in low-earth orbit (less than 483 km, or 300 miles) may experience atomic oxygen bombardment with an apparent flux of 10^{7} to 10^{16} cm^2/s (Ref 2).

A potential problem created by these vacuum levels is that conventional liquid lubricants, which usually have relatively high vapor pressures ($\geq 1.3 \times 10^{-4}$ Pa, or 1×10^{-6} torr, at room temperature) and surface diffusion coefficients ($\geq 1 \times 10^{-8}$ cm^2/s, or 1.5×10^{-9} $in.^2/s$) with low surface tensions ($\sim$0.018 to 0.030 N/m, or 18 to 30 dyne/cm), can either volatilize or creep away from the area of mechanical contact. The result is high friction, wear, or mechanical seizure.

The volatility problem can cause lubricant vapor pressure to limit the achievable vacuum baseline of the system. Further, this problem can cause the lubricant to migrate to and condense on (that is, contaminate) sensitive surfaces, such as solar cells, optics, or the material to be probed in a surface science experiment. However, the volatility problems of liquid lubricants can be circumvented by design features that include proper confinement geometries, or by using new synthetic oils that have extremely low vapor pressures, or both. These two solutions are reviewed in the section "Types of Vacuum Lubricants" in this article.

Another potential tribological problem created by vacuum stems from the removal of reactive gases, particularly water vapor, oxygen, and some carbonaceous species, that are present in the atmospheric environment. Normally, these reactive gases chemically passivate the near-surface region (1 to 5 nm, or 0.04 to 0.2 μin.) of most materials, especially metals, significantly inhibiting the welding (adhesion) of surfaces upon contact. These passive layers are often brittle and are worn away during mechanical contact.

The presence of reactive gases in the atmosphere continually repassivates the material, but, in vacuum, such repassivation can be inhibited or eliminated. Therefore, the force of adhesion between freshly exposed metal surfaces will be quite strong upon contact. The joined areas will only separate by fracture, generally accompanied by material transfer from one surface to another. This process of adhesive wear results in the consumption of extra power to drive the mechanism (with possible total prevention of any motion) and degrades the dimensional tolerance of the mechanism components, causing mechanical noise (for example, torque hash, vibration) in precision systems. Thus, contacting metal surfaces that might not require lubrication in atmospheric conditions may require antiseize lubricants to prevent cold-welding in vacuum.

Ceramics also can be lubricated by carbon-containing reactive gases. However, along with semiconductors and polymers, ceramics are not as susceptible to the "cold-welding" phenomenon as are metals.

There are two categories of systems in which ultrahigh-vacuum lubricants are needed: systems in terrestrial vacuum chambers and systems in space vehicles. The first category includes chambers used for surface science experiments; analytical instruments, such as electron microscopes; thermal vacuum testing chambers; thin-film deposition chambers; and other materials processing equipment primarily used in the semiconductor industry. Such systems often have manipulators to move objects within the most critical vacuum region. Contamination by the lubricant is a prime issue for terrestrial vacuum systems, whereas lifetime is a lesser concern, because the lubricant can be periodically replaced by breaking vacuum.

In space vehicle systems, human intervention is essentially impossible (except infrequently, when a satellite in low-earth orbit can be retrieved by a manned shuttle). Therefore, both lifetime and contamination are of great concern.

Although the conditions of mechanical contact in vacuum systems are varied, some generalizations can be made. Because most mechanisms do not operate continuously, there are periods of boundary contact (when lubricant film thickness is less than the contacting surface roughness) between component surfaces. Similarly, boundary contact also develops when oscillating mechanisms change direction. In such situations, the chemical interaction of contacting surfaces, often modified by the presence of lubricants, is critically important.

Both sliding and rolling elements are designed into vacuum systems. Each element requires proper consideration of lubricant specification to prevent cold-welding, to promote low-torque noise performance, and to ensure adequate service life. Other mechanical parameters that are important in the design of moving assemblies and in the selection of the proper lubricant include the expected loads and contact stresses, the geometry of the contact (the conformity of the surfaces and the possibility of lubricant confinement), and the relative velocities (rotational speed) of the contacting surfaces.

Temperatures encountered by vacuum components usually range from 0 to 75 °C (32 to 165 °F), although mechanisms within infrared sensors are cryogenically cooled. Lubricants that function above 200 °C (390 °F) are beyond the scope of this article. Interested readers are referred to other sources (Ref 3, 4, 5).

Another possible condition for lubricants in vacuum is the requirement for electrical conductivity. Some satellites maintain attitude stability by spinning the entire vehicle while the antennas and sensors are continually despun to allow them to remain pointed at fixed objects. Other satellites have rotating panels of solar cells that track the sun to maintain constant power and to keep batteries charged. Electrical signals and power must be transmitted across a rotating interface, which consists of sliding wipers that have a conductive lubricant. This issue will be explored later in the text.

Yet another condition is the possible use of high-speed bearings in satellite systems, such as those in fly wheels used for momentum stabilization and in turbomachinery (rocket motors). Because of frictional heating in such bearings, lubricants (usually oils or greases) are required that can conduct heat efficiently among rolling elements and maintain low overall operating temperatures. (The unusual case of liquid hydrogen and liquid oxygen pumps, as used in the space shuttle main engines, involves solid lubrication of the bearings with fluid, or fuel, coolants. The involvement of the fluids in lubrication is probably minimal).

Ideal Tribological Situations and Considerations

Tribology often does not receive sufficient and timely consideration during the design phase of a mechanical system that is to function in vacuum. Such inattention can convert an expensively fabricated mechanism into scrap material, increasing system cost and causing schedule delays. This section of this article reviews the ideal or desirable characteristics of tribological contact in vacuum, as well as the general principles involved in achieving these characteristics.

The ideal characteristics for lubricants in vacuum are:

- Low vapor pressures
- Acceptable lubricant creep or migration (including little or no lubricant debris formation)
- Long life (meeting system service life with margin)
- Low friction (including low power consumption, low heat generation, low disturbances, and low torque noise)
- No wear/no significant deformation
- Temperature insensitivity
- Suitable electrical conductivity

Low Vapor Pressure. As stated previously, low vapor pressures are desirable to prevent lubricant loss away from the region of mechanical contact, which can lead to mechanism seizure, and to prevent contamination of critical surfaces. Conventional mineral oils, even those that are super refined, or molecularly distilled, consist of a broad distribution of molecular species. The lighter-weight members of the distribution, which can be significant in number, are volatile and result in a moderately high vapor pressure ($\sim$1.3 × 10^{-4} Pa, or 1 × 10^{-6} torr) for the oil. Generally, 20 to 30% of such an oil will evaporate before the vapor pressure drops significantly (Ref 6).

Conversely, synthetic hydrocarbon oils, such as poly-α-olefins, neopentyl polyolesters, and other tailored polymers, are made with very narrow distributions of molecular weights. Therefore, both vapor pressure and viscosity are controlled to give optimum values. Less than 3% of these oils evaporates in a high-vacuum chamber at elevated temperatures (pressure $\geq$1.3 × 10^{-4} Pa, or 1 × 10^{-6} torr, at 100 °C, or 212 °F).

Additives included in oils to provide antiwear or antioxidation protection usually have higher evaporation rates and vapor pressures than the base oils themselves. Such differences can cause problems, because if the additives evaporate, they can become sources of contamination and deplete the base oil of protection. Solid lubricants generally have negligible vapor pressures relative to liquid lubricants.

Acceptable Lubricant Creep or Migration. Another phenomenon that can cause problems similar to those of high vapor pressures is surface diffusion, or creep, of the liquid lubricant away from the contact region. Creep is associated with characteristically low (0.018 to 0.030 N/m, or 18 to 30 dyne/cm) surface tension of the lubricant on the component surface. Such low surface tension is desirable, because it promotes wetting. Therefore, creep is generally countered at the system design level by including antimigration barriers, as discussed in the section "Types of Vacuum Lubricants."

Extremely low surface tension ($\sim$0.018 N/m, or 18 dyne/cm), and, therefore, significant creep problems are encountered with synthetic perfluorinated polyalkylether oils. These oils have been used extensively in spacecraft because they can have even lower vapor pressures than the above-mentioned synthetic hydrocarbons. However, the hydrocarbons are preferred in many applications, because problems with creep are considerably reduced and they can be formulated with additives to produce far superior lubricants. Although not in common use at present, another class of oils known as silahydrocarbons (Ref 7, 8) offers potential advances for vacuum uses.

For solid lubricants, there is a similar concern about the presence and migration of particles generated from detached film debris. This possible problem is not well documented. Therefore, line-of-sight barriers and the effects of gravity should be considered to contain particle migration. In space, particulate motion may be exacerbated by the lack of gravity. On earth, prudent designers should locate mechanisms below critical surfaces or operations, allowing gravity to pull particles away harmlessly.

Long Life. A lubricant must have a long operational life to be considered successful. However, long life in this sense is relative to the anticipated service life of the mechanism. The point is that a lubricant should be chosen that has an adequate endurance life (including a reasonable safety margin) and not necessarily the best endurance life, because other performance properties and design issues also have to be considered.

Low Friction and Wear. Low friction is important to vacuum mechanisms, in order to reduce the consumption of power, which is supplied to spacecraft by batteries and solar cells, and is therefore finite. Low friction also reduces heat generation. For mechanisms that are controlled either electronically or in a feedback loop, a stable ("hash-free") friction coefficient (low noise) is particularly important to maintain proper control. In spacecraft, attitude control is maintained by momentum transfer mechanisms (control moment gyroscopes, momentum wheels, or reaction wheels) or by spinning most of the vehicle. Variable friction of the bearings at the despin interface can cause the vehicle to wobble or tumble.

Lubricants that promote low friction also retard wear and the plastic deformation of contacting surfaces. Such wear and deformation can lead to loss of component tolerance, which, in turn, can cause increased torque noise and/or variable torque levels, or outright mechanism failure. At the atomic level, reducing friction is synonymous with minimizing chemical bonding between contacting surfaces.

There is a positive relationship between friction and chemical reactivity; the friction coefficient of metals against themselves in vacuum correlates with the position of the metal on the periodic table (Ref 9). For example, the d-shell metals on the left side of the table, which are more reactive, have been found to have higher friction coefficients. Thus, it is desirable for the surfaces of contacting components to have low chemical reactivity. The lubricant modifiers surface composition to achieve this reduced reactivity. In unlubricated situations, low surface reactivity favors the selection of either polymers or ceramics.

Ceramics are particularly interesting because their bonding properties not only yield lower surface reactivity, but higher elastic modulus and strength characteristics. The latter two properties help resist deformation and irreversible loss of tolerance. The designer should only select component materials that have elastic limits greater than the operational stresses of the mechanism to avoid plastic deformation or fracture and subsequent loss of component tolerance.

The ideal tribological contact can also be viewed from the macroscopic continuum perspective. For example, the friction coefficient between unlubricated or dry lubricated surfaces is (Ref 10):

$$\mu = (\tau_s)\,(A)/W \qquad \textbf{(Eq 1)}$$

where μ is the friction coefficient, τ_s is shear strength of the weakest material or interface, A is the true contact area, and W is the normal contact load. The τ_s is related to kinetic friction force, F_k, by:

$$F_k = (\tau_s)\,(A) \qquad \textbf{(Eq 2)}$$

For a Hertzian contact in which a smooth sphere is sliding against a flat surface, Eq 1 can be rewritten (Ref 11):

$$\mu = (s/W)\,(3R/4E)^{2/3} \qquad \textbf{(Eq 3)}$$

where R is the radius of the contacting sphere and E is the effective modulus of the contacting materials. For a given load, the use of a lubricant or surface modification process that reduces the shear strength of the interface will reduce friction. If the lubricant film or surface-modified region is thin, the load is supported primarily by the substrate. Increasing the substrate modulus decreases the contact area for a given load, which also reduces friction.

The designer can vary the surface composition of components either directly or by placing lubricants on the contacting surfaces, as will be discussed in the section "Types of Vacuum Lubricants" in this article. Component sliding can, in

principle, occur by the shear or relative motion of atoms along only two adjacent contacting lattice planes. Thus, the above atomistic and macroscopic arguments mean that the ideal contact consists of a thin surface zone (including the lubricant, if present, and component surfaces) having low shear strength (or low reactivity), with the bulk material(s) of the components providing a high-modulus, underlying support. The ideal surface zone or lubricant film thickness has been found to be between 0.5 and 1.0 μm (20 and 40 μin.) (Ref 11).

Temperature Insensitivity. Lubricants must provide acceptable friction performance within the operational temperature limits of the system. Solid lubricants generally have less temperature sensitivity than liquids and greases. Again, the designer must remember to consider all lubricants that have adequate temperature characteristics for the given application, and not necessarily to choose the lubricant with the best temperature characteristics. The thermal conductivity characteristics must also be viewed with similar criteria.

Suitable Electrical Conductivity. For most mechanical contacts in vacuum, electrical conductivity across the contacting surfaces and through the lubricant is not an issue. However, conductive lubricants are required in sliding electrical contacts found in many space systems. These contacts transmit power and signal between different spacecraft sections that move relative to each other, that is, motion often occurs between the main body of the spacecraft and other subsystems, such as solar cell arrays, antennas, and sensors. As will be discussed below, solid-lubricant composites are frequently used.

Types of Vacuum Lubricants

Three types of lubricants are used in vacuum environments: solid (dry), liquid, and grease. There is also a fourth approach, which is to use no lubricant at all, but to rely instead on the low reactivity of the contacting surfaces. The component materials have to be carefully chosen and, perhaps, have their surface compositions modified to lower reactivity. Descriptions of most solid and liquid space lubricants, as well as conditions for use, are given in Ref 12, which is a comprehensive treatise that should be consulted before choosing a vacuum lubricants. This section defines and reviews the available lubricants, and assesses their favorable and unfavorable properties. Whenever appropriate, methods of application or processing are included.

Solid (Dry) Lubricants. There are four types of solid, or dry, lubricants available for vacuum applications: soft metals, lamellar solids, polymers, or other soft solids (Table 1). Composites of these four lubricant types or combinations of one or more of them with matrix or support materials are also available.

Table 1 Potential solid lubricants for use in vacuum

Soft metal films
Au, Ag, Pb, In, Ba
Lamellar solids
Dichalcogenides (MoS_2, WS_2, $MoSe_2$)
Pthalocyanines
$CdCl_2$, $PbCl_2$
Intercalated graphite
Boron nitride
Polymers
PTFE, FEP, polyacetal, polyimide
PEEK, UHWPE
Phenolic and epoxy resins
Other low shear strength solids
Oxides: Cd, Co, Zn
Sulfides: Bi, Cd
Fluorides: Ca, Li, Ba, rare earths

Source: Ref 13

The major advantages of solid lubricants, as indicated in Table 2, are that they have negligible vapor pressures and some are quite insensitive to temperature. Therefore, they are the only lubricants suitable for cryogenic and high-temperature applications. Accelerated testing is valid for solid lubricants if the same wear mechanism is operative at different test

speeds (which can be verified by microscopy). Because space missions often exceed 5 years, accelerated ground testing becomes essential for the qualification of new lubricants. Generally, solid lubricants have lower friction coefficients in vacuum than greases, and can have lower friction coefficients than liquids. For example, MoS_2 films have been developed with friction coefficients lower than 0.1. Although Teflon has been listed as the material with the lowest friction coefficient known, at 0.02 (Ref 14), MoS_2 films can have considerably lower values, as low as 0.007 under the right conditions (Ref 11).

Table 2 Relative merits of solid and liquid lubricants for use in vacuum

Dry lubricants
Negligible vapor pressure
Wide operating temperature
Negligible surface migration (debris can float free)
Valid accelerated testing
Short life in laboratory air[(a)]
Debris causes frictional noise
Friction speed independent
Life determined by lubricant wear
Poor thermal characteristics
Electrically conductive
Wet lubricants
Finite vapor pressure
Viscosity, creep, and vapor pressure all temperature dependent
Seals required
Invalid accelerated testing
Insensitive to air or vacuum
Low frictional noise
Friction speed dependent
Life determined by lubricant degradation
"High" thermal conductance
Electrically insulating

Source: Ref 13

(a) Depends on type and matrix; for example, some polymers and bonded solids, especially graphite, behave well in air.

The major disadvantage of solid lubricants is their shorter lifetime relative to liquids or greases. Once a solid lubricant is pushed out of the contact zone, lubricant resupply generally does not occur (except for transfer film schemes, as described shortly), as it does for liquids or greases. Also, failure is quite abrupt (catastrophic, compared to graceful failure observed for most fluid lubricants), often with no prior performance degradation visible. The solid lubricant that is pushed out of the contact zone forms debris, which can, in turn, form bumps and lead to torque disturbances in precision bearings or become unwanted particulate material.

Solid lubricants can be applied by rubbing (burnishing) a power or a solid block of lubricant against a component surface, resulting in transfer of the lubricant to the critical surface, or by applying the lubricant as a thin film to the component prior to mechanism use. The rubbing approach can be used to develop a source of lubricant resupply if some portion of the mechanism is fabricated from the lubricant. Ball-bearing cages (retainers) made of polymer-based composites or of leaded bronze have been used in this way. The disadvantage of the rubbing approach is that lubricant transfer can be sporadic or nonuniform, yielding lubricant bumps or bare regions on the contacting surfaces. For precision mechanisms, unacceptable torque noise can result.

Solid-lubricant films can be applied by either rubbing or burnishing, although careful procedures have to be followed to maximize even coverage. Another alternative that is used for lamellar compounds is to mix the lubricant with a binder and a solvent and apply the mixture by dipping, painting, or spraying. The resulting bonded films often require air or heat curing after application. Bonded films are generally several micrometers thick, which often does not allow for the lowest possible friction of low shear strength materials, and which is dimensionally unsuitable (too thick) for many precision components. However, the bonded-film technology is well established and is quiteeffective and appropriate for many low-cycle applications that cannot tolerate seizure (Ref 12, 15).

Another approach to applying thin films of dry lubricants is to use vacuum deposition techniques for uniform coverage of components in precision systems. When film thickness is less than 1 μm (40 μin.), low and steady friction is obtained, as shown in Fig. 1 (Ref 16). For precision mechanisms, the films can be applied by sputtering, ion plating, or other ion beam assisted techniques to obtain even, controlled lubricant coverage. Ion cleaning of the substrates prior to deposition can be used to improve film adhesion to the components. A major disadvantage of solid lubricant thin films is that there is no means of lubricant resupply. Therefore, lubricant endurance life relative to system service life is of prime importance when considering solid lubricants.

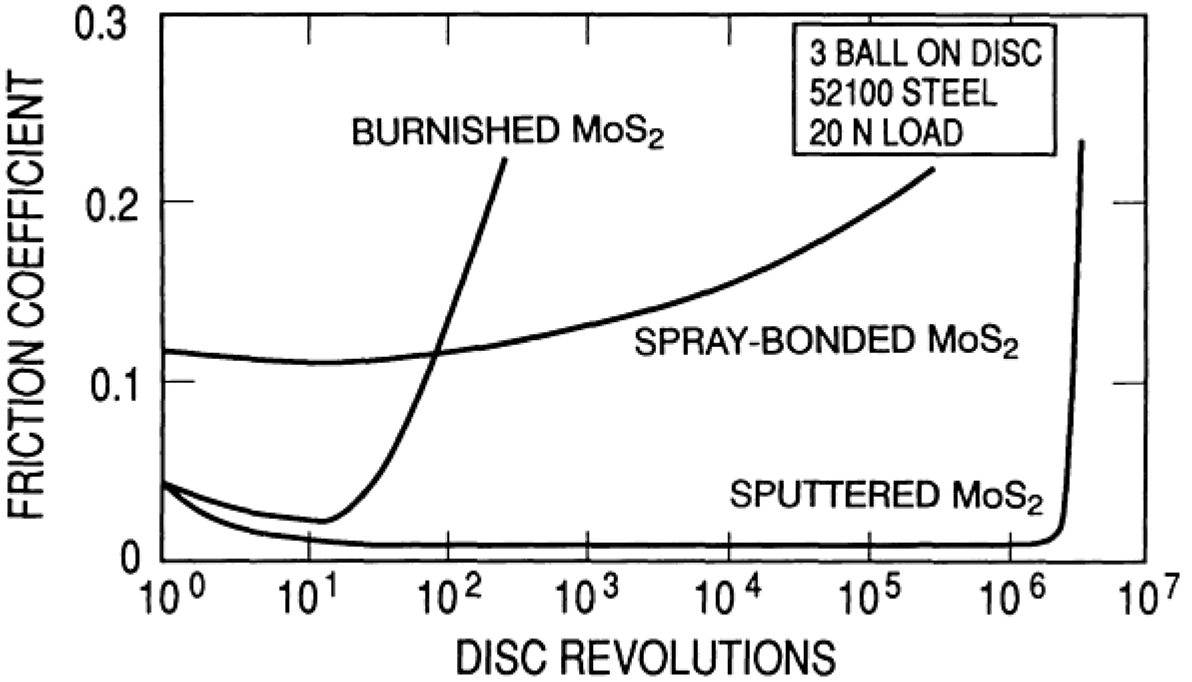

Fig. 1 Friction coefficient of various types of MoS_2 as a function of cycles in pin-on-disk tests. Source: Ref 16

Soft metals, including lead, gold, silver, and indium, have all been used as lubricants in vacuum applications (Ref 17). Of these metals, lead has had the most success and use. Burnishing and electroplating have been used to apply lead. However, deposition by ion plating provides the best adhesion and is preferred for uniform coverage. Optimum performance of lead and other metals is achieved at approximately 1 μm (40 μin.) thickness. Ion-plated lead films have been particularly effective in spacecraft bearings found is solar array drive mechanisms, especially in European satellites. Silver and gold are useful in situations requiring electrical conductivity. However, silver is generally too hard for most applications, and gold work-hardens quite easily. Lead remains soft at room temperatures, and evidence indicates that it can lubricate at 20 K (Ref 17).

Lamellar solids that are in relatively wide use as lubricants include the disulfides and diselenides of Mo, W, Nb, and Ta. Graphite is also a lamellar solid lubricant, but the pure material is not suitable for vacuum applications, as will be discussed below (Ref 5, 15). Some other doped or intercalated layered solids have been investigated for their lubrication properties, but they are not in wide use (Ref 18). The anisotropic, planar crystal structures of lamellar solids provide low-shear planes for lubrication. These solids also have high load-bearing capacity when compressed in a direction perpendicular to their low-shear planes. This load-bearing capability is an advantage of lamellar solids, compared to solid polymer lubricants.

Of the lamellar solids, MoS_2 films deposited by sputtering have been the most widely investigated and developed, since early in the space program (Ref 19, 20) and especially since the late 1980s (Ref 11, 21, 22, 23, 24, 25). MoS_2 films have a lower friction coefficient than lead films ($\leq$0.01 versus 0.1 in vacuum, respectively), which lowers mechanism torque and power consumption (always a concern on spacecraft). MoS_2 films are also superior to lead films in pure sliding applications. Sputter-deposited MoS_2 has superior endurance and a lower running friction coefficient than either burnished or bonded MoS_2, as shown in Fig. 1.

The performance of sputter-deposited MoS_2 is critically dependent on film microstructure, which includes composition, morphology, crystallinity, and preferred orientation (Ref 19, 26). These properties, in turn, are very dependent on deposition conditions; the presence of water vapor during deposition is a particularly insidious variable (Ref 27). The general trend in film development in recent years has been the production of dense films with low porosity, because porosity leads to large-scale film debris generation early in wear (Ref 26). Most films grow with their low-shear basal planes perpendicular to the substrate. Reorientation of the basal planes to a parallel alignment with the substrate occurs during wear.

Stress-induced crystallization has also been observed after sliding wear in some dense films that were disordered as-deposited (Ref 28). There are several deposition practices that can yield these dense films, including high growth rates (Ref 23), low deposition pressures (Ref 24), ion bombardment during film growth (Ref 29, 30), and the incorporation of dopants (Au, Ni, water vapor) that are either co-sputtered continuously (Ref 26, 27, 31, 32) or deposited as multilayers (Ref 33). Some of these films have an initial preferred orientation of low-shear basal planes parallel to the substrate.

MoS_2 is very sensitive to water vapor, although not as sensitive as polyimides, which are discussed in the next section. If MoS_2-lubricated components are stored in a humid environment, significant oxidation will occur over months, forming MoO_3, which is an inferior lubricant (Ref 34). This storage problem is especially relevant for satellites (and vacuum mechanisms) that are assembled at least a year before launch (use). Satellites containing MoS_2 have to be stored in dry, inert-gas environments until shortly before launch.

In fact, there are often several environmentally sensitive materials on satellites that mandate controlled storage. However, recently developed MoS_2 films that have dense morphologies may have better storage oxidation resistance, although no oxidation data are currently available. Such storage has the added benefit of better maintenance of vehicle cleanliness, although the moisture issue can cause some contention, because electrical systems often prefer a moderate relative humidity to prevent static electrical discharges.

MoS_2 does not lubricate as well in a humid environment as in vacuum, where friction coefficients decrease and endurance increases (Ref 15). Indeed, MoS_2 performs at its best in vacuum. [If a MoS_2-coated components rests in vacuum, then water vapor will deposit and slightly oxidize the top surface over time. The extent of oxidation depends on the vacuum level. An initially higher friction will be observed. However, the oxidized layer is quickly removed by either frictional heating and volatilization or by being pushed aside. The underlying MoS_2 exhibits a lower friction coefficient than the top surfaces (Ref 17, 25)].

With regard to water vapor effects, MoS_2 is a direct complement to graphite, which is an excellent lubricant in atmospheric environments. However, the low shear strength of graphite is critically dependent on the intercalation of absorbed gases, especially water vapor (Ref 35, 36). At pressure below $\sim 10^{-2}$ Pa (10^{-4} torr), such gases desorb from graphite, and its friction coefficient dramatically rises. Intercalated graphite compounds that work well in vacuum have been developed (Ref 5). These compounds are not widely available and so far have only been applied by burnishing or used in bonded films (Ref 37).

Although other disulfides and diselenides have been considered for vacuum applications, none of them have the endurance of MoS_2. Although, MoS_2 is a semiconductor, it is routinely used for sliding electrical contacts. $NbSe_2$, which is a semimetal in its natural state, should, in principle, be better for this application. Unfortunately, $NbSe_2$ is not a good lubricant in semimetallic form. It becomes a good lubricant only when it is intercalated with electron donor atoms (which could be excess Nb atoms), whereupon it also becomes a semiconductor (Ref 22).

A widely used additive for liquid lubricants in automotive applications is WS_2, which also performs well at higher temperatures and is more oxidation resistant than MoS_2. Although WS_2 has been deposited by impact under high air pressure in one commercial process, experience has shown that it should be considered primarily as an antiseize compound for limited-use (low-cycle) vacuum applications. Sputter-deposited films of WS_2 or WSe_2 codeposited with MoS_2 can have properties comparable to, or even better than, sputtered MoS_2 films (Ref 38, 39). However, MoS_2 is much more common and generally has superior endurance in vacuum applications.

Polymers and Polymer Composites. Polymers, consisting of anisotropically bonded (highly linear) molecules, can provide low friction surfaces in vacuum, if the molecule chains align properly at the contacting surface. However, because the load-bearing capability of polymers is generally low, additives are required to strengthen the polymer to avoid ploughing into the bulk.

For vacuum applications, polymer composites, rather than pure polymers, are generally used (Ref 40, 41). Because these composites have structural integrity, self-lubricating composite components can be fabricated that can, in principle, provide a continual source of solid lubricant to critical components.

To date, polytetrafluoroethylene (PTFE) has been the polymer used the most in vacuum. This is because PTFE performs well in vacuum and in the presence of absorbed vapors. However, PTFE has a tendency to cold-flow under load, necessitating a binder to restrain the polymer bulk, that is, to prevent ploughing. Some polyimides appear to be excellent in vacuum because they exhibit low friction coefficients without significant cold-flowing of the bulk (Ref 42). However, polyimides are very sensitive to water vapor absorption. Water molecules appear to hydrogen bond to the polymer molecules and then inhibit molecular shear. Thermal pretreatment of polyimides appears to be essential for good performance in vacuum.

Polymer composites include other materials that are added for several reasons: to increase load-carrying capacity, to lower the friction coefficient and promote a low wear rate, and to increase thermal conductivity. Table 3 lists polymers and additives that can be included in self-lubricating composites. Both fibers and particulate additives can be used, although fibers are more effective for increasing composite load-carrying capacity. Studies indicate that, in some composites. MoS_2 facilities polymer transfer to a critical component; the polymer is the primary lubricant, not the MoS_2 (Ref 22, 43).

Table 3 Plastics and fillers for self-lubricating composites

Material	Maximum useful temperature	
	°C	°F
Thermoplastics		
Polyethylene (high MW and UHMW)	80	175
Polyacetal (homo- and co-polymer)	125	255
Nylons (types 6, 6.6, 11)	130	265
Poly (phenylene sulphide)	~200	390
Poly (tetrafluoroethylene)	275	525
Poly (*p*-oxybenzoate)	300	570
Thermosetting		
Phenolics	~150	300
Cresylics	~150	300
Epoxies	~200	390
Silicones	~250	480
Polyimides	~300	570
Reinforcements		
Glass fibers	. . .

Table 4 lists some available self-lubricating composites and their possible uses in space. When a polymer composite is selected for an application, contact stress is probably the most important property to consider. The ideal composite must

support, in the bulk of the material, the dynamic stresses of the application, and must allow for the formation, by local deformation, of a low shear strength layer at the surface.

Table 4 Self-lubricating composites and possible uses in space

Composite type	Use
PTFE/glass fiber	Bearing cages
PTFE/glass fiber/MoS_2	Bearing cages, gears
Ployacetal homopolymer/co-polymer	Bearing cages, gears, bushings, brakes
Reinforced phenolics	Bearing cages, gears
Polyimide/MoS_2	Bearing cages, gears
PTFE/woven glass fiber/resin	Bushings
PTFE/bronze sinter	Bushings, rotating nuts

Nonpolymer-based Composites. Two examples of nonpolymer-based composites are particularly worthy of attention. Leaded bronze composites, as one example, have been fabricated into bearing retainers (Ref 11, 17). When used in conjunction with lead-coated bearings (for example, in solar array drive mechanisms), the lead in the retainers provides an effective supplemental source of lead when the original film is worn. Additionally, composite blocks of silver, MoS_2, and either graphite (Ref 44) or copper (Ref 45, 46) are used as brushes in sliding electrical contacts. The silver provides conductivity and structural integrity, the MoS_2 lubricates in vacuum, and the graphite or copper may lubricate in air.

Liquid Lubricants. Examination of Table 2 would suggest that the merits of solid lubricants frequently exceed those of liquid lubricants in vacuum applications. However, liquid lubricants are often used in space applications, particularly on U.S. systems. In the early years of the space program, liquid lubricants were understood better than solid lubricants. Thus, mechanisms were engineered to make low vapor pressure liquids work in vacuum applications (Ref 36, 47). Early success with liquids slowed the incorporation of solid lubricants in U.S. space systems. In contrast, European-designed space systems have often incorporated solid-lubricant technology as it has evolved (Ref 13).

The primary advantage of liquid lubricants over solid lubricants is their long life in high-cycle applications, such as in gyroscopes. Long life results because liquid lubricants can be resupplied and they have low frictional noise in bearing applications. Another advantage is that liquid lubricants have high thermal conductance, which may assist in managing thermal stability on spacecraft. However, for terrestrial vacuum systems, these advantages often do not outweigh the disadvantage of potential contamination from fluids. Therefore, in terrestrial vacuum systems, the use of modified surfaces and/or lubrication by solids or greases is the preferred approach for manipulators and other mechanisms.

A particular disadvantage of liquid lubricants for space applications is that accelerated testing, while desirable, is difficult because of the synergistic dependence of lubricant properties, such as film thickness, on operational parameters, such as contact speed, load, and temperature. It is reasonable to compare the performances of two or more different fluid lubricants in tests in which operational conditions are intentionally more severe than for the expected application. But extreme care is required in the selection of the parameters to be accelerated, and specific acceleration factors should never be quoted for an application without complete theoretical justification. Such justification would have to involve a rigidly verified, mechano-chemical model for determining operational life of the system (or component) of interest.

For space applications, contamination and lubricant loss are minimized by proper lubricant selection and mechanism design. Low vapor pressure lubricants do exist, as shown in Table 5 and Fig. 2. Their lubrication properties will be discussed subsequently. If a component is not entirely sealed, lubricant loss by vapor transport is generally diminished by incorporating molecular seals, often of a labyrinth geometry (Fig. 3), into the bearing design (Ref 44, 47). Contamination, via vapor transport, of critical surfaces away from the tribocontacts can also be avoided by the use of vents into space, pointed away from critical surfaces and away from the leading (front) edge of the vehicle.

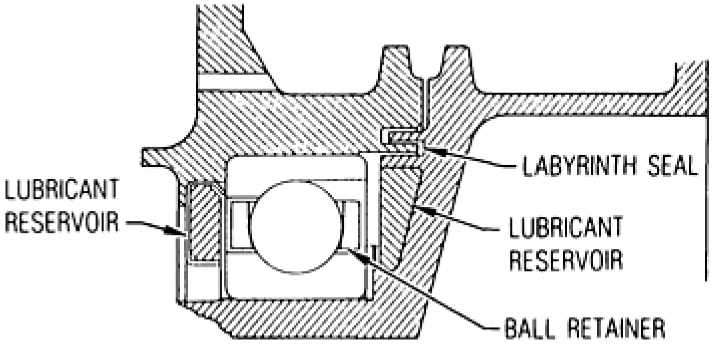

Fig. 3 Schematic of a bearing configuration showing a labyrinth seal. Source: Ref 47

The pumping speed of space vacuum is essentially infinite. There are no surfaces to reflect gas molecules back to the spacecraft. However, processes have been proposed involving photoelectric charging of emitted molecules and reattraction or collision with "ambient" molecules in the vicinity of a spacecraft and redirection toward critical surfaces (Ref 48, 49, 50). Lubricant migration by creep can be countered by anticreep barriers that are primarily made of ultralow surface energy (~0.011 N/m, or 11 dyne/cm) fluorocarbon coatings (Ref 51).

If lubricant loss does occur, either a passive or positive-feed resupply method is required. The passive method generally uses lubricant-impregnated porous solids. Oil is provided to a contact region as long as there is some positive driving force (heat or centrifugal force) to overcome the capillary forces of the porous medium. Oil-soaked phenolic retainer materials were once thought to be lubricant resupply sources for bearings. However, both theoretical and experimental studies have shown that such materials can act as sinks, further depleting the lubricant supply unless they are properly saturated with oil. This saturation process can actually take years to complete at ambient temperature (Ref 44, 52). Porous nylon-based materials, polyimides, and copolymer foams of acrylonitrile have been used as reservoirs in several mechanisms, but they can be subject to the same potential problems as phenolic retainer materials.

The positive-feed method uses positive-feed suppliers with centrifugal oilers or controlled pumps. This method has been used for higher-load (requiring larger bearing sizes) and/or longer-life mechanisms.

Several categories of liquid lubricants that either have been or could be used for vacuum/space applications include: silicone oils, mineral oils, perfluoropolyalkylethers, and other new synthetics (including poly-α-olefins, polyolesters, and multiply-alkylated cyclopentanes). Except for gyroscope applications, these lubricants generally encounter boundary contact conditions at some time during their service life. Boundary lubrication additives are available for many of these lubricants and will be reviewed after the base stocks are discussed.

Silicone Oils. The low vapor pressures and low pour points of some silicone oils led to their early use in space applications. However, these oils are only moderately effective lubricants. One problem is that some of these oils tend to form polymers on the bearing surface, which leads to torque noise. Another problem is that these oils creep readily on metal surfaces. Because of these problems and the availability of better alternatives, silicone oils would not be used on contemporary spacecraft. However, these oils are used as damper fluids and thermal conduction media in some instances.

Mineral oils that are highly refined have been a popular choice for sealed mechanisms, such as momentum wheels, reaction wheels, and despin mechanisms. Mineral oils from numerous manufacturers have been used successfully (Ref 12). A series of super-refined gyroscope lubricants is also available. These lubricants comprise a homologous group of natural polymers that allows the designer to choose a fluid having particular viscosity characteristics for a specific application (Fig. 4) (Ref 53). Mineral oils also can be formulated with antiwear and other additives.

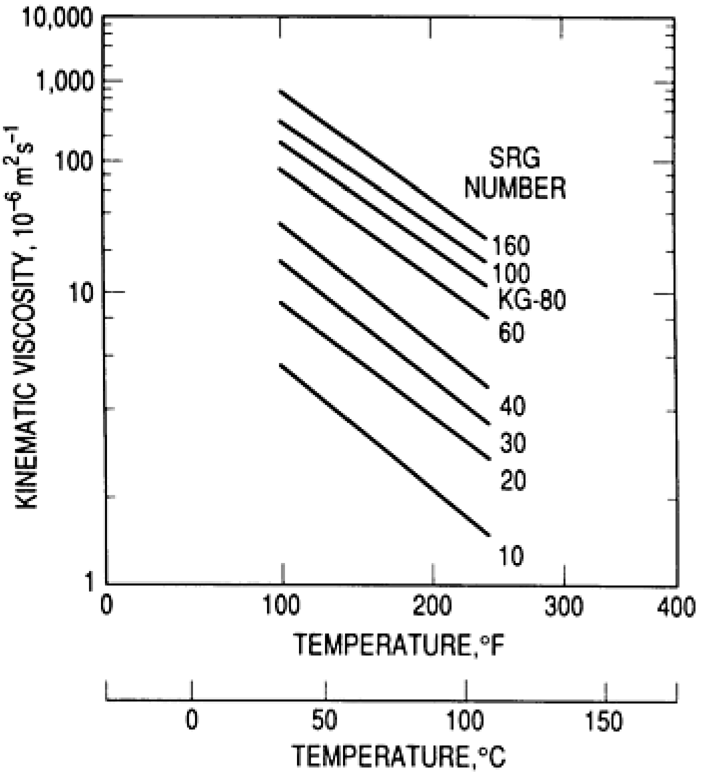

Fig. 4 Viscosity versus temperature for a homologous series of super-refined mineral oils. Source: Ref 53

Perfluoropolyalkylether (PFPE) lubricants have lower vapor pressures, lower pour points, and higher viscosity indexes than mineral oils (Table 5). They are therefore useful in space mechanisms that are not completely sealed or that are somewhat cooler (>200 K) than would be acceptable for mineral oils. In particular, one of the PFPEs has a very high viscosity index and is exceptionally useful over a wide temperature range.

PFPEs perform reasonably well under non-boundary contact conditions. However, these lubricants have definite limitations when used for applications involving boundary contact, particularly on steel surfaces (Table 6). Conventional antiwear additives do not dissolve into the PFPE fluids, although a new class of compatible additives has been reported (Ref 54). During boundary contact in the absence of additives, fluorine from the PFPE can react with iron to form FeF_3, a catalyst for the further breakdown of the polymer (Ref 55). More fluorine is released, which sustains a chain reaction.

Table 6 Factors that influence PFPE fluid degradation

Promote degradation	Retard degradation
Starved conditions	Fully flooded conditions
Low specific film thickness	High specific film thickness
Linear structure (*z*)	Branched structure (*y*)
Aluminum/titanium substrates	Hydrocarbon contamination
52100 bearing steel	440C steel and ceramic coatings
Temperatures greater than 200 °C (390 °F)	Low ambient temperatures
Sliding surfaces	Rolling surfaces
Vacuum environment	Atmospheric conditions

Lubricant degradation by polymerization leads to high bearing torque noise and excessive wear. The substrate-induced degradation can be retarded by substituting one or both of the steel surfaces with either ceramic components or ceramic-coated steel (or, presumably, by using the new additives). Both TiC- and TiN-coated steel and Si_3N_4 components have shown improved performance, as will be discussed in the section on surface modification (Ref 56).

PFPEs have extremely low surface tensions (~0.018 N/m, or 18 dyne/cm) and, therefore, creep very readily over metal and other surfaces. Because of their similar chemical structures, the lubricants also dissolve fluorocarbon coatings that are used as antimigration barriers. Commercially available PFPEs and their properties are listed in Table 5, and their molecular structures are shown in Fig. 5. The acetal groups present on the Fomblin Z25 or Braycoat 815Z polymers are particularly reactive under boundary conditions.

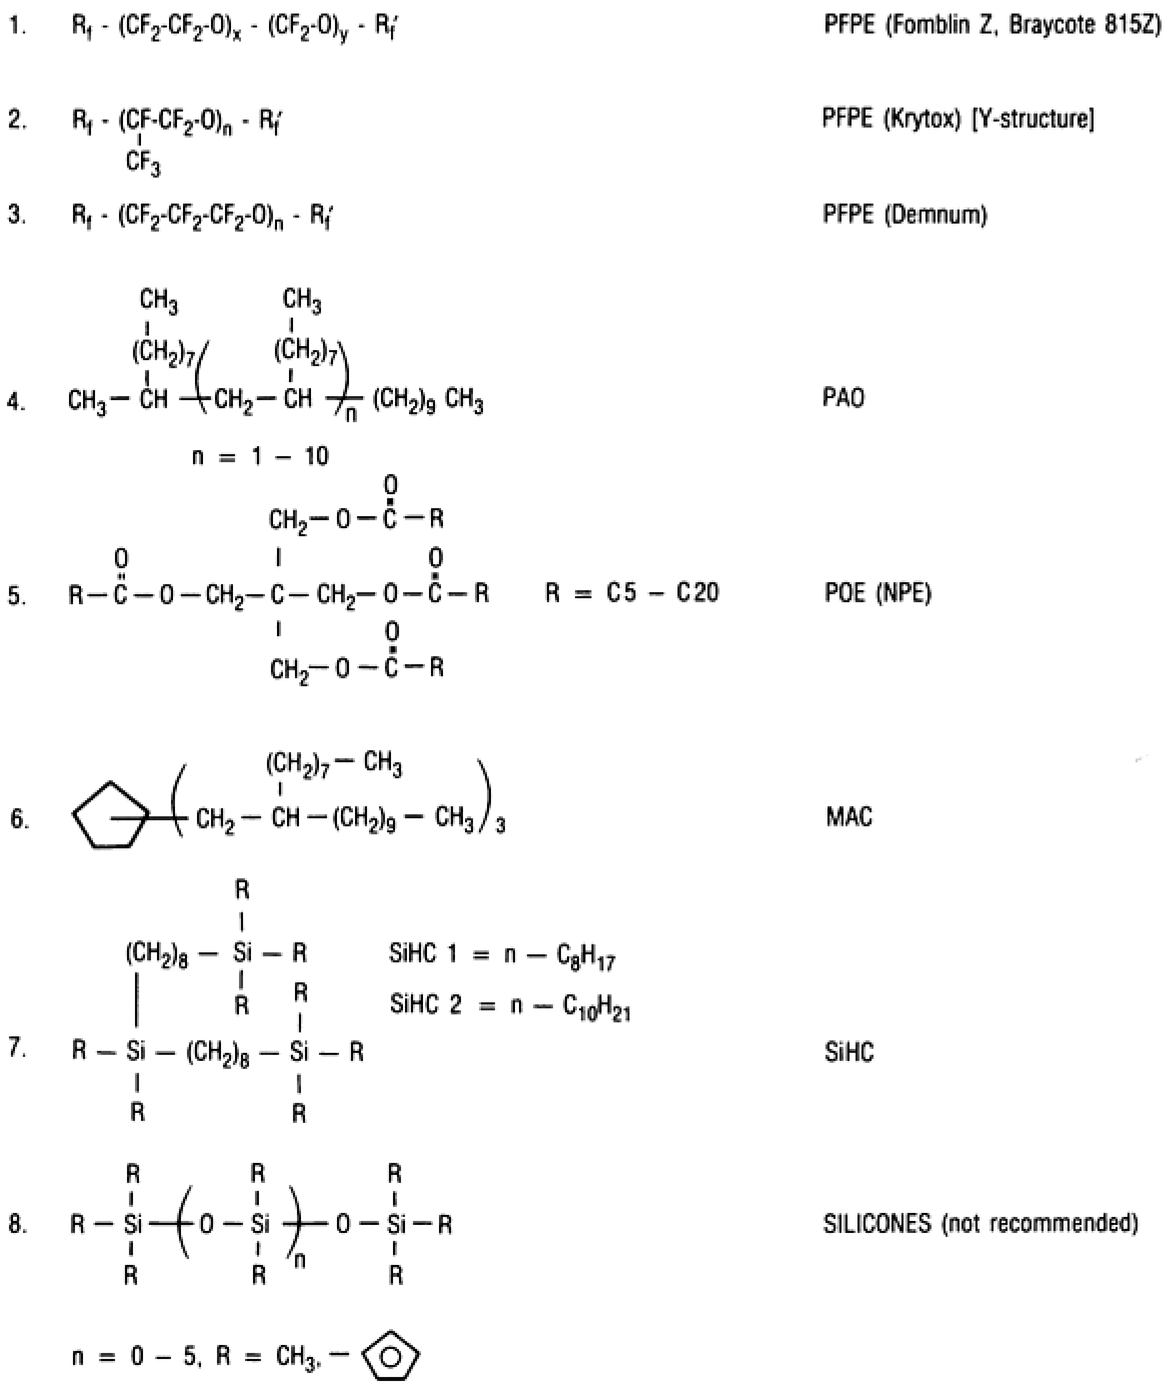

Fig. 5 Nominal molecular structure of selected fluid lubricants for space/vacuum applications

Other Synthetic Lubricants. Poly-α-olefin (PAO), polyolester (POE), multiply-alkylated cyclopentane (MAC), and other hydrocarbon polymer (HP) oils can be synthesized and blended to produce viscosity, vapor pressure, pour point, and other properties in a controlled way to suit various needs (Ref 44, 57, 58, 59, 60, 61, 62). Vapor pressures that are as low as those of linear PFPEs have not been obtained for the PAOs and POEs, but they can be lower than those of conventional mineral oils. Vapor pressure studies of the MAC oils are currently underway, and extrapolations based on measurements

at higher temperatures (125 to 175 °C, or 255 to 345 °F) suggest that room-temperature vapor pressure of at least one MAC oil should be low, as listed in Table 5 (Ref 63). Outgassing studies of selected PAOs and POEs (specifically, a neopentyl ester) show that removal of relatively high-vapor-pressure light fractions, which account for ≤3% of the as-received lubricant, reduces the vapor pressure by several order of magnitude without affecting viscosity at room temperature (Fig. 2).

These synthetic hydrocarbons can be blended with conventional additive packages to provide the same type of protection against wear, oxidation, and corrosion as achieved by natural hydrocarbons. However, for vacuum applications, the low vapor pressures of the base stocks make the additives the most volatile constituents of blended lubricants. Therefore, new additives are being developed that will be compatible with the base stocks and will have the desired low volatilities.

Laboratory screening tests have shown that synthetic hydrocarbons give the longest wear lifetimes in a simulated boundary-lubrication test facility. Bearing tests with a fixture designed to simulate the oscillatory motion of a weather scanner have shown that a PAO provides near-freezing (0 °C, or 32 °F) temperature capability and significantly outlasts both a silicone oil and a PFPE (Fig. 6) (Ref 58, 59, 60, 61, 64). PAO oils have given very good performance in lightly loaded, high-speed gyroscope bearings. Tests are presently aimed at determining the utility of these synthetic oils in more demanding applications, such as in the spin bearings of momentum and reaction wheels.

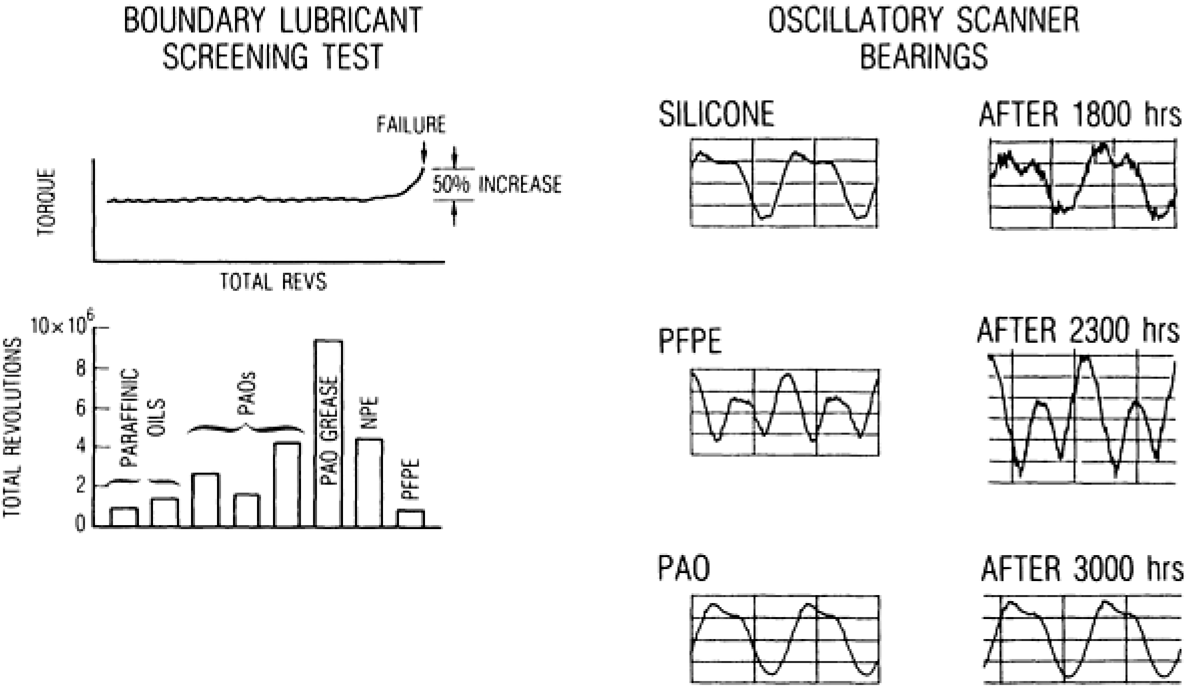

Fig. 6 Life-test results for various lubricants investigated with a boundary lubricant screening test (left) and oscillatory scanner-bearing test (right). Silicone and PFPE failed after the indicated times, whereas the PAO test continues. Source: Ref 44

Silahydrocarbons represent another relatively new class of synthetic lubricants with vapor pressures acceptable for vacuum applications and the capability to be compounded with additives (Ref 7, 8). Their tribological performance has not been thoroughly tested in specific applications, but the results of conventional four-ball and traction tests are very encouraging (Ref 65).

Additives. Liquid lubricants are formulated with additive packages in order to provide, for example, low friction and antiwear protection in elastohydrodynamic or extreme-pressure conditions, and to retard lubricant oxidation or substrate corrosion during atmospheric storage. Most of these additives were developed for use under atmospheric conditions, with oxygen and water vapor, and were compounded with base stocks on a highly empirical basis. In vacuum, once water vapor and reactive gases are removed, it is doubtful that most additives work in an identical chemical-mechanistic manner to the way they operate at atmospheric pressures. Furthermore, the nature of the interactions of these additives (which

were developed for steel substrate surfaces) with newly emerging ceramic components (such as SiC, Si_3N_4, TiC, and TiN) is unknown. Additive surface chemistry is currently an active topic of study by many tribologists and surface scientists.

Antiwear or extreme-pressure (EP) additives are often required when liquid lubricants are used in mixed or boundary regime applications in vacuum. Numerous examples exist where antiwear additives, such as tricresol phosphate, improve the operation of bearings and provide longer life. In boundary-lubrication situations, the modern designer must carefully consider the relative merits of liquid and solid lubricants. Liquid lubricants have long life and low torque, but require additives and, possibly, reservoirs and molecular vapor seals in the design. Solid lubricants operate well in boundary conditions without reservoirs or seals, but have a finite life. Another option, surface modification, is also worthy of consideration. Common EP additives include naphthenates of lead and other metals and dialkyldithiophosphates of zinc or antimony.

The role of antioxidation additives in vacuum lubricants is to prevent degradation of lubricants during storage. Common types of such additives include hindered phenols, as well as amines, such as polyphenyl α-naphthylamine.

Antirust additives can be particularly important for components stored in air that are coated with the PFPE oils, because these oils do not offer the same oxidation protection to the substrate as do other oils. Unfortunately, common antirust additives do not dissolve in the fluorocarbons any better than antiwear materials. For one of the PFPE greases, $NaNO_2$ is added by first being adsorbed onto bentonite clay and then being suspended, together with the clay, to form the grease.

Grease lubricants comprise oils compounded with a pore-network-forming thickener, such as a soap or a fine-particle suspension. Thorough descriptions of greases and their properties are provided in Ref 66 and 67. For results of an extensive testing program of greases in vacuum, see Ref 68. A very brief overview of grease lubricants is provided here for reader convenience.

Depending on the type of oil and the nature of the thickener, greases can be formulated for various applications that involve a variety of components with different types of contact (such as slow- or high-speed angular contact ball bearings, journals, and gears). Oils in greases can be from any of the categories discussed in previous sections. However, the solubility properties (chemical compatibility) of the oil will determine the selection of thickener and, hence, the grease properties. Because mineral oils and certain synthetics have good solvent properties, they can be formulated with soaps of different cations to make what are known as channeling greases. Such greases are pushed out of the way and form a path (channel) when the balls of a bearing pass through the grease. When working properly, oil will continually diffuse out of the mounds of grease on the edges of the ball path to supply lubricant to the contacting surfaces. If a grease is fluid enough that it tends to fill the spaces between balls, it is a "slumping" (non-channeling) grease. The consistency of a grease depends on the type of thickener used and the relative amounts of oil versus thickener.

Because both PAO and PFPE oils are poor solvents for soaps, greases of these oils are made by suspending fine particles of inert materials in the oils until their consistency becomes thick, like a grease. Two common thickeners of this type are a finely ground silica and another powder that is simply designated as a fluorocarbon telomer. One drawback to this type of grease is that the thickener can get into the ball path of a precision bearing and, being solid, can cause noisy operation.

The primary purpose for using grease in a vacuum application is that it can act as a reservoir for supplying oil to contacting surfaces. A bearing properly packed with grease will also suffer less oil loss that is due to either creep or physical spattering because of the physical barrier the grease can provide. However, because the lubrication properties of any grease can only be as good as those of the base oil, care must be exercised in selection of the base oil. For example, formulation of a volatile oil into a grease cannot prevent the oil from contaminating a vacuum system. Rather, a low-volatility oil must be used.

Surface Modification with and without Lubrication. The fourth approach for providing low friction and limited wear in vacuum is to use no lubricant at all. Instead, the low reactivity of the substrate surface can be relied upon to prevent cold-welding. This option can work very well for lightly loaded applications that have low-duty cycles. For mechanisms in terrestrial vacuum systems, this approach is often a tempting first choice. When a component fails to operate properly, vacuum can be broken and a lubricant can be applied and tested for the application.

Conversely, spacecraft-mechanism performance cannot be left to chance, and most mechanisms that experience more than light loads and/or have frequent use will require tribological modification in the contact zone. The modification approaches in this section do not have the same historical degree of proven success as the lubricants mentioned in the

previous sections, because the modifications are simply too new. Nonetheless, the authors believe that these emerging technologies will be used increasingly in the future, either alone or in conjunction with lubricants.

Because metals generally do not have unreactive surfaces once their passive layers are worn away, chemical modification of the surface region or complete materials substitution is required. The basic idea is to avoid metal-to-metal contact that might cause either cold-welding or adhesive wear. Ceramics often are covalently bonded materials and generally have a lower reactivity than metals (gold is one exceptionally inert metal). In particular, the carbides and nitrides of silicon and titanium (SiC, Si_3N_4, TiC, TiN) have excellent attributes: they are hard (resist plastic deformation), chemically inert (resist cold-welding/adhesive wear), and have high melting temperatures (resist chemical interdiffusion between contacting surfaces). They are also commercially available, either as ceramic components or as ceramic coatings on bearing steels.

An alternative is to ion implant C, N, or metals into steel surfaces to create a hard surface region. Another future alternative may be polycrystalline diamond coatings. However, although hard carbon films are used for some computer disk drive applications, diamond films cannot yet be applied to metals without overtempering and distortions, and their tribological properties still need extensive investigation.

Ceramic and Hard Coat Contact. TiC coatings formed by chemical vapor deposition (CVD) onto steel have been used for over a decade in the tool industry to prolong tool life. The CVD of TiC coatings is also commercially available on 440C balls for bearing applications (Ref 69). The high temperatures (>1000 °C, or 1830 °F) used in the CVD process, in which $TiCl_4$ and H_2 and N_2 gases react on the hot steel substrate to form TiC, soften the steel. Consequently, the balls have to be heat treated again to regain hardness after deposition, and anisotro phase transformations during the second heat treatment distort the balls into egg-shaped structures. The balls are then repolished to regain sphericity. Balls are available with a 9.5 mm (0.375 in.) diameter or less. Larger sizes distort to tolerances greater than the allowable coating thickness, resulting in "bald spots" after polishing. TiC-coated balls have been used without additional lubricant in the primary deployment mechanism of the recent space telescope solar array. These balls have also been used with PFPE oil for the Spacelab instrument pointing system (Ref 70).

TiN and TiC coatings produced by sputtering also have been used for years in the tool industry. The lower operating temperatures of the sputtering process, particularly some high-rate variations (Ref 71, 72) can, in principle, avoid the second heat treatment problems associated with CVD. There have been very limited studies of sputtered TiN in bearing or gear applications in vacuum. Eccentric bearing tests in vacuum showed an order of magnitude increase in life when TiN-coated components were compared to uncoated 440C steel. In both cases, the bearings were lubricated with a PFPE oil (Ref 73).

Solid ceramic parts, such Si_3N_4 balls formed by hot isostatic pressing, are commercially available with diameters up to 65 mm (2.5 in.) (Ref 74). Appropriate polishing can produce balls down to a Grade 3 finish. Grades 3, 5, and 10 are usually produced. Such balls have been used in hybrid bearings (ceramic balls and steel races) operated in ultrahigh-vacuum, either unlubricated or with solid or liquid lubricants. Eccentric bearing tests of PFPE-lubricated hybrid bearings in vacuum (Si_3N_4 balls against 440C steel races) showed an order of magnitude increase in life over an all-steel configuration. The gains observed with the Si_3N_4/steel hybrid were identical, within experimental error, to gains obtained with all TiN-coated components (Ref 63). The results emphasize the improvements that can be obtained when metal-to-metal contact is avoided, even by the elimination of only one metal surface from the contact. When used with PFPE oils, the ceramics appear to retard chemical degradation of the lubricant by iron in the steel substrate.

Although the tribological improvements of using bulk ceramics or ceramic coatings on steel appear similar, basically because metal-to-metal contact is eliminated, there are important differences in bulk properties that must be considered. The ceramic coatings are thin enough (<3 μm, or 120 μin.) that the majority of the load is carried by the steel substrate. Therefore, the modulus of the steel determines the stress levels generated. Si_3N_4 has a Young's modulus (310 GPa, or 45 × 10^6 psi) that is 50% higher than that of steel. Thus, higher contact stresses are generated in the ceramic than in the steel at any particular load. In addition, the thermal coefficient of expansion (3.5 × 10^{-6}/K) and the Poisson's ratio (0.28) must be taken into account when ceramics are combined with steel races in a given application. Tighter race conformance to the ball relative to steel bearings is sometimes required to reduce stresses, but the result can be increasing operating friction or torque.

Ion implantation of steel surfaces is a potential alternative to coatings or bulk ceramics (Ref 74, 75, 76). Energetic (100 keV) ion beams of various species (such as B, C, N, and Ti) are directed toward the substrate. Such species can form compounds in the near-surface region (<0.1 μm, or 4 μin.) or simply disrupt the surface structure (render amorphous), so that wear resistance can increase. This approach does not change the dimensions of the component. Sometimes, substrate

cooling is necessary when high-flux beams are used. The process, as originally developed, was line-of-sight, but isotropic plasma implantation techniques have become available (Ref 77). Ion implantation has been used in many different terrestrial applications. In a vacuum application, ion implantation is being tested for possible use in the main-engine bearings of the space shuttle to provide improved corrosion and wear resistance. (During use, these bearings get very hot and lubricants do not survive; stored bearings rust in condensed moisture.) A terrestrial bearing study of balls made of TiC-coated 440C, of Si_3N_4, or of ion-implanted (Ti, C) 52100 balls showed comparable improvements in performance for each modified material, compared to 52100 balls in fretting tests (Ref 78). In gyroscope spin tests, the implanted balls showed slight evidence of wear relative to the ceramic or ceramic-coated balls, but all three types performed better than the standard 52100 balls.

Specific Applications

Space Environments. Although the functions or missions of different spacecraft systems vary widely, there are many similarities in their mechanical requirements. There is a large body of literature on the design and applications experience of spacecraft mechanisms, including discussion of tribology issues (Ref 79). Table 7 lists mechanical components often found on spacecraft and is arranged according to the type of mechanical contact. The list is not meant to be exhaustive, but is typical of components that have exhibited specific problems (Ref 80). Recent articles (Ref 81) are all devoted to various aspects of tribology of space systems throughout the world. The space program of each country is treated individually, and there are some general articles on different technologies.

Source: Ref 44

It is important for the reader to understand that the field of space tribology is undergoing major advances in lubricant technology. Such advances are being driven by two trends: (1) the required lifetimes of spacecraft are increasing, making some of the past lubricant practices inadequate; and (2) mechanical component failures are starting to become the life-limiting systems on spacecraft, because the traditional failure points (power systems, electronics, and contamination problems) are using newer technologies that exceed the lifetimes of the tribosystems (Ref 45, 46, 48, 49, 50). The tribology advances include new or improved tribomaterials and the generation of more extensive test data to qualify these tribomaterials for various applications. Table 7 also lists materials technologies either in use or available for implementation on various spacecraft components. The different symbols in the table correspond to a critical or less stringent requirement or to a preferred or alternative technology. The reader is referred to the references for more details concerning vacuum applications.

Terrestrial ultrahigh vacuum (UHV) environments, or chambers, are used primarily by:

- Surface scientists conducting chemical experiments or analytical measurements (such as spectroscopy, diffraction, or microscopy), or both, on the first few atomic surface layers of materials
- Scientists and engineers synthesizing or fabricating materials with features or structures of micrometer to nanometer scale
- Engineers testing hardware intended for vacuum applications

All three groups require extremely clean, stable environments to obtain reproducible results. Contamination from lubricants in the form of vapors, migrating liquid lubricant molecules, or particulate debris is not acceptable. Designers try, as much as possible, to keep mechanical components of such systems external to the vacuum and rely on feed-throughs, magnetic couplings, or bellows to transmit or facilitate component motion. However, UHV systems often contain manipulators to move materials within the chamber or between chambers. Rotatable fixtures are also required in line-of-sight deposition processes to adequately expose nonplanar substrates to the deposition flux. If the manipulators are used frequently, undergo moderate to heavy stresses, or have tight-tolerance components, some lubrication is generally required to avoid frequent mechanism repair (which necessitates breaking vacuum). Lubricants for pumps are not covered in this article, because that technology is well developed, and the pump manufacturers are quite capable and flexible in meeting customer requirements for specific applications.

The general strategy that has been used is to avoid metal-to-metal contact and to have minimum lubrication. For example, PTFE and polyimide polymers (pure or composites) have been used to make bearing bushings for UHV manipulators. Recently, Si_3N_4 balls have been used to make hybrid bearings for UHV mechanisms. (Presumably, TiC- or TiN-coated materials would also work.) The Si_3N_4 has been used without lubricant or with spray-deposited WS_2 for more demanding applications (Ref 82). WS_2 has also been used on steel. Sputter-deposited MoS_2 has been used on deposition fixtures and on a cryogenic (helium) manipulator for an acoustic microscope (made of steel), resulting in lower operating torque of these mechanisms.

Grease (polytetrafluoroethylene, or PTFE, base) has also been used in a robot manipulator operated in a molecular beam epitaxy (MBE) system (Ref 83). The MBE robot has many gears, bearings, and lead screws. Over 20 robots have been built, and some have operated over 5 years without maintenance. The grease was selected instead of solid lubricants partly because of a desire to avoid particle generation. Micrometer-sized particles have unusual migration tendencies in vacuum (easily propelled by electrostatic charges) and are devastating to the fabrication of submicrometer devices. The particle-generation properties of solid lubricants as a function of film properties (for example, porosity) have not been systematically studied. Further work is needed and is in progress (Ref 84). The designer should place mechanisms below critical surfaces in vacuum, so that gravity will move away debris from the sites of inevitable wear. Containment barriers should also be considered that are interposed in the line of sight between critical surfaces and the lubricated sections of mechanisms.

PTFE-based greases are also used to lubricate Viton seals between UHV and air on sliding manipulators. Such seals are usually in multiple series, with differential pumping between each seal.

When selecting tribomaterials, the designer should review their temperatures stabilities, load-bearing capabilities, moisture sensitivities, and achievable tolerances. Obviously, the vapor pressure of the tribomaterial must be below desired system operating pressure. Because UHV systems are routinely baked out, the vapor pressure and load-carrying capacities of the tribomaterials must not degrade by such heating. Moisture sensitivity is important if the mechanism is routinely stored and/or operated in air. Polyimides are extremely sensitive to water vapor (these polymers absorb as much as 2%

moisture, and minutes or hours of moisture exposure will require subsequent bake-out), whereas PTFE is not. However, polyimides have load-bearing capabilities superior to those of PTFE. MoS_2 is more sensitive to water vapor exposure than WS_2 (MoS_2 will significantly oxidize over a period of months to a year), yet MoS_2 has better sliding wear endurance in vacuum. (MoS_2 oxidation can be effectively avoided at atmospheric pressure by storage of the lubricated component in a dry or inert gas, desiccated environment.) Sputter deposition can yield solid-lubricant coatings to better tolerance than either burnishing or spray methods. Sputter-deposited films can also be prepared that will resist oxidation upon standing (not operating) in air for many months, and such films should be considered for conventional uses. Bonded films, though subject to greater debris formation, are generally much more resistant to oxidation. A typical procedure for applying bonded films is to run the film in (burnish) after the normal application and then remove any debris (with a vacuum brush) before using.

Internal Combustion Engine Lubricants

Syed Q.A. Rizvi, The Lubrizol Corporation

Introduction

AN INTERNAL COMBUSTION engine burns fuel within itself. The products of combustion drive the mechanism that converts the latent energy of the fuel into mechanical energy.

Most engines currently used in transportation and industry are of the internal combustion type. The prime reasons for their popularity are their high thermal efficiency and their light weight, in relation to their power capability.

There are four general types of internal combustion engines: four-stroke cycle engines, two-stroke cycle engines, rotary engines, and continuous combustion gas turbine engines (Ref 1). The four-stroke and two-stoke cycle engines are based on the reciprocating piston principle, and are the most common. They include both compression ignition (CI) and spark ignition (SI) types. Although the CI and SI engines have many common features, they differ in the manner in which the fuel and the air are mixed. In CI engines, the intake system supplies only air, which is compressed before the fuel is injected into the combustion chamber. In SI engines, the fuel and the air are mixed in either the carburetor or intake port (fuel injection) prior to entry into the combustion chamber.

Four-stroke CI and SI engines are used in most automotive applications. Depending on the cylinder arrangement, four-stroke engines can be subcategorized as in-line, V (vee), opposed-piston, and radial types. Two-stroke SI engines are commonly used in lightweight applications (outboard motors, motor scooters, motor cycles, snowmobiles, and chain saws), whereas two-stroke CI engines are used in on-highway trucks, city buses, low-speed marine applications, and some railroad diesel applications.

Lubricants and Lubrication

All engines must be lubricated in order to preserve the integrity of the system for its designated lifetime. The extreme temperatures in internal combustion engines make lubrication complex. The lubricants that are suitable for use in these engines are expected to reduce friction, dissipate heat from internal parts, minimize deposit formation, and prevent corrosion and wear (Ref 2).

The world lubricant market for 1990 was estimated at 10.2 billion gallons, of which North American consumption represented over 28% of the total (valued at $6.5 billion). The centralized economies consumed over 29%; Western Europe, over 16%; Japan and Australia, over 14%; Latin America, nearly 7%; and Africa and the Middle East, over 4%. Engine oils, that is, internal combustion engine lubricants, accounted for 51% of the total lubricant use; general machine fluids accounted for 23%; process oils, 17%; metalworking fluids, 7%; and greases, 2%.

In most applications, the lubricant or oil is delivered from a reservoir to those parts of the equipment that require lubrication and cooling. The lubricating system can be full-pressure, splash, or modified-splash types (Ref 3, 4). Most automotive engines use a full-pressure system, in which the oil is pumped from the oil sump to the main bearing and connecting rods, and then up the connecting rods to the piston pin. In overhead valve engines, a portion of the pumped oil travels through push rods (in some cases), over rocker arms, past valve stems, and down the valve guides. In many engines, the cylinder walls and piston pins depend on splash lubrication by the oil that is thrown off the main bearing (Ref 4). Figure 1 depicts the lubrication system of a cam-in-block overhead valve engine.

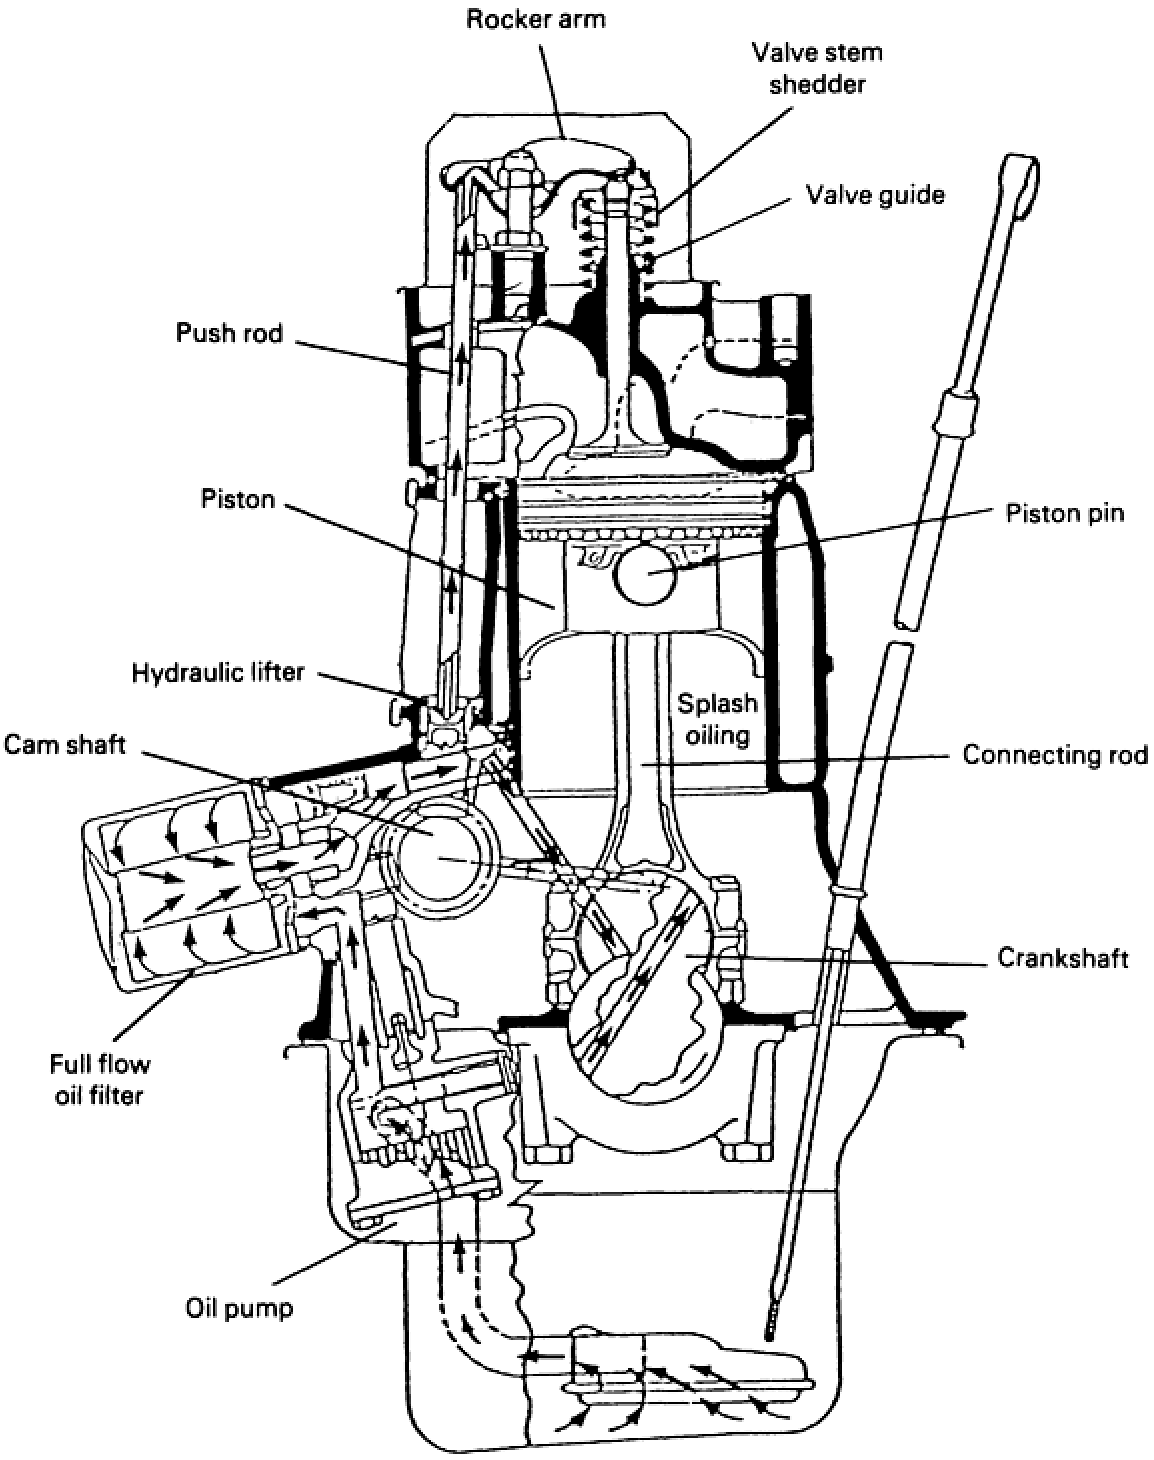

Fig. 1 Lubrication mechanisms in cam-in-block overhead block valve engine. Source: Ref 4

The main purpose of lubrication is to reduce friction by forming a film between two moving surfaces. The strength and durability of this film is related to the viscosity of the lubricant and to the speed and load experienced by the moving surfaces.

The relationship of coefficient of friction (μ) and oil film thickness with lubricant viscosity (*Z*), equipment speed (*N*), and equipment load or pressure (*P*) are shown as the Streibeck curve in Fig. 2 (Ref 5). The ratio of $(ZN)/P$ is related directly to the oil film thickness, but inversely to the coefficient of friction. This implies that high lubricant viscosity, high equipment speed, and low equipment load will allow the formation of a thick lubricant film and, hence, the equipment

will encounter little or no friction. (The initial drop in the coefficient of friction while moving from fluid-film to mixed-film lubrication reflects a decrease in viscous drag because of a decrease in lubricant viscosity.) Conversely, low lubricant viscosity, low equipment speed, and high equipment load will create a situation where the film thickness will be inappropriate and the equipment will encounter high friction.

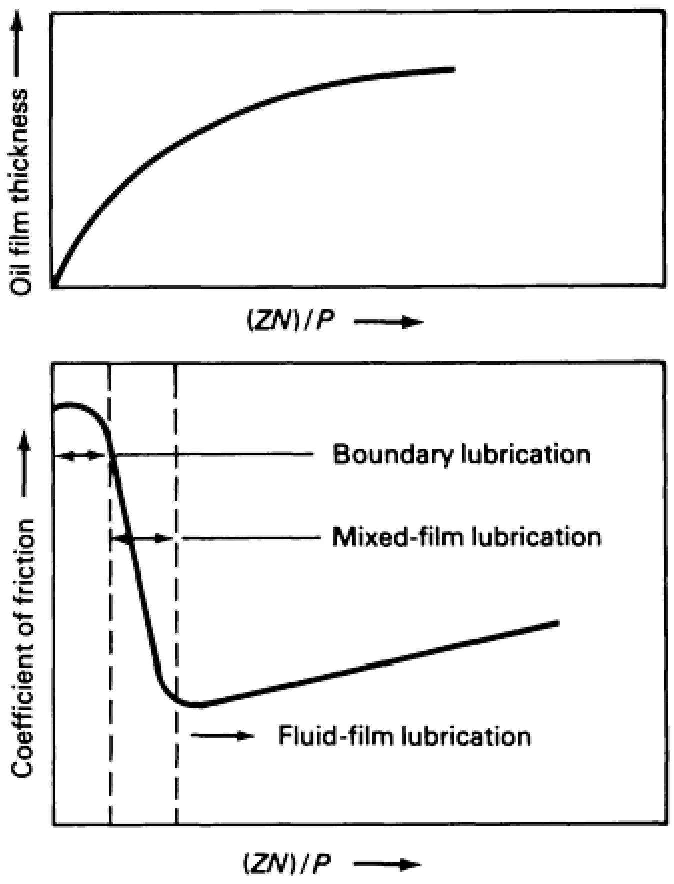

Fig. 2 Streibeck curve showing lubrication regimes. Source: Ref 5

Depending on the lubricating environment, lubrication can be divided into fluid-film, boundary film, and mixed-film types. The three states of lubrication are shown in Fig. 3 (Ref 6).

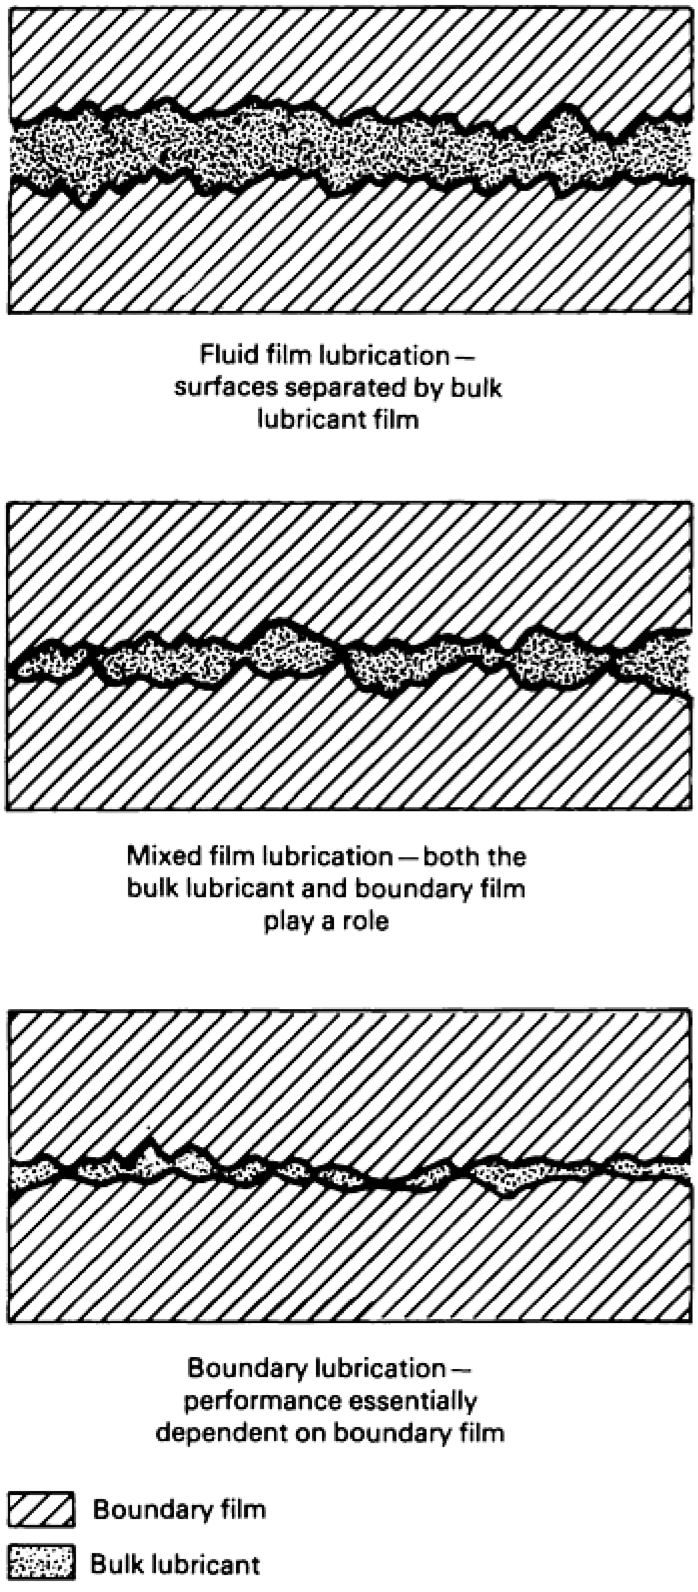

Fig. 3 Lubricant film thickness versus lubrication regimes. Source: Ref 6

Fluid-film lubrication, also known as hydrodynamic lubrication, is most desirable. This type of lubrication depends on the viscosity of the lubricant, and is effective only when the load in the contact zone is low. Under these circumstances, the sliding surfaces are separated by a lubricant film that is several times the thickness of the surface roughness.

Another type of hydrodynamic lubrication, referred to as elastohydrodynamic lubrication (EHD) (Ref 7, 8), commonly occurs during automotive gear operations. The lubricant is exposed to high contact pressures and undergoes a large viscosity increase. This results in an extremely rigid lubricant film, which causes elastic deformation of the surfaces in the lubricating zone.

Boundary lubrication simulates the other extreme of the lubricating environment. High loads and very slow speeds produce extreme pressures that can lead to the lack of effective lubrication and, hence, promote maximum metal-to-metal contact. If not controlled, the resulting dry metallic friction will cause catastrophic wear and, ultimately, total seizure. Reactive chemicals, called antiwear and extreme pressure agents, provide protection in this kind of lubricating environment. Although boundary lubrication is encountered in certain parts of the engine, such as the valve train, cylinder bores, and piston rings, most of the lubrication in an engine is hydrodynamic in nature.

Mixed-film lubrication falls between the two extremes described above and contains characteristics of each. There are regions of no metal-to-metal contact, as well as regions of metal-to-metal contact.

Specifications

The physical characteristics and performance of engine oils are defined by the Society of Automotive Engineers (SAE) viscosity grades, American Petroleum Institute (API) service classifications, U.S. military specifications, and the original equipment manufacturer (OEM) requirements.

Viscosity is one of the most important properties of a lubricant. It can be defined as the resistance of a lubricant to flow. Viscosity classification systems for engine oils are described by SAE Standards J 300 (Ref 9) and J 1536 (Ref 10). The basic viscosity grade categories for engine oils are determined by the Crankcase Classification System devised by SAE. The SAE uses test methods that are approved by the American Society for Testing and Materials (ASTM). There are a total of 11 viscosity grades, ranging from 0W to 25W, and from 20 to 60. Each viscosity grade must meet a number or requirements.

Monograde viscosity oils with the letter "W" (winter) must meet the minimum borderline pumping temperature, maximum low-temperature viscosity (at a prescribed temperature), and the minimum kinematic viscosity requirements at 100 °C (212 °F). ASTM test procedures D 2802 (modified) and D 445 are used to determine low- and high-temperature viscosities, and ASTM D 3892 is used to determine the borderline pumping temperature. Monograde oils without the letter "W" must meet the high-temperature (100 °C) viscosity requirement only. Multigrade oils should satisfy the appropriate requirements of both the "W" and the non-"W" grades. The winter requirement of being pump-able at low temperatures and the nonwinter requirement of sufficient viscosity at high temperatures ensure proper lubrication and protection of engine parts during all-season operation. These requirements, along with those of the U.S. military, are summarized in Table 1 (Ref 11).

Table 1 Viscosity requirements for engine oils

Property	SAE viscosity grades for crankcase oils, SAE J 300										
	0W	**5W**	**10W**	**15W**	**20W**	**25W**	**20**	**30**	**40**	**50**	**60**

(i) ASTM D 445.

(j) At -25 °C (-15 °F).

Service Classifications. Engine oil performance requirements are established by the API, ASTM, and SAE. These requirements are based on standardized tests and are described by the the API Engine Service Classification System, which was first introduced in 1969 and 1970. The API service symbol (Fig. 4), established in 1983, is devised to communicate engine oil quality and performance to the general public in order to help them select oils that meet manufacturer recommendations for use in the intended application (Ref 12). The upper part of the symbol displays the API service category; the center part, the SAE viscosity grade; and the bottom part, the energy-conserving feature, if applicable. Only licensees are authorized to display this symbol. The total number of such licensees at year-end 1990 in the U.S. and Canada was 210. In countries outside North America, there were 53 licensees.

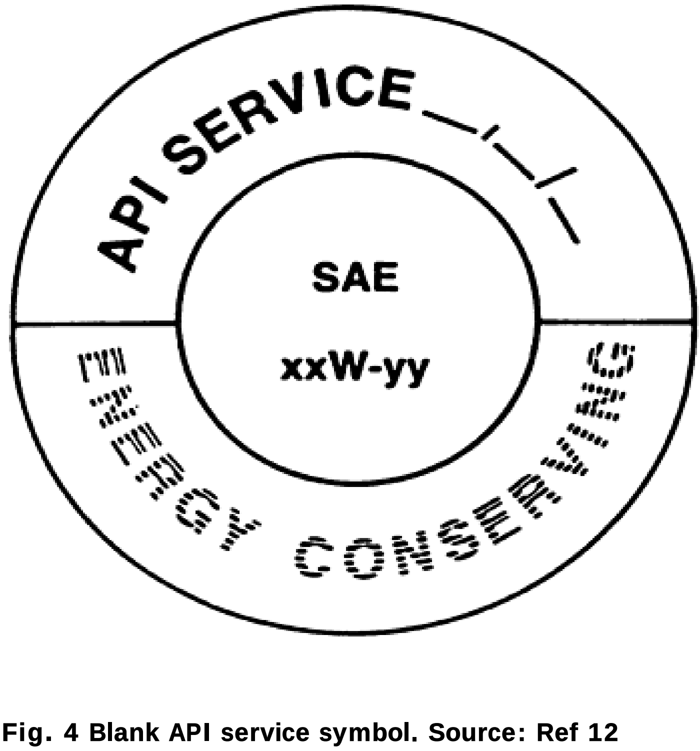

Fig. 4 Blank API service symbol. Source: Ref 12

API service categories for gasoline engine oils range from SA to SG, where S stands for service, and are used by service stations, garages, and the like. For diesel engine oils, the API categories range from CA to CE, where C stands for commercial. The most recently introduced API categories, SG and CF-4, are designed for the most severe operations (Ref 13). In general, oils that meet higher service requirements are suitable for use in the lower service class in the same category. The API SA to SF categories for gasoline engines and CA and CB categories for diesel engine oils are obsolete and are satisfied by API SG and CC (and higher service classes), respectively. Only the most recent categories appear within the symbol described above.

The SAE defines the need for a category, the ASTM develops or selects the test techniques, and the API develops the user language to define it. The engine oil classifications for gasoline engines are provided in Table 2, and those for diesel engines, in Table 3 (Ref 14). The performance requirements for some of these categories are available in Ref 15. The performance criteria measure protection against rust, varnish, deposits,sludge, wear, high-temperature oil thickening, and ring sticking. Figure 5 and 6 show the engine parts that are commonly rated.

Table 2 Engine oil classification systems for automotive gasoline engine services

API service categories	Previous API service categories	Related industry definition	Engine test requirements
SA	ML	Straight mineral oil	None
SB	MM	Inhibited oil only	CRC L-4[(a)] or L-38: sequence IV[(a)]
SC	MS (1964)	1964 MS warranty approved	CRC L-38; sequence IIA[(a)]; sequence IIIA[(a)] sequence IV[(a)], sequence V[(a)]; Caterpillar L-1[(a)] (1.0% sulfur fuel)
SD	MS (1968)	1968 MS warranty approved	CRC L-38; sequence IIB[(a)]; sequence IIIB[(a)], sequence IV[(a)]; sequence VB[(a)]; Falcon rust[(a)]; Caterpillar L-1[(a)] or 1H[(a)]
SE	None	1972 warranty approved	CRC L-38; sequence IIB[(a)] or IIC or IID; sequence IIIC[(a)], or IIID; sequence VC[(a)] or V-D
SF	None	1980 warranty approved	CRC L-38; sequence IID; sequence IIID; sequence V-D
SG	None	1989 warranty approved	CRC L-38; sequence IIID; sequence IIIE; sequence VE; Caterpillar 1H2
ILSAC	None	Proposed	CRC L-38; sequence IID; sequence IIIE; sequence VE; Caterpillar 1H2, sequence VI

Military and OEM Requirements. The needs of U.S. military equipment differ from those of commercial equipment. The military operates large and diversified fleets of vehicles that contain two- and four-stroke cycle engines, air-cooled and liquid-cooled, ranging from 1.5 to over 745 kW (2 to over 1000 hp). U.S. military specifications are designed to identify performance requirements of lubricants used in its tactical and combat ground equipment. Although military specifications parallel the performance requirements of API service designations, their development does not always follow the development of the API categories.

Most OEMs accept the performance requirements established by the API categories. However, certain manufacturers have additional requirements to qualify oils for use in their equipment. The Mack EO-K/2 specification is one example of such a requirement.

The API performance classification system, SAE viscosity grades, and OEM performance requirements enable the design of engine oils that are well suited for specific end-use applications. New demands placed on lubricants, because of changing technology, require the continual revision and upgrading of performance specifications.

Lubricant Classification Based on End-Use

Depending on the application, lubricants can be classified by the categories described below.

Gasoline and heavy-duty diesel engine oils are identified by the API engine service classification system and OEM performance requirements. API SG, CE, and CF-4 designated oils deliver top performance and are suitable for use in most modern engines.

Stationary diesel engine oils are used in engines that are commonly employed in industries such as agriculture, oil and gas exploration, chemical processing, and papermaking, and for generating power to drive pumps, compressors, drilling equipment, and other auxiliary machinery. API CD and CD-II oils are often considered suitable for use in these engines.

Railroad diesel engine oils are typically SAE 40 viscosity grade for monograde oils and 20W-40 for multigrade oils, and are derived from paraffinic and naphthenic base oil bends. These oils have a sufficient base reserve (total base number of 10-20) to neutralize acidic combustion by-products. The total base number (TBN) is the acid-neutralizing power expressed in terms of mg of potassium hydroxide (KOH) per gram of the lubricant. These oils have a limit on the amount of zinc present (10 ppm maximum) because of the tendency of zinc-containing antiwear agents to attack silver

piston pin bushings formerly used in railroad engines. Most of these oils are formulated to meet API CD level performance, but the final approval depends on lubricant performance in a number of OEM-specified tests.

Marine diesel engine oils have two main categories: oils for low-speed engines and oils for medium-speed engines. Low-speed, crosshead engines are used for large ocean-going ships. Medium-speed, trunk-piston engines are usually used for ships of lesser size.

Low-speed two-stroke cycle engines use heavy fuel and are typically of the crosshead type. These engines are equipped with diaphragms and stuffing boxes, which separate power cylinders from the crankcase. This allows the use of different lubricants for the power cylinders and the crankcase (Fig. 7) (Ref 16).

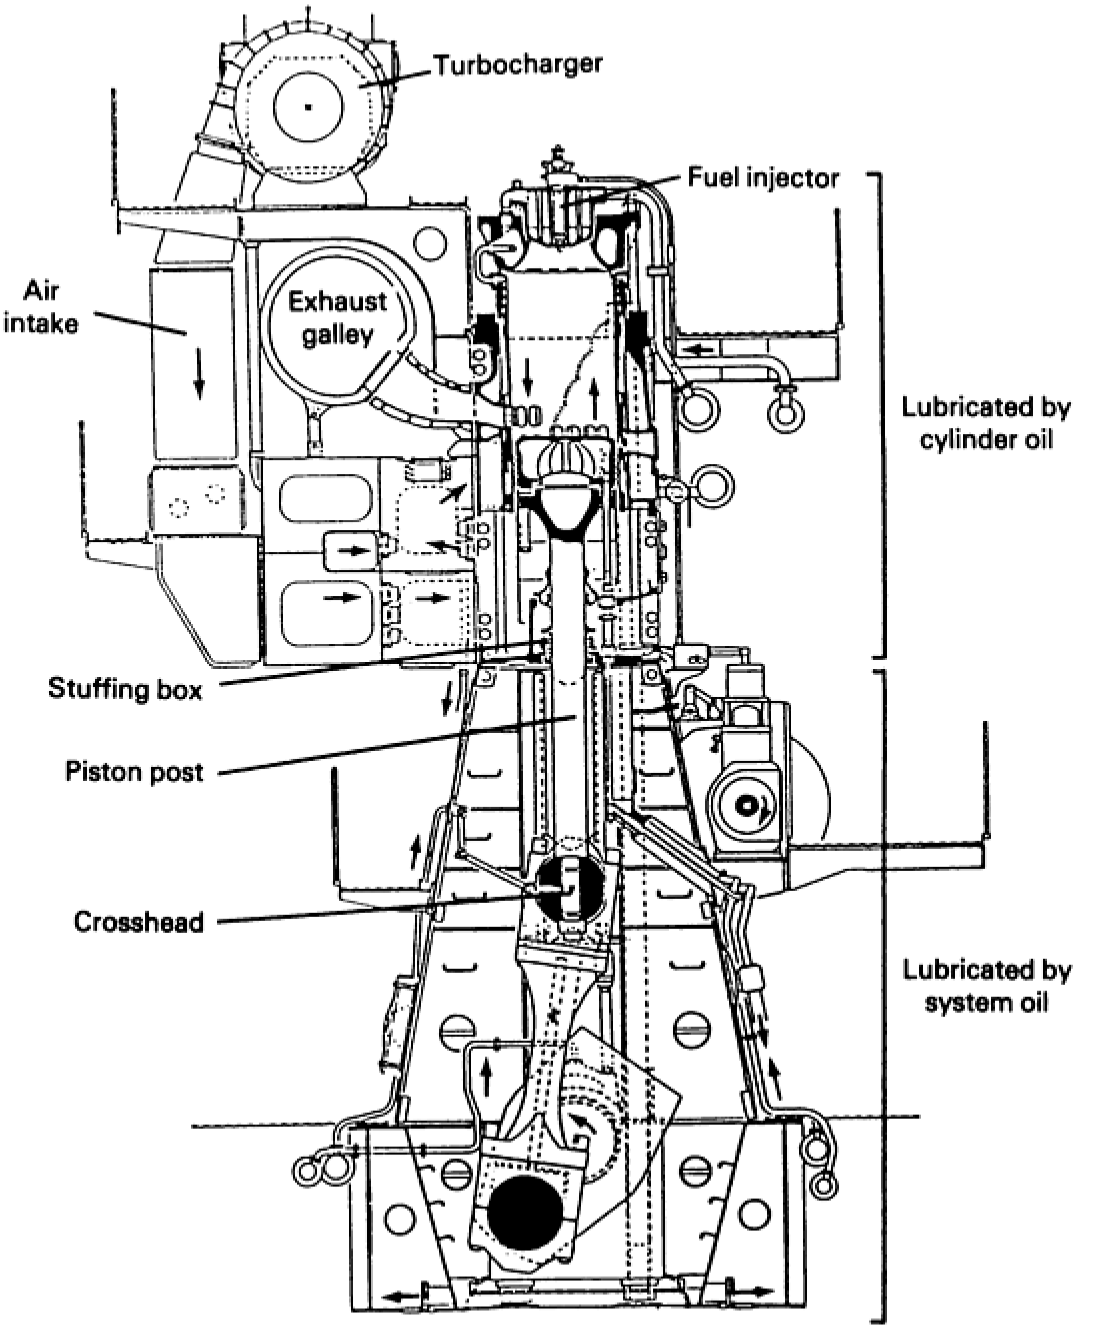

Fig. 7 Cross section of crosshead marine diesel engine. Source: Ref 16

The cylinder oil lubricates piston skirts and cylinders, and handles corrosive combustion products from heavy fuel. Therefore, it provides wear protection and engine cleanliness. Marine cylinder lubricants are typically SAE 50 viscosity grade, and have a suitable base reserve (TBN between 60 and 100) to neutralize the acidic combustion products arising from sulfur in the fuel. The cylinder oils are once-through lubricants because they are injected into the cylinder and burned with the fuel.

The crankcase lubricant lubricates bearings, gears, and other engine components. Crankcase or system oils are SAE 30 viscosity grade and are formulated to handle rust, oxidation, deposits, and wear. They typically have a TBN that ranges from 2 to 9.

Medium-speed trunk-piston engines have a single lubricating system and are run on distillate or heavy fuels. They use a lubricating oil of SAE 30 or 40 viscosity grade and have a TBN that ranges from 12 to 40, depending on the fuel quality. Again, the base reserve is necessary to neutralize acidic combustion products that are due to fuel sulfur. For marine lubricants, water tolerance is an additional desirable property that ensures that their lubricating ability will not suffer in case of water contamination. Lubricants with API CD performance are commonly used in this application.

Natural gas engine oils are used in stationary engines that operate on natural gas. Natural gas engines can be two-stroke or four-stroke cycle, and either naturally aspirated or turbocharged. In addition to stationary applications in the natural gas industry, these engines are used in petroleum refining, for power generation, and in agricultural irrigation service.

Lubricant performance is established by OEM specifications. The API CD oils are suitable for use in this application. The OEMs use sulfated ash to recommend oils for their equipment, with a preference for ash levels of 0.5% or less. Generally, the four-stroke engine manufacturers encourage the use of higher-ash oils than the two-stroke engine manufacturers. The SAE has determined the need for new engine categories for engine oils that are intended for use in this application and has requested that the API and ASTM define such categories and write user language.

Aviation engine oils are of two types: those used in piston engines and those used in turbine engines. The aircraft piston engines utilize engine oils to lubricate the crankshaft, connecting rods, pistons, rings, bearings, and other moving parts. Ashless dispersant oils that range from SAE 30 to 60 viscosity are used most widely.

Jet turbine engine oils are formulated using synthetic base stocks, usually polyol ester and ester types, which are used to lubricate metal surfaces whose temperatures are up to 675 °C (1250 °F). Their main function is to control deposit formation on the hot surfaces. A mineral oil based lubricant will not provide satisfactory performance at these high temperatures, because of insufficient stability. U.S. military specifications MIL-L-23699C and MIL-L-7808G are used to select lubricants for use in this application.

Two-stroke cycle engine oils generally pertain to lubricants designed for the SI (gasoline-fueled) two-cycle engines. Two-stroke cycle engine oils for the CI (diesel-fueled) engines were described in the section on marine diesel engine oils. Two-stroke SI engines are commonly used in marine outboard engines, motorcycles, mopeds, motor scooters, all-terrain vehicles, snowmobiles, and chain saws. The performance of two-stroke cycle engine oils is described by SAE service classifications (Ref 17) and National Marine Manufacturers Association TC-W II performance requirements.

The SAE miscibility and fluidity grades, described in SAE J 1536 (Ref 10), assess the ability of a lubricant to mix with the fuel at prescribed temperatures. Lubricant performance is assessed on the basis of its ability to protect against deposit formation, ring sticking, piston and cylinder scuffing, preignition, spark plug fouling, and exhaust port blocking. TC-W II specified oils are the most recommended oils for use in modern outboard cooled engines. A TC-W III specification is under consideration at this time.

Two-stroke cycle engine oils can be either ashless or ash-producing. Ashless oils dominate the U.S. two-stroke cycle engine oil market because of their preferred use in outboard engines. Ash-producing oils are more cost effective, and are widely used in nonoutboard applications.

Lubricant-Related Causes of Engine Malfunction

Most of the problems associated with internal combustion engine lubrication are related to the by-products of combustion, their entry into the crankcase through blowby, and lubricant decomposition. This implies that fuel and lubricant quality and combustion are both important parameters. The major causes of engine malfunction that are due to lubricant quality are deposit formation, lubricant contamination, oil thickening, oil consumption, ring sticking, corrosion, and wear.

Deposit Formation. The two main sources of lubricant contamination are blowby from the combustion chamber and gases and volatiles from the crankcase, which are vented into the intake manifold as an antipollution measure (Ref 18). The blowby is a mixture of nitrogen oxides (NOx), sulfur compounds (SO_2, SO_3, H_2SO_4), carbonyl compounds, hydrocarbons (unburned fuel), peroxides and radicals, air, water, and carbon dioxide. These species are blown past the piston rings and down the valve guides into the crankcase. There, they can interact with each other and the lubricant to form harmful products. Such products include soot, carbon, lacquer, varnish, and sludge (Ref 19).

Soot is an important particulate contaminant in crankcase lubricants. It can be derived from the inefficient combustion of fuel and the burning of lubricating oil that passes along pistons into the combustion chamber. Fuel-derived soot, which is more commonly encountered in diesel operation, is due to the use of fuel with a wide boiling range, which, under certain operating conditions, does not burn completely.

Soot is not pure carbon and contains an appreciable amount of hydrogen, oxygen, and sulfur in a combined form. Soot particles are basically hydrocarbon fragments with hydrogen atoms partly stripped off. These particles are strongly attracted to each other and to polar compounds in the oil, and tend to form aggregates. Soot deposits are soft and flaky in texture and are commonly found in the combustion chamber.

Carbon deposits, more prevalent in diesel engine operation, are hard and result from the carbonization of the liquid lubricating oil and the fuel on hot surfaces. Carbon deposits have lower carbon content than soot and, in most cases, contain oily material and ash. Carbon deposits are commonly found on the piston top lands and crowns, in the piston ring grooves, and on the valve stems.

Lacquer and Varnish. The unburned air-fuel mixture and either oxidized or partially oxidized reactive intermediates in the blowby promote lubricant oxidation. This results in the formation of a variety of oxygenated products which, when exposed to high temperatures, result in lacquer and varnish (Ref 20). The term lacquer usually describes this type of deposit in diesel engines, whereas varnish is used to describe such deposits in gasoline engines. Lacquer is often derived from the lubricant and is generally water-soluble. Varnish, on the other hand, is fuel-related and is acetone-soluble.

Lacquer is commonly found on pistons and cylinder walls, and in the combustion chamber. Varnish occurs on valve lifters, piston rings, and positive crankcase ventilation (PCV) valves.

Sludge. Three major causes of sludge formation are oxidation of the lubricant, oxidation and combustion products in the blowby, and the accumulation of combustion water and dirt. Sludge can vary in consistency from that of mayonnaise to that of a baked deposit. Heat can drive off water and thereby cause a change in consistency. Low-temperature sludge, more prevalent in gasoline engines, is more watery in appearance and forms at temperatures below 95 °C (205 °F). High-temperature sludge, more common in diesel engines, forms above 120 °C (250 °F). Sludge is commonly found in areas of low oil velocity, such as crankcase bottoms and rocker boxes.

Mechanism of Deposit Formation. The volume of deposits in an engine depends on the fuel quality, engine operating conditions (speed, load, and temperature), quality of combustion and blowby (its oxygen content, presence of sulfur and nitrogen compounds, and so on), and the integrity of the seal between the combustion chamber and crankcase.

Low-temperature deposits (soot, varnish, and low-temperature sludge) are usually encountered in gasoline engines subjected to intermittent (stop and go) driving, because this type of operation does not allow the engine to achieve the optimum temperature necessary to drive off contaminants (Ref 18).

High-temperature deposits (carbon, lacquer, and high-temperature sludge) are typically found in gasoline engines that experience long continuous operation and in diesel engines (Ref 20). These deposits result from thermal and oxidative degradation of the lubricant and additives. Additional stresses on the lubricant stem from the increased emphasis on cleaner exhaust emissions and efficient combustion of fuel at high temperatures; the use of power accessories, such as air conditioning; and body-style changes that affect cooling.

Nitrogen oxide in the blowby (a consequence of combustion) and high temperatures cause oxidative and thermal degradation of the lubricant. The result is the formation of oxygenated products that act as precursors to deposit-forming species. These products have 15 to 50 carbon atoms and contain hydroxy and carboxy functional groups. They are polyfunctional molecules with the ability to polymerize thermally to form higher molecular weight products.

If the oxygen content of the precursors is low, and the polymer product is of low molecular weight and good oil solubility, then only oil thickening is observed. However, if the oxygen content of the precursors is high, and the polymerization results in products of low lubricant solubility, then varnish and resin are formed. When the polymerization occurs on hot metal surfaces, varnish is formed, and when it occurs in the bulk lubricant, resin is formed.

Because of its low solubility in the lubricant, resin tends to separate out on metal surfaces as lacquer, which can be amber or black in color. At low soot levels, the interaction of resin and soot results in resin-coated soot particles, which separate out on piston surfaces as black lacquer. At high soot levels, extensive interaction between soot and resin forms soot-coated resin particles that have little or no ability to adhere to metal surfaces. Instead, they accumulate as deposits in areas of low oil flow, such as in the grooves behind the piston rings (Ref 20). Sludge results from the interaction of the oxygenates with soot in the presence of oil and water.

Deposit levels depend on fuel quality. In the case of sulfur-rich fuels, the oxidation of sulfur results in the formation of sulfur acids, which catalyze the rearrangement of hydroperoxides to carbonyl compounds and their subsequent polymerization to resin. The addition of basic detergents, which are used in diesel engine oils (for marine and railroad use) to counter the adverse effects of sulfur, helps to alleviate this problem.

Oil thickening can result from a combination of oxidative degradation of the lubricant and the accumulation of insolubles (Ref 21). The auto-oxidation of the lubricant, accelerated near the oxidation inhibitor depletion stage, can lead to oxygenated products, which can cause a viscosity increase through polymerization (Ref 20). The contaminant-related thickening arises from the suspension of fuel-derived insolubles in the bulk lubricant.

Oil consumption is related mainly to the lubricant that travels past the piston rings and valves and burns in the combustion chamber. Burning of the lubricant, along with inefficient fuel combustion, leads to soot and carbon deposits on the inside of the combustion chamber, piston top land, ring grooves, and so on (Ref 19). The extent of oil consumption depends on a number of lubricant and equipment design-related factors. The viscosity, volatility, and seal-swell characteristics of the lubricant play an important role in this regard.

A certain minimum amount of oil is necessary for proper lubrication of the cylinder walls and pistons. High oil consumption is indicative of problems in pistons and cylinders, such as increased wear of the cylinder, bore polishing, stuck piston rings, or out of square grooves (Ref 4). Under these circumstances, the blowby gases have an increased chance of entering the crankcase, which is likely to further complicate the situation.

There is some evidence that oil consumption contributes toward particulates in diesel emissions. A consolidated effort is being made by OEMs and the lubricant marketers in the United States, Europe, and Japan to minimize these particulates, because of environmental concerns. One of the strategies to achieve this goal is to use lower-thickness oil films. This strategy is quite effective, except that beyond a certain limit, the oil film thickness will be ineffective for proper lubrication, and ring/liner scuffing problems will occur. Lubricant volatility is another important factor responsible for increased oil consumption. Lighter base oils that are used to formulate multigrade diesel oils not only contribute to the formation of a less-effective lubricating film, but also can readily leak past the piston rings and burn (Ref 22).

Ring Sticking. The major cause of ring sticking is the formation of deposits in the piston grooves. The consequence is a loss of oil seal, which not only favors blowby, but also results in poor heat transfer from the piston to the externally cooled cylinder wall. This is quite serious, because thermal expansion of the pistons will lead to loss of compression and, ultimately, to engine seizure.

Corrosion and Wear. Diesel fuel with a high sulfur content causes piston ring and cylinder wear, especially in large, slow-speed, marine diesel engines. Corrosive wear, more commonly associated with combustion and oxidation products, results from the attack of either sulfur acids or organic acids on ferrous surfaces. This happens when the engine operating temperatures are below the dew point of these acids. The organic acids can originate from thermo-oxidative decomposition of the lubricant or the additive system. This kind of wear is controlled by using lubricants that have a base reserve.

Lubricant Formulation

The inherent ability of mineral oil to act as a lubricant is not sufficient for most modern applications. Synthesized chemicals, called additives, are blended in base stocks, such as mineral oils, to help them perform effectively in demanding lubricating environments. A finished lubricant comprises a base fluid and a performance package, and, in the

case of multigrade oils, a viscosity modifier. The performance package can constitute as much as 30% of the total composition, depending on the desired performance level and the severity of end-use requirements.

Base fluids, or lubricant base stocks, are either of mineral or synthetic chemical origin. Mineral oil base stocks are obtained directly from petroleum fractionation, whereas synthetic base stocks are manufactured through transformations of petroleum-based organic chemicals. Partially synthetic base stocks are compatible mixtures of mineral oil and synthetic base stocks.

Mineral oil base stocks (lubricating oils) are obtained from the crude oil fraction, which boils at temperatures greater than 340 °C (645 °F) through a series of separation processes. These processes include vacuum distillation, solvent extraction, and wax removal. Some base stocks are hydrotreated or hydrocracked to improve color, oxidation resistance, thermal stability, and viscosity (Ref 23).

The more highly refined oils have little or no sulfur, and are therefore more prone to oxidation. The oxidation resistance of oils, which are more susceptible to oxidation because of the presence of unsaturation, can be greatly improved through hydrogenation. Most automotive and industrial lubricants, as well as greases, use solvent-extracted base oils. Both solvent-extracted and hydrotreated base oils are primarily used for premium products, such as turbine, hydraulic, and circulating oils.

Mineral oil bases stocks typically contain hydrocarbon molecules that contain from 20 to 70 or more carbon atoms. These base stocks are sometimes characterized as being a paraffinic, naphthenic, or aromatic type, depending on the nature of the hydrocarbons present. Paraffinic base stocks contain long saturated hydrocarbon chains; naphthenic base stocks contain five- or six-membered saturated cyclic rings; and the aromatic base stocks contain unsaturated cyclic (aromatic) rings. In reality, none of the base stocks are composed of a single structural type. Instead, they contain mixed structures, with one or the other predominating. Paraffinic base stocks, for example, contain all three types of structures, but paraffinic structures are present in the largest amount. The relative distribution of each type of hydrocarbon structure has a significant effect on the viscosity-temperature relationship and the pour point of the base stock.

The viscosity-temperature relationship of an oil is expressed in terms of its viscosity index (VI), which indicates the degree of change in viscosity of an oil with a change in temperature within a given temperature range. A high VI signifies a relatively small change, and a low VI, a large change. The VI of an oil can be determined by measuring the kinematic viscosity of the oil at 40 °C (105 °F) and 100 °C (212 °F), and by using ASTM tables (Ref 24).

Paraffinic base stocks are generally preferred because of their high viscosity index (HVI). However, because they contain a substantial amount of wax, they have high pour points. Naphthenic base stocks, which have lower viscosity indices, are preferred only in certain applications, because of their lower wax content and lower pour points. Aromatic stocks are the least preferred, because of their poor oxidation resistance, tendency to form black sludge at high engine operating temperatures, low VI character, and their suspected carcinogenic nature. The relationship between various lubricant properties and structures is shown in Table 4.

Table 4 Relationship between properties and hydrocarbon structures

Hydrocarbon types		Main properties
Straight chain paraffin		Viscosity varies little with temperature; good oxidation resistance; high pour point
Branched chain paraffin		Viscosity varies little with temperature (except when divided); good oxidation resistance; may have low pour point
Naphtha rings with short paraffin side chain		Good oxidation resistance; low pour point; viscosity varies greatly with temperature; becomes pseudoplastic under cool conditions
Aromatic rings with short paraffin side chain		Pour point varies according to structure; good thermal stability; viscosity varies greatly with temperature; easily oxidizes
Naphtha rings with long paraffin side chain		Viscosity varies little with temperature; good oxidation resistance; may have low pour point
Aromatic rings with long paraffin side chain		Viscosity varies little with temperature; may have good oxidation resistance if cycles are not numerous; may have low pour point

Source: Ref 25

Source: Ref 25

Synthetic base stocks are manufactured by chemical reactions such as alkylation, polymerization, and esterification. Commercial synthetic fluids include synthetic hydrocarbons (alkylaromatics and polyolefins), organic esters (dibasic acid esters, polyol esters, and polyesters), and miscellaneous other organic materials (phosphate esters, polyalkylene glycols, and polyphenyl ethers) (Ref 26, 27, 28, 29). Polyolefins, dibasic acid esters, polyol esters, and polyalkyleneglycols (polyether glycols) are the most widely used synthetic lubricants. Their chemical structures and principal applications are shown in Fig. 8 (Ref 25).

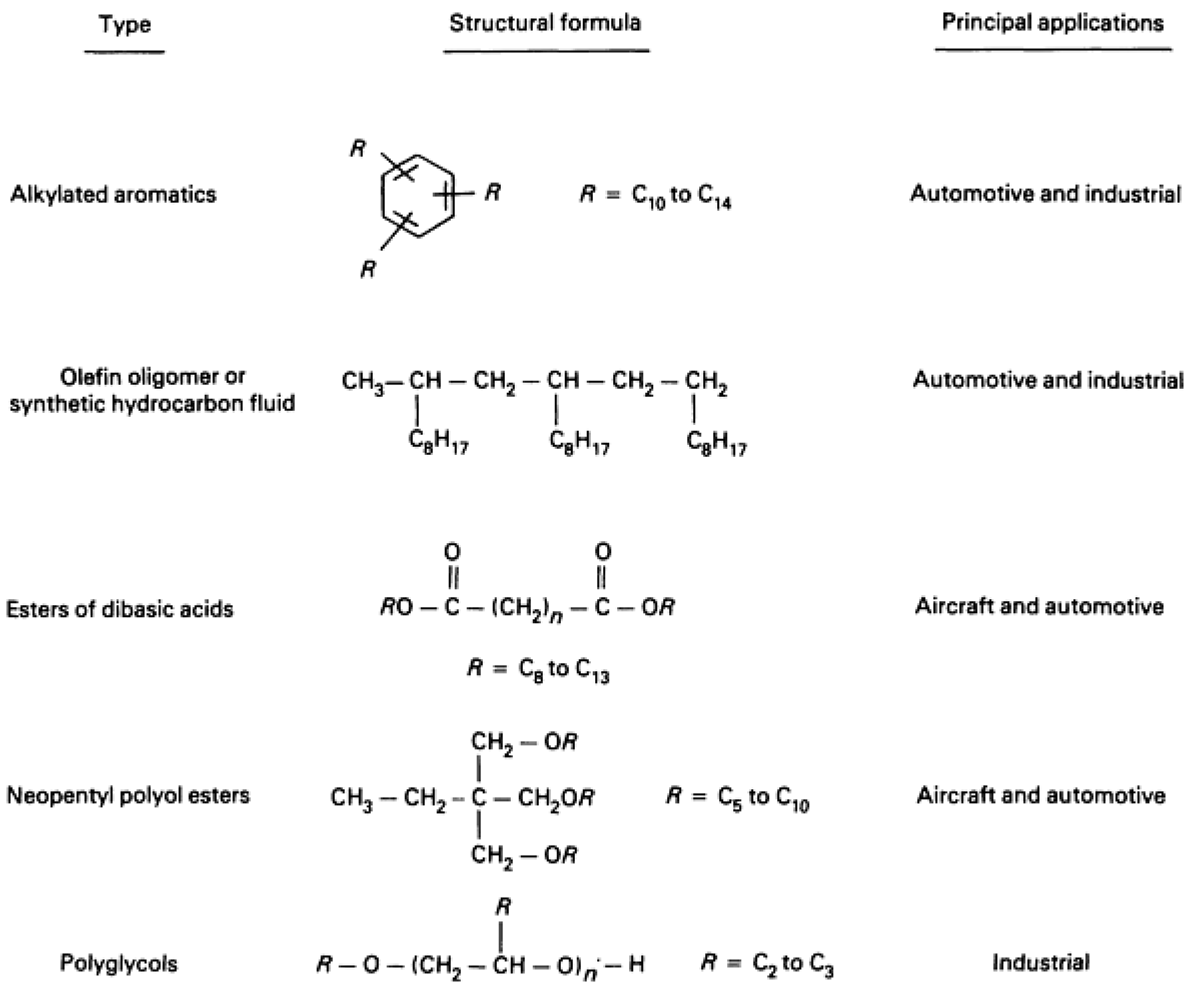

Fig. 8 Synthetic base stocks and their uses. Source: Ref 27

Synthetic base stocks are used in situations where mineral oil base stocks do not provide satisfactory performance, because of their inherent limitations. Synthetic base stocks can be devised to possess any number of unique and desirable properties. Commonly sought properties include enhanced thermal stability, high viscosity index, fire resistance, low pour point, low volatility, and low toxicity (Ref 28).

Table 5 compares some physical properties of hydrofinished HVI stocks and synthetic base stocks. The levels and types of additives used in either synthetic or partially synthetic base stocks (blends of synthetic base stocks and mineral oils) are similar to those used in mineral oils.

Table 5 Physical properties of hydrofinished high viscosity index (HVI) stocks and synthetic base stocks

Type	Kinematic viscosity, mm^2/s			Viscosity index	Pour point		COC flash

Performance Package

The performance package contains a number of chemical compounds (additives) that are blended in base stocks to make them suitable for use as lubricants.

The quality and quantity of additives in the performance package depend on the properties of the base fluid and the intended application. The functions of a lubricant are to limit and control friction, metal to metal contact, overheating (from friction and combustion), wear, corrosion, and deposits. The specific properties that the lubricant should have in order to perform these functions include suitable viscosity, slipperiness, high film strength, low corrosivity, low pour point, good cleansing and dispersing ability, nontoxicity, and low flammability. In addition, the lubricant should not foam, that is, it should be capable of getting rid of air (oxygen) to minimize oxidation and maintain its lubricating characteristics.

The viscosity of the oil should be such that it can provide proper lubrication, both at low temperatures and at the high temperatures encountered during engine operation. This implies that oil viscosity at low temperatures should not interfere with starting and lubrication during the warm-up period, and that loss of viscosity at high temperatures is minimal. As a general rule, large clearances and high loads demand high viscosity, and high speeds demand low viscosity.

The oiliness and film strength of the lubricant are related to its ability to reduce friction and wear under boundary lubrication conditions and to protect against corrosion. The oil itself should not be corrosive, and it should provide protection against corrosion.

The pour point is one of the means used to determine the flow characteristics of lubricants at low temperatures. Lubricants that contain wax will provide little or no lubrication below their pour point, because wax crystals can separate and cause blockage of the oil pump inlet.

Detergency is the property related to the ability of a lubricant to keep engine internal surfaces clean through film formation and by neutralizing the acidic products of combustion and oxidation. If not controlled, these products will promote the formation of engine deposits. Dispersancy is the ability of the lubricant to suspend harmful products through association.

The lubricant should resist oxidation in order to minimize the formation of harmful products, such as acids, lacquer, and sludge. These products will adversely affect engine performance.

These functions are carried out by additives such as dispersants, detergents, antiwear agents, friction modifiers, oxidation inhibitors, corrosion inhibitors, pour-point depressants, foam inhibitors, and viscosity improvers. Descriptions of these additives and their functions are provided in Ref 30 and 31, as well as in the article "Lubricant Additives and Their Functions" in this section of this Volume.

Performance Testing

All engine oils are performance tested prior to being introduced to the marketplace. Trade associations and technical societies that contribute to testing and approval processes in the United States are the API, ASTM, Chemical Manufacturers Association, Motor Vehicles Manufacturers Association, SAE, and the National Marine Manufacturers Association. The Coordinating European Council, in western Europe, and the Japanese Automotive Standards Organization and Society of Automotive Engineers, Japan, establish the performance requirements in those countries. The need for a new performance level may relate to new engine design, current equipment problems, or future goals.

As a preliminary step, a number of oils with demonstrated field performance are selected as reference oils. These oils are run in the laboratory using production engines from various manufacturers simulating actual service conditions. The engine parts are periodically examined to closely monitor the performance of the lubricant. A good correlation between field performance and laboratory performance standardizes the test to evaluate new lubricants.

The development of laboratory engine tests is costly and time consuming. Therefore, future performance requirements have to be anticipated and defined as accurately as possible. This can only be done through the cooperation of equipment manufacturers, lubricant and additive marketers, and the end users. The laboratory engine tests are expensive to house, operate, and maintain. Despite continued efforts to devise tests to evaluate lubricant performance quickly and inexpensively (Ref 25), no good substitute for engine tests has yet been found.

A number of key processes make up a quality test. These include the quality of parts, engine build, operating procedures, and test ratings. Low part-to-part variability is extremely critical to proper evaluation of the lubricant. If parts vary in quality, then it is difficult to assess whether the test results reflect the effectiveness of the lubricant or part-to-part variance. The way an engine is assembled also has an impact on engine test results. Therefore, it is important that the test engines are built according to an established procedure and with parts of good and consistent quality.

The ASTM has the prime responsibility of ensuring that the defined operating procedures for a particular test are followed. Most modern testing facilities use computer data acquisition and control systems to monitor the operation of a test. Ratings are conducted by qualified raters, who are trained by a self-policing industry-supported group. Previously, much emphasis was placed on the operations and ratings of a test. That emphasis is being supplanted by the realization that all four elements are equally important when conducting a quality test.

Several controlling bodies ensure that the established test procedures are properly carried out, and that the ratings are consistent among industry laboratories. In the United States, such bodies include the Test Monitoring Center (TMC), the ASTM surveillance panels, and the SAE Lubricants Review Institute (LRI).

The TMC, a key part of the ASTM monitoring system, is a neutral body that deals with the calibration and monitoring of test facilities to assure that the engine tests are conducted according to the procedures described by ASTM (Ref 32). The TMC also supplies the reference oils, validates stands for reference purposes, and approves laboratories for testing. If a laboratory is not operating according to the established guidelines, in the opinion of the TMC, then the TMC has the authority to invalidate it. Because the TMC oversees most test laboratories, it provides statistics and identifies trends.

The surveillance panels are composed of experts, usually from the test laboratories, who monitor a specific test and make sure that the test runs as prescribed and is providing consistent and on-target results.

The LRI ensures that the candidate products meet U.S. military performance requirements. In order to obtain approval, the additive or lubricant supplier submits the selected parts from the prescribed tests, along with test parameters and test results. If these are acceptable, a recommendation for approval is granted for the pertinent military specification. Final approval is granted by the military upon review of the LRI recommendation and supporting documentation. Because many candidate products also meet the requirements described by SAE J 183 and are marketed in the private sector, the results of the LRI recommendations also impact commercial oils (Ref 33).

Once the lubricants have met all the requirements established by SAE, API, and ASTM, some lubricant and additive marketers choose to field test their products. This is the final test of lubricant performance. It involves testing in fleets and can take one year or more. The test employs commercial vehicles or vehicles that involve extensive use. The engines in these vehicles are examined periodically to assess lubricant performance (Ref 34). A lubricant with demonstrated good performance in laboratory engine tests and field tests is ready for the marketplace.

Introduction to Wear

K.C. Ludema, University of Michigan

PERHAPS THE BIGGEST CHALLENGE in solving wear problems is that of anticipating the type(s) of wear to which components will be subjected. Material can be removed from a solid surface in only three ways: by melting, by chemical dissolution, or by the physical separation of atoms from the surface. The last method can be accomplished either by the one-time application of a high strain or by cyclic straining at lower magnitudes. Mechanical and chemical processes may operate separately or together, such as abrasion in a corrosive medium.

There is no organized catalog containing exact descriptions of the states of stress or chemical conditions imposed on materials subjected to wear over a large range of applications because the mechanics of sliding and other forms of wear have not been rigorously defined for all cases. However, a great deal of information is available on the wear response of materials within smaller ranges of conditions.

Lacking a first-principles means to select and match materials to any wear situation, a combination of failure analysis and simulative testing is required. The articles in the Section "Wear Monitoring and Diagnosis" of this Handbook describe the tools of wear analysis and provide guidance on how to observe the wear processes in the proper scale and with the proper perspective. The articles in the other Sections on Wear address various wear types, describing their mechanisms and mitigation. The classification of wear types is somewhat arbitrary, but all the major environments in which wear commonly occurs are covered.

The terms used in the following articles to describe wear vary based on the author's background and on the industry in which he works. Many terms are subjective to some extent. For example, we often refer to a sliding environment as "abrasive" when we feel gritty substances on or near the wearing surfaces. In fact, the wearing materials may not have been abrasively worn at all, but instead by some other process, such as by the chemical action of the environment. The reader is referred to the Glossary for more formal definitions of many of the terms associated with wear; however, not all terms and colloquial jargon are contained there. Instead, their context will be a guide to their meaning.

The major creative act in designing for wear resistance still lies with the designer. The articles in this section can serve only as general guidelines. They have been written mostly by research-oriented authors who study specific wear mechanisms by experiments that attempt to isolate only the mechanism of interest. Practical devices almost always wear by a sequence or combination of wear mechanisms. Neither designers nor researchers can anticipate which combinations will occur without experience from actual service. The wise course, then, is simulative testing, provided that one is armed with a solid knowledge of mechanisms and equipped with the proper perspective for observing what is going on.

Finally, because we cannot be certain that any given wear part will be used in a manner that we might anticipate, we apply methods of monitoring and diagnosis to enhance our powers of observation. Many of these issues are discussed in more detail in the articles that follow.

Surface Damage

Sture Hogmark, Staffan Jacobson, and Olof Vingsbo, Uppsala University (Sweden)

Introduction

THE TYPES OF DAMAGE that surfaces display as a result of tribocontacts will be surveyed in this article. Surface damage in this context is defined as topographical or microstructural changes, or both, in a surface layer. Micrographs of various sorts will obviously have a dominant role in this description, which can be thought of as an introduction to "tribography," defined as a micrographic description of topographical and structural modifications in tribocontacts. Diagnosing surfaces with respect to the mechanisms and processes that caused the damage, and relating those mechanisms to the geometry, materials properties, and other characteristics of the tribosystem, can be instrumental in reaching a deeper understanding of tribological components. The final objective of tribographical efforts is to achieve better tribosystems.

Surface damage to a tribosystem is most often generated in many consecutive small steps by a number of different micromechanisms that are active in the tribosurface. The observed damage is thus the cumulative effect on a macroscale of these micromechanisms. The present tribographical approach is based on a direct classification of surface damage features, as displayed on the resulting surface, rather than on the traditional classification by wear mechanisms that were active in producing it.

Classes of Surface Damage

In principle, a tribosurface may exhibit damage of a single type, but generally the pattern is a combination of two or more types. Examination and interpretation may be quite complex, but a classification into the idealized types illustrated in Fig. 1 is convenient and will be used in this article.

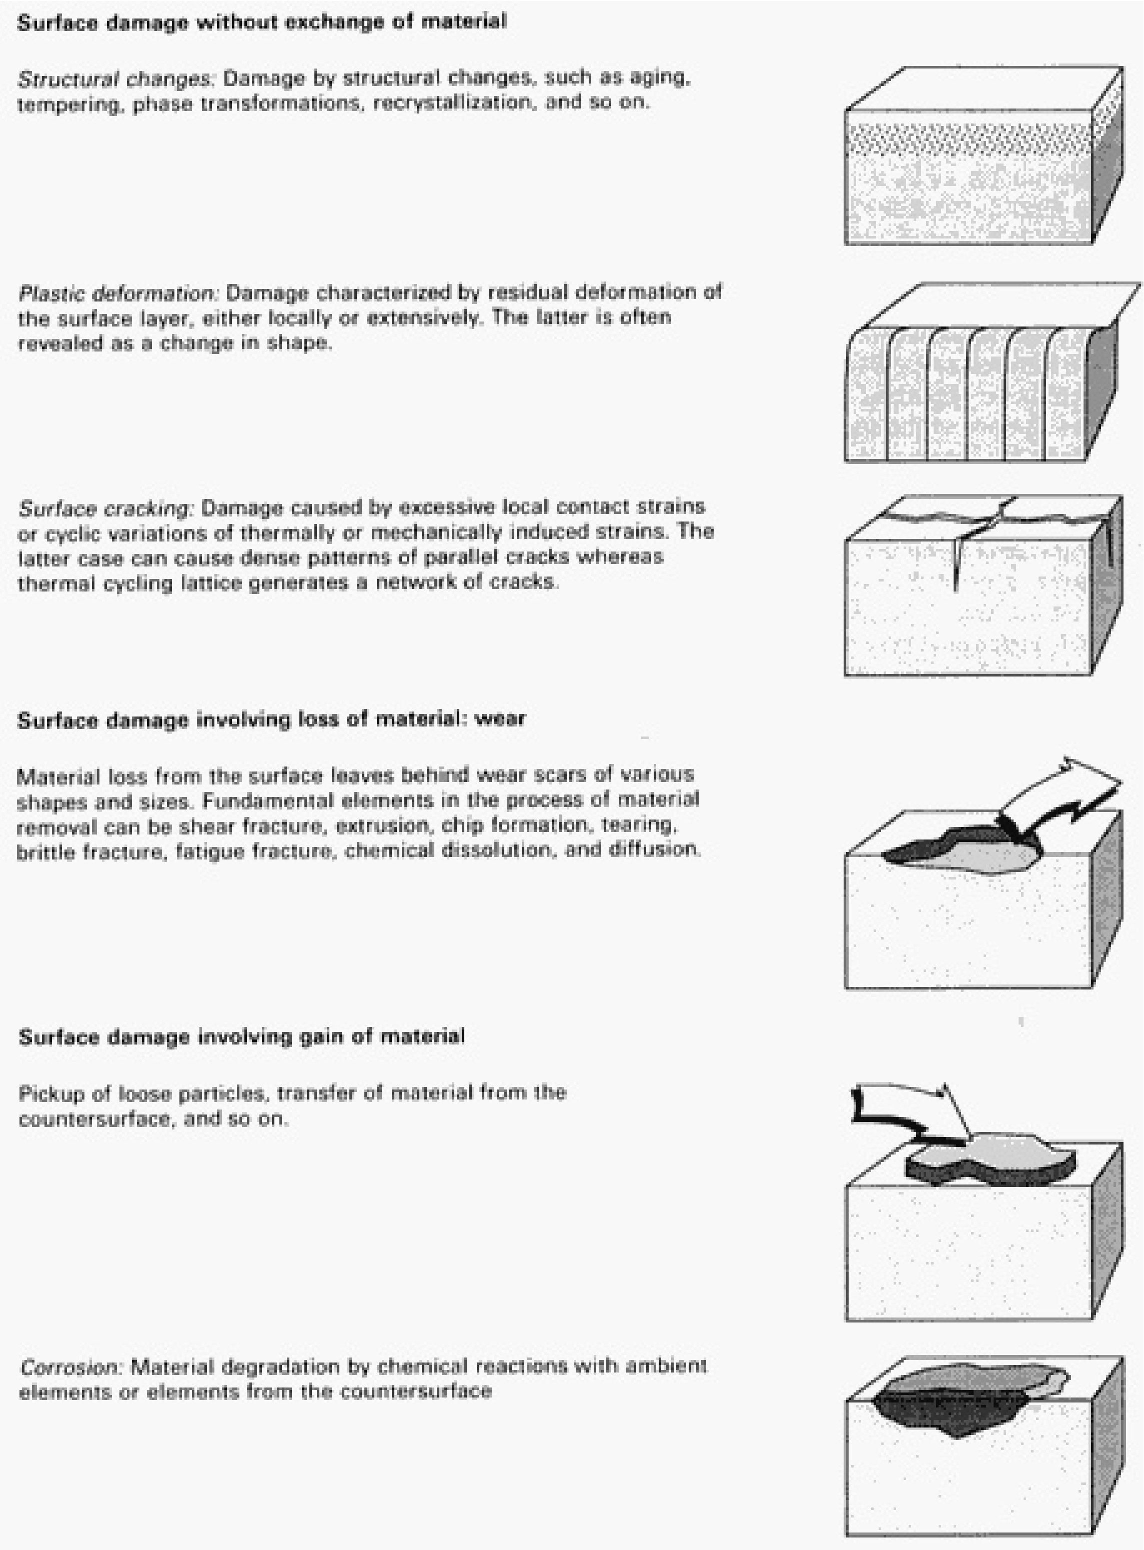

Fig. 1 Classification of surface damage

All the types of damage shown in Fig. 1 will in practice influence a surface layer. It can be noted that, using the present definition--topographical or structural changes of a surface layer--damage is not necessarily harmful. The loss of material and plastic deformation involved in the "running-in" of an engine naturally "damages" the virgin tribosurfaces, but is still favorable to the engine. Similar examples will be presented. It is obvious from Fig. 1 that loss of material is only one type of surface damage, but it is frequently the most important.

Interaction Between Different Types of Damage. The fact that the damage observed on a tribologically loaded surface normally is a combination of two or more of the types illustrated in Fig. 1 indicates that several mechanisms have been operating simultaneously. The overlapping mechanisms generally do not operate independently, but interact to mutually increase the effects of one another. An example of such synergistic interaction is the simultaneous corrosion and wear involved in high-temperature erosion. The oxidized layer is more prone to erosive wear, which in turn increases the oxidation rate by exposing bare metallic surfaces to the atmosphere, and so on.

Occasionally, however, the combined effects can lead to a net reduction of the individual effects. One example of such a counteractive interaction is the suppression of severe adhesive wear of metals in sliding contacts by the formation of an oxide layer. The oxide layer reduces the adhesive forces between the sliding bodies, which diminishes the probability of shear fracture of the metal surfaces. In favorable cases, the friction is reduced and the adhesive metallic wear is replaced by a mild wear of the slowly growing oxide layer.

Diagnosis of Surface Damage

Properties of the Surface Layer. Figure 1 demonstrates that, although surface studies render much information, they must be supplemented with microstructural studies on cross sections to give a more complete picture. The structure and even the composition of the damaged surface layer are often very different from those of the virgin material. Hence, it would not be relevant to consider the properties of the virgin material even if measured in the actual state of local stress and temperature.

The designation "active layer" refers to the surface layer with its composition, structure, thermal, and mechanical properties *during* the tribological contact, whereas the "relaxed (post-worn) layer" is the same layer with properties reached after unloading and cooling to ambient temperature (see Fig. 2). An important part of tribography is to study the relaxed layer, deduce its active state, and from there draw conclusions about mode of failure, improved design, materials selection, or other aspects depending on the purpose of the investigation.

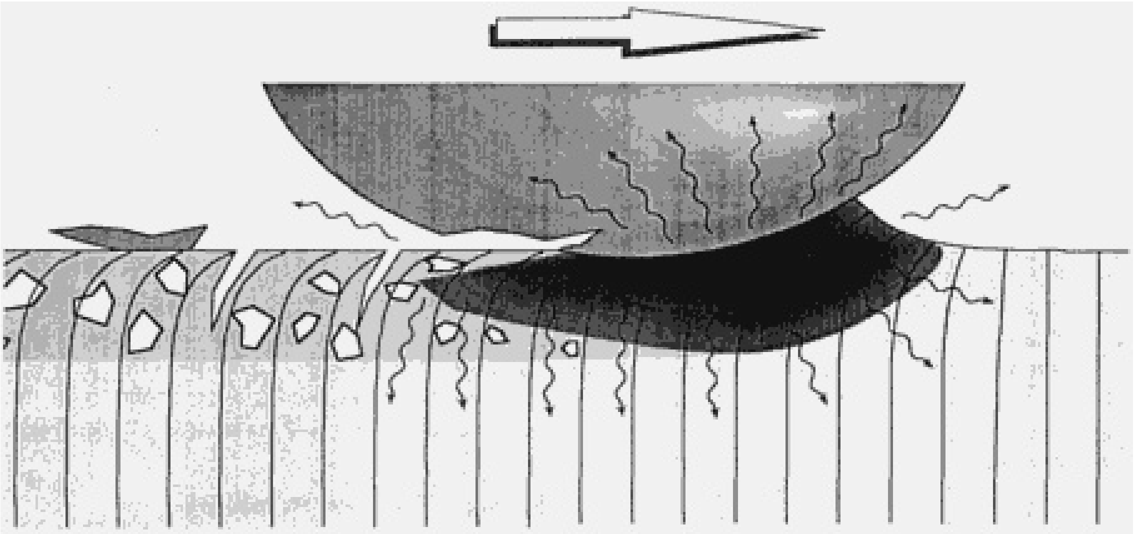

Fig. 2 Schematic of a single triboevent generating an active layer by transforming the original surface material under the influence of high normal and shear forces and frictional heat. Relaxation of this layer, involving additional phase transformations, will occur some time after the contacting asperity has passed.

Effects of the Surface Damage. When diagnosing a damaged surface by tribographical examination, it is important to be attentive to the type of problem the damage is causing--that is, to identify which type of damage sets the "life-limit criterion." The effects of a certain type of damage and the recommended action for reducing the problem vary greatly from case to case. For consumable wear parts, the only action to be taken should be to try to reduce the dominant wear mechanism, whereas there is no need to worry about transfer particles and so forth. When the requirements on the topography are high, however, as in rolling bearing surfaces and printing cylinders, small scratches, transfer particles, or even surface cracks may be detrimental to the function of the system. Generally, the problems can be divided into the following groups:

- Material losses eventually consume the wear part (for example, excavator teeth, shoe soles)
- Material losses deteriorate the function (by causing cutting edge blunting, excessive bearing clearance, and so on)
- Disadvantageous topography, structure, or composition deteriorates the function (for example, rough topography of forming tools or on optical lenses)
- Wear particles deteriorate the function (by causing abrasive wear, by contaminating end products such as in food processing, and so on)

There are also numerous examples of surface damage that may be highly beneficial to the function. During the running-in phase of many machines, for example, tribosurfaces are smoothed by wear and plastic deformation, which leads to improved conformity, reduced stress concentrations, and enhanced lubrication. A further mechanism is the formation of wear-protective overlayers, such as those frequently formed on cutting tool edges or on hot rolls. Friction-reducing layers also are sometimes formed on the tribosurface--in dry sliding between polymers and metals or in lubricated systems with oils containing chemically active additives, for example.

Relative Importance of Rival Wear Mechanisms. If more than one wear mechanism can be identified in a tribosurface, an inexperienced person examining the surface tends to overestimate the importance of large, spectacular scars, even if they are sparsely scattered over an otherwise smoothly worn surface. However, for cases where material loss is the lifetime-limiting damage, reducing the overall wear rate is the primary task. The wear rate, in turn, is determined by the volume of the produced wear particles and the frequency at which they are produced. If large scars cover only a small portion of the surface, they are the result of rare events, even more so if they are deep. In fact, for steady-state wear, the relative amount by which a mechanism contributes to the total wear is approximately proportional to the area fraction occupied by the scars of that mechanism. Thus, in combating the wear of devices with rival mechanisms operating, efforts should be focused on the mechanism that damages the largest surface area fraction and not on the mechanism that produces the largest individual scars. An example of surface damage caused by two competing wear mechanisms on the thread of a percussion drill coupling is shown in Fig. 3.

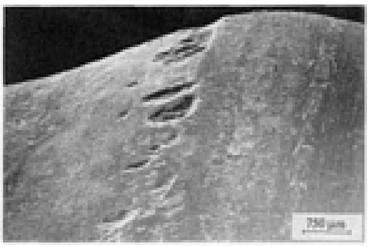

Fig. 3 Scanning electron micrograph of a thread of a percussion drill coupling. Mild abrasive and coarse pitting wear mechanisms dominate the wear to a fraction of 85% and 15%, respectively.

Selected Tribographical Examples

A number of tribographical examples of surface damage will be discussed in this section, applying the damage classification system shown in Fig. 1. The examples range from quite idealized to complex combinations of damage types.

Surface Damage Without Exchange of Material

Damage by microstructural changes, practically free from accompanying plastic deformation, is observed in ball bearing rings after many revolutions at high load. At a depth under the raceway, corresponding to maximum shear stress, the steel undergoes a phase transformation from tempered martensite to a dark etching zone of fine-grained high-carbon ferrite and residual martensite. At the center of the zone, a second transformation generates two differently oriented families of ferrite disks (Fig. 4). The excess carbon from the martensite is redistributed to form carbide lamellae between the ferritic disks. The driving force for these transformations is provided by the steep elastic stress gradients associated with each ball passage, which promote carbon diffusion in the martensitic matrix.

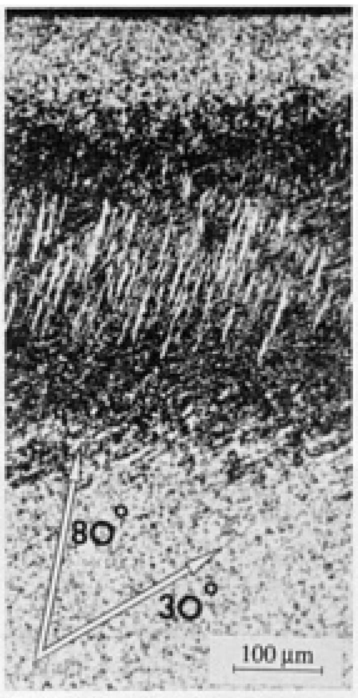

Fig. 4 Optical micrograph showing stress-induced phase transformation and successive development of a dark etching zone with parallel white etching ferrite disks under the raceway of an AISI 52100 steel ball bearing ring

Similar stress-induced changes in martensitic structure are frequently observed beneath the contact surfaces of gear teeth. It is not yet fully understood whether this kind of material transformation is beneficial or detrimental to the load-carrying capacity and wear resistance of ball bearings, gears, and similar components. It has been observed, however, that continued running at high load will eventually cause spalling, with associated cracks propagating preferentially along the new phases.

Damage Dominated by Plastic Deformation. Overloaded tribological components can suffer from gross plastic deformation. An example of this is the pearlitic carbon steel in Fig. 5. Extreme conditions of stress and temperature close to the surface soften the material locally, thus making it prone to plastic deformation. The outermost surface layer has reached a temperature above the austenitization level, which is evident from the fact that the relaxed layer had a microhardness of about 1200 HV, indicative of a later martensitic transformation (see below).

Fig. 5 Optical micrograph of a pearlitic carbon steel sample plastically deformed and phase transformed by a single-pass sliding contact against a cemented carbide cylinder. A continuous layer of friction martensite has formed in the superficial layer, while a dual phase of pearlitic and ferritic grains is found in an intermediate layer. Toward the surface, the pearlite grains have been partially transformed to martensite and the ferritic grains have recrystallized. No material has been lost from the surface.

The example shown in Fig. 5 was collected from sliding experiments against a cylindrical cemented carbide countersurface, with the cylinder axis perpendicular to the direction of sliding. Because of a vanishingly small angle of

attack between the contacting surfaces, there was virtually no loss of material. This form of damage is similar to that intentionally produced by the burnishing surface modification technique.

This example also illustrates the previous discussion about active and relaxed layers. Originally, the material had a homogeneous pearlitic structure. During the triboevent, the surface layer was heavily deformed and the temperature increased enough to transform the top layer into austenite, which consequently was its active phase. Transformation of austenite to untempered martensite occurred immediately after the triboevent by quenching through heat dissipation into the bulk material.

The importance of employing cross-sectional micrographs to fully understand the response of a material to tribological contacts is evident. The fact that the structure, and thus the mechanical properties of the surface layer, have been totally transformed cannot be ascertained from topographical imaging alone.

Plastic deformation of a surface without loss of material may also occur under the action of abrasive grains of nonaggressive geometry. Grooves surrounded by ridges are formed by local plastic flow of material. Such deformation may be detrimental when a high surface finish is required. Similarly, plastic deformation without loss of material often occurs in the initial phase of particle erosion of ductile materials (Fig. 6).

Fig. 6 Scanning electron micrograph showing plastic deformation without material loss in a cemented carbide surface exposed to single-particle impact. The binder phase (cobalt) has been extensively plastically deformed, while the hard carbides have been pushed around without deforming but have occasionally partially deadhered from the matrix. The surface has also been damaged by the pickup of fragments from the erosive SiC particle. Courtesy of Mikael Olsson

Damage Dominated by Surface Cracking. Surface cracks in tribosurfaces are usually caused by cyclic straining, which in turn is generated by some combination of cyclically varying frictional forces and frictional heating. The crack nucleation requires the presence of tensile stresses and a relatively brittle surface material. In principle, there are two ways in which tensile stresses can be generated in a tribocontact:

- Heat expansion of the surface layer beyond the compressive yield limit, followed by cooling, introduces tensile stresses in the plastically deformed layer
- Friction force directly generates tensile stresses at the trailing end of tribocontacts (Fig. 2)

In addition, materials which initially are ductile may become progressively embrittled after cyclic straining, and thereby prone to crack nucleation. The main plane of crack propagation is normal to the direction of the tensile stress.

Excessive strains caused directly by the friction force usually result in a pattern of parallel cracks perpendicular to the sliding direction, whereas friction-induced thermal cycling yields isotropic strains and a corresponding network pattern (Fig. 7). Because the cracks do not primarily involve material losses, they may well be tribologically harmless, unless they lead to secondary effects, such as enhanced corrosive attack (stress corrosion), reduced fatigue life, or spalling. Tribocracks are less likely to be observed in systems with ductile materials. At high wear rates, where the outermost layer is continuously worn off at a rate higher than that at which crack propagation would have occurred in the absence of wear, tribocracking is also suppressed.

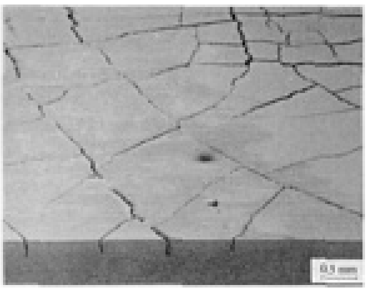

Fig. 7 Scanning electron micrograph of surface and cross sections showing cracks in a hydraulic steel piston. The reciprocal sliding was horizontal.

Surface Damage Involving Loss of Material: Wear

Damage Dominated by Shear Fracture. Plastic shear deformation of a surface is one of the telltale signs of adhesive wear. Depending on the application and the severity of the deformation, smearing, galling, scuffing, scoring, or seizure are also signs of adhesive wear. Typical of severe shear fracture is the generation of a scalelike topography (Fig. 8). Occasionally, fragments lost from the mating surface can be picked up and observed at the end of the groove at which they have just formed (see "A" in Fig. 8). Another groove, formed in a similar manner, can be seen at the top left of Fig. 8. Note that a picked-up fragment may be capable of scoring its own material if it has been strengthened during previous triboevents by successive mechanical and thermal cycling, causing a gradual decrease in grain size and, in the case of steels, repeated martensitic transformations (Fig. 5).

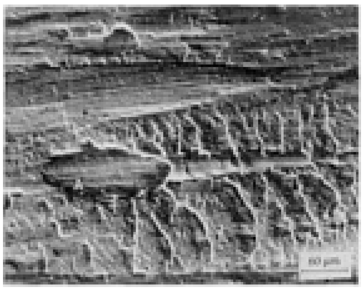

Fig. 8 Scanning electron micrograph showing damage dominated by shear fracture typical of severe adhesive wear. Pin surface from pin-on-disk sliding between two identical AISI D1 steel specimens. Sliding direction of counterface was from right to left.

This type of severe surface damage is indicative of a system that in action showed high friction, high wear rate, and a high noise level. It usually terminates the life of sliding components and should by all means be avoided, at least by selection of different materials for the two mating surfaces if not by redesign or improved lubrication.

Another instructive example of complex surface damage is presented in Fig. 9, which shows the microstructure of the subsurface layer of a special brass component that has been slid against steel. The grain morphology has been affected by massive plastic flow in the direction of counterface sliding, changing from the arbitrary shapes at great depth, via elongation into thin parallel disks, to a hardly resolvable microstructure of very fine grains close to the surface. The superficial layer has also undergone dynamic recrystallization during continued sliding and frictional heating.

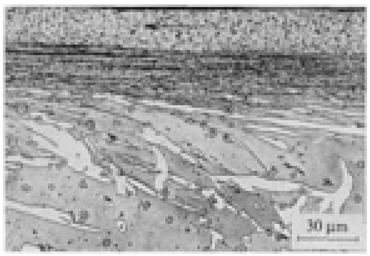

Fig. 9 Optical micrograph showing the subsurface morphology of special brass damaged by shear fracture, plastic deformation, and microstructural changes, when slid against steel

As in the case of the steel surface shown in Fig. 8, the mechanism of material loss for the example illustrated in Fig. 9 was severe shear fracture. Initially, brass patches adhered to the steel surface; loose, flakelike brass particles were subsequently produced at an unacceptably high rate.

Damage by shear fracture is directly related to the shear force transmitted between the mating surfaces. This force, in turn, is related to the tendency of different mating materials to form solid solutions or intermetallic compounds with each other. In general, materials having a hexagonal close-packed (hcp) structure exhibit lower adhesive wear than either a body-centered cubic (bcc) or a face-centered cubic (fcc) structure material. Additional information is available in the article "Sliding and Adhesive Wear" in this Volume.

Damage Dominated by Extrusion. Extrusion is a type of surface damage that can occur in certain tribological systems with sliding or rolling contact. Material is plastically squeezed ahead of a traversing asperity or a rolling element. The latter case is exemplified by Fig. 10, which shows extrusion of surface material from the originally hard chromium-plated surface of a carbon steel loop. The loop was used to attach a steel spring to the frame of a hospital bed. The rocking motion of the spring against the loop broke up the chrome layer and squeezed the underlying steel to the sides of the contact area.

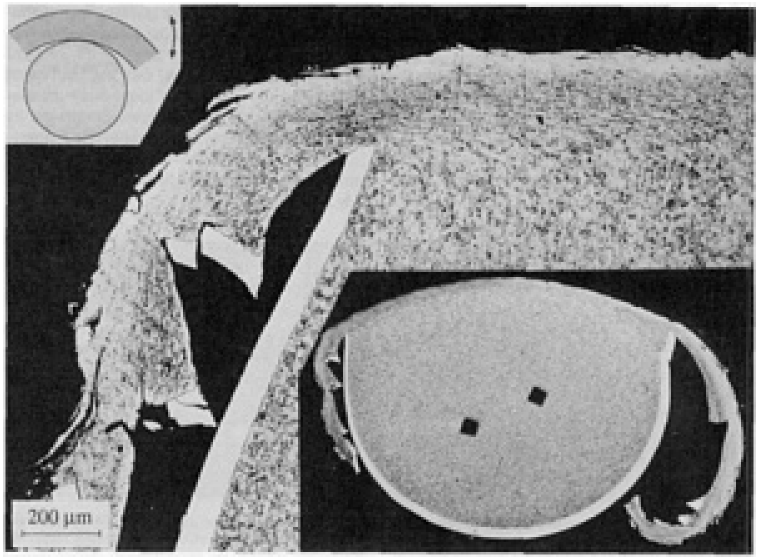

Fig. 10 Optical micrograph showing extrusion of surface material from a hard chromium-plated steel loop. Insets: overview and contact geometry

The extrusion of burrs limited the life of the loops both by gradually decreasing their strength and by generating a potential source of injury for the hospital staff. About 50 loops in each of about 5000 beds had to be replaced. The key to avoiding these premature failures was using a harder steel in the loops.

Damage Dominated by Chip Formation. The plowing action of a hard abrasive particle against a softer surface may cause plastic deformation without material loss. Conditions can also be such that a chip is cut out of the surface (Fig. 11). After the chip is lost, the surface scar does not primarily reveal the loss of material, but the abrasive wear can generally be identified by, for instance, the associated cumulative changes of the bulk shape of the worn part. Material loss by chip formation is usually accompanied by heavy plastic deformation of material in the ridges and under the grooves and further by microstructural changes in a surface layer similar to those presented in Fig. 5 and 9. Typical surface damage resulting from abrasive wear of a road grader blade is shown in Fig. 12.

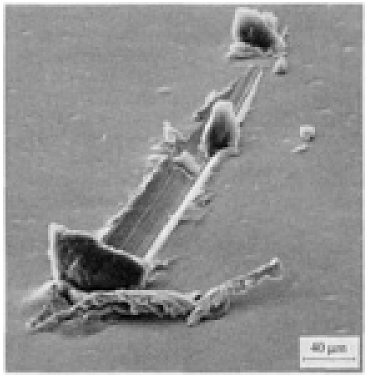

Fig. 11 Scanning electron micrograph showing surface damage by chip formation, plastic deformation, and pickup of fragments of a ceramic particle abrading a copper surface

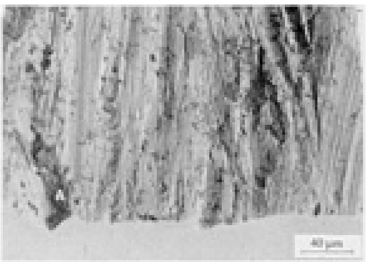

Fig. 12 Scanning electron micrograph of the surface and cross section of a road grader blade worn against gravel. The surface has been damaged by chip formation, plastic deformation, and pickup of silica, revealed as dark, rough patches at A.

Damage Dominated by Tearing. Tearing is a mode of material separation typical of polymeric materials. It is initiated by local stiction between the mating surfaces, followed by material being pulled or torn out of the surface, often leaving elongated tongues or strings as wear debris or still loosely attached to the surface, as in Fig. 13. Figure 13 shows a small piston pump used in analytical equipment for medical applications. The prime cause of failure was leakage caused by local tearing, which destroyed the surface topography. Furthermore, wear particles contaminated the pumped medium.

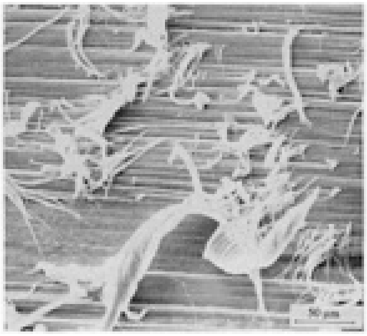

Fig. 13 Scanning electron micrograph showing damage caused by tearing in the cylinder surface of a small polytetrafluoroethylene (PTFE) piston pump used to portion human body liquids into an analytical instrument.

The tearing mechanism requires strong adhesion to the countersurface combine with an anisotropic cohesion of the material. Polymeric materials often fulfill the latter condition by having a high degree of structural texture.

The material being torn out of the surface may also form rolls (Fig. 14). This mechanism of material loss is best characterized by rubber erasers.

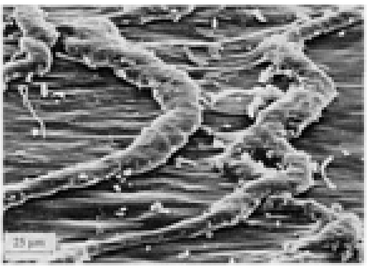

Fig. 14 Scanning electron micrograph showing roll formation associated with tearing of material from the surface of polyurethane during sliding against a flat metal surface. Sliding direction of counterface was from left to right.

Damaged Dominated by Brittle Fracture. Brittle fracture is a common mode of surface failure of hard and relatively brittle materials such as ceramics, ceramic coatings, cemented carbides, cermets, and hardened steels. It is initiated by tensile stresses high enough to exceed the fracture stress of the surface material in its active state. These stresses can be caused by a number of tribomechanisms. The type of damage can vary from a relatively large-scale fracture (Fig. 15) to fragmentation on a microscale (Fig. 16). It is obvious that the tool shown in Fig. 15 has lost its original shape and thus its performance. The erosion rate of the alumina shown in Fig. 16 was unacceptably high in its intended application as a mechanical face seal, but could be dramatically reduced by toughening the alumina matrix with SiC whiskers. Scratching by abrasive particles can also cause brittle fracture. In the case of optical lenses and protective glass surfaces, this type of damage sets the life limit (Fig. 17).

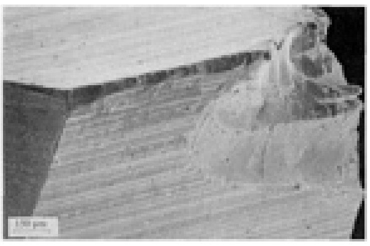

Fig. 15 Scanning electron micrograph showing brittle fracture of a cemented carbide tool tip used to cut aluminum

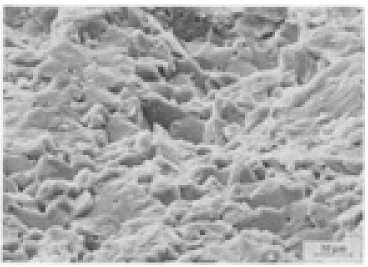

Fig. 16 Scanning electron micrograph showing brittle fracture by particle erosion of an Al_2O_3 surface (250 μm SiC particles, 70 m/s velocity, 90° angle of impingement). Courtesy of Mikael Olsson

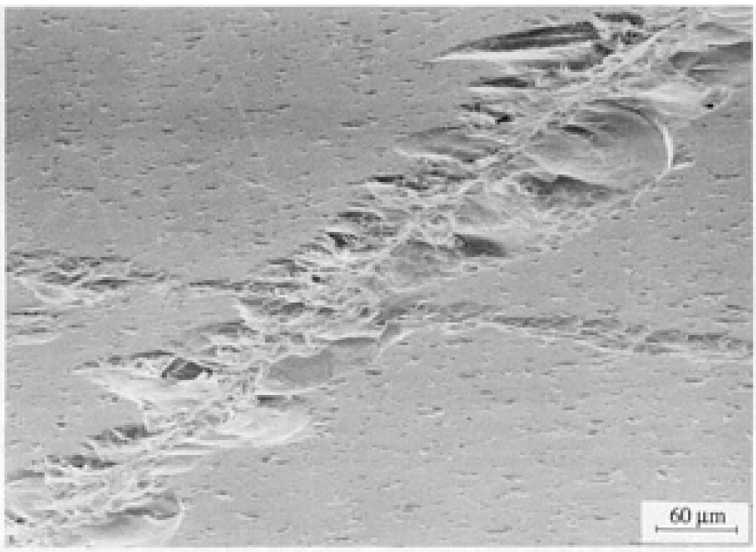

Fig. 17 Scanning electron micrograph showing brittle fracture in a watch glass caused by scratching against hard particles. The scratches impair the transparency of the glass.

Brittle fracture is often associated with very high wear rates. To prevent this type of damage, high point loads should be avoided. In sliding contacts, this can be accomplished by using very smooth surfaces and rounded shapes and by avoiding large abrasive particles or sharp countersurfaces. Ceramic surfaces that have been damaged by brittle fracture develop a very rough and vitreous topography. Also, once the tribological response of brittle materials has changed from a mild wear regime to severe brittle fracture, the mild regime is most unlikely to be reestablished even if the load is strongly reduced. This is in contrast to ductile metals, where a severely worn surface often can be "healed" by continued mild sliding.

Damage Dominated by Fatigue Fracture. Surface fatigue fracture is usually the result of repeated unidirectional or reciprocal sliding and is often seen on the same types of materials that suffer brittle fracture. In addition to hardness and toughness in the active state, the thermal expansion coefficient of the surface material plays a major role.

Figure 18 shows a punch tool used to cut austenitic stainless steel that reveals a characteristic crack pattern perpendicular to the direction of work material sliding. Thus, the cracks are caused primarily by the friction force, and not by thermal cycling. Initially, no material loss was associated with the cracking, and consequently tool performance did not suffer. However, spalling began to accelerate the wear after a certain number of cuts, thereby increasing the punch clearance and deteriorating the tolerances of the cut product. Finally, one of the transverse cracks initiated a large-scale fracture of the punch edge, instantly ending the tool life. Figure 19 illustrates another example of surface fatigue fracture, combined with plastic deformation of the surface to a mirror finish.

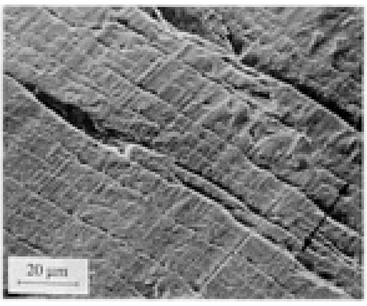

Fig. 18 Scanning electron micrograph showing fatigue fracture in a tool steel (AISI D1) punch used to cut 1 mm (0.04 in.) stainless steel sheets

Fig. 19 Scanning electron micrograph revealing two damage mechanisms on a steel cam follower, run against a steel cam. Smoothing by plastic deformation and wear by surface fatigue-induced fracture. Note the surface cracks partially surrounding the wear craters.

Low-amplitude oscillatory sliding between tribosurfaces, or so-called fretting, may lead to surface fatigue fracture and fretting-accelerated corrosion when the amplitude is so small that mating contact surface protrusions reestablish contact during each half-cycle. Because of the convex shape of the protrusions, the contact pressure is highest at the center of the contact area and falls to zero at the rim. This leads to mixed stick-slip conditions, with a central patch where the surfaces adhere ("stick") and a surrounding annular area where slip occurs. The stick-slip transition region is characterized by high stress concentrations and is the site for surface fatigue crack nucleation (Fig. 20).

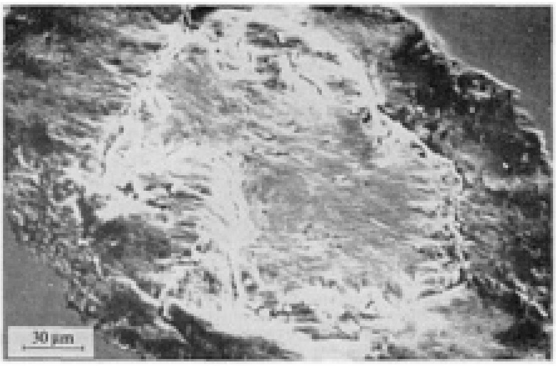

Fig. 20 Scanning electron micrograph showing surface damage in stainless steel, typical of fretting-induced fatigue fracture. A crack loop surrounds the unaffected stick patch.

Damage Dominated by Dissolution or Diffusion. A chemically aggressive environment may attack tribosurfaces and remove material by dissolution. In lubricated systems with chemically active lubricants, dissolution of the surface material may, in fact, dominate the material loss. The effect is promoted by frictional heating.

In metal cutting, the tool material has been observed to dissolve by solid-state diffusion through the tool/workpiece and tool/chip interfaces. This dissolution or diffusion mechanism can account for a considerable portion of the tool wear, particularly in wear-resistant cemented carbide tools used at high cutting speeds. It often acts preferentially--for example, for cemented carbides on the cobalt matrix.

It is generally difficult to diagnose damage by dissolution or diffusion, because it does not leave any signs in the form of scars or phase transformations. This mechanism should be considered if the wear rate is very low for the prevailing contact temperature and the topography is extremely smooth on single-phase materials or if chemically more inert phases of multiphase materials protrude from an otherwise smooth surface.

Damage by Interaction Between Corrosion and Fracture. A typical example of the appearance of surfaces damaged by corrosive wear is illustrated in Fig. 21, which shows two sections of links of a galvanized steel chain used to anchor a small dingy. In service, the chain was frequently subjected to light stretching and some movement, which led to rubbing between individual links. Links that were above the water surface suffered negligible corrosive attack and displayed negligible wear. The submerged links suffered only mild corrosion, but experienced very severe wear in those parts that were in mechanical contact. In this case, the cyclic removal of the parabolically growing oxide layer and the resulting exposure of the bare metallic surface to water generated the high wear rate. Above the water surface, the mechanical contact between the links was identical, but the corrosive conditions were less aggressive, and the zinc coating was not even penetrated.

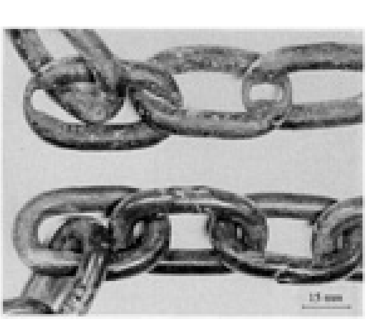

Fig. 21 Wear by corrosion and shear fracture of two sections of a galvanized steel chain partly submerged in water. Note the extreme difference in wear rate between the underwater (top) and above-water (bottom) links, caused by the synergistic effects between corrosion and wear. The general corrosion rate was low.

One possible mechanism of interaction between corrosion and material loss due to fracture is clearly illustrated by the particle erosion of an oxidized surface in Fig. 22. The oxide layer is spalled off in an area much larger than the impact crater, while the substrate is almost unaffected.

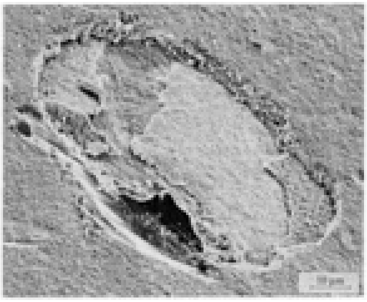

Fig. 22 Scanning electron micrograph showing particle-impact-induced brittle fracture that caused spalling off of oxide layers on cobalt. Courtesy of Asa Hammarsten

Surface Damage Involving Gain of Material

Transfer of material from one of the tribosurfaces to the other or pickup of loose wear debris occurs frequently in many tribological situations, particularly in the adhesive wear of ductile materials. Generally, the added material may:

- Clad to the surface (Fig. 23)
- Become embedded in the surface (Fig. 24)
- Successively build up a more or less complete coating on the surface (Fig. 25)

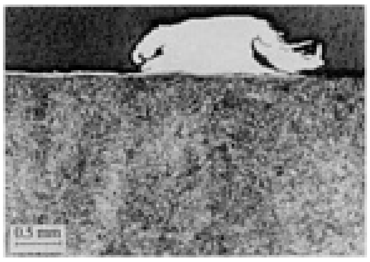

Fig. 23 Optical micrograph of cross section of a patch of wear debris on a quenched and tempered steel surface, transferred from the high-speed steel (HSS) counterface during sliding contact in a crossed-cylinders test. Having been in constant contact with the countersurface and thus frictionally heated to a higher temperature, the normally more wear-resistant HSS material has been worn by adhesive shear fracture, while the countersurface has been damaged by the transferred debris. Courtesy of Mikael Olsson.

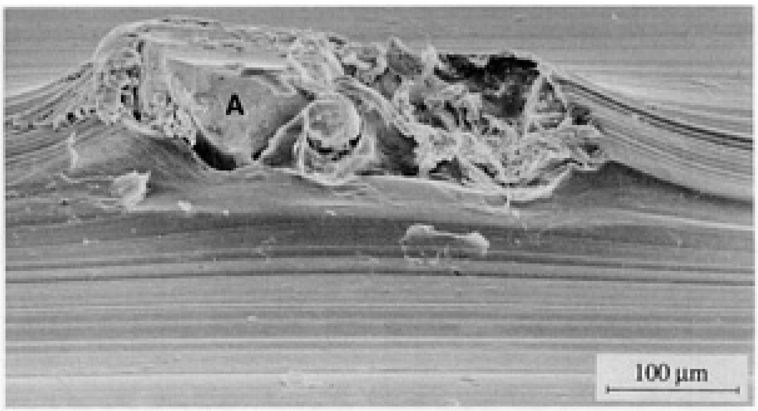

Fig. 24 Scanning electron micrograph showing metallic wear debris at A, picked up from the counterface material and embedded in a PTFE surface during reciprocating sliding. The particle acted highly abrasively on the countersurface and has been moved cyclically back and forth by the friction forces.

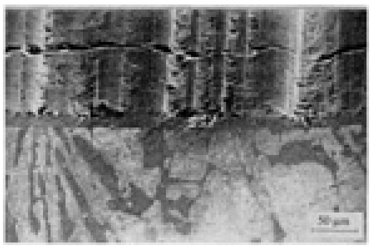

Fig. 25 Scanning electron micrograph showing the top surface and cross section of a hot roll with a protective oxide layer transferred from the heat (work material). As long as the layer adheres to the roll surface, the oxide coating protects the underlying metal efficiently by continuous pickup of oxide at the same rate as the simultaneous loss by wear. Courtesy of Lynn Erickson

Transferred material may be either detrimental or favorable to the performance of a tribosurface. In some cases it can protect the surface from wear, while simultaneously causing an increase in the wear rate of the countersurface, as demonstrated by Fig. 23 and 24. It can also efficiently protect the coated surface without harming the countersurface, as shown by Fig. 25. In this case, in addition to the high-temperature oxidation properties of the worked carbon steel, the composition and surface temperature of the roll material are crucial factors for the formation of the oxide layer. In service, as a matter of fact, rolling with the initial metallic roll surface should be avoided; surprisingly, a surface "damaged" by picked-up oxide is ideal for rolling.

Damage Dominated by Contact-Generated Corrosion. Tribo-accelerated corrosion is a common form of surface damage. The corrosion is often problematic as it leads to an increased wear rate or to a disadvantageous topography. In the case of fretting corrosion of electrical contacts (Fig. 26), the oxide layer can be life-limiting by building up an unacceptably high contact resistance. The corrosion is accelerated by vibrations that facilitate exchange of atoms across the oxide layer, both by forming microcracks and by directly promoting diffusion.

Tribography as a Tool

The previous sections of this article have classified and illustrated the appearance of surface damage and have related it to the generating mechanisms and processes. The next step would be to formulate a "recipe" of actions to improve the tribological behavior of a system. This subject will not be covered here, but a few examples are offered to demonstrate a fruitful method of reasoning, utilizing the findings of a tribographical investigation.

Whenever a surface is shown to have suffered from *plastic deformation,* a number of counter-measures are possible. Plastic deformation is caused by exceeding the yield stress of the material in the active state. The applied stress can be reduced by increasing the load-bearing area, decreasing the load, applying more efficient lubricants, and so on. The yield stress can be increased by improving the cooling and thus reducing the softening in the active state, by exchanging the material, or by applying a hard surface coating.

Brittle surface fracture is initiated whenever the fracture strain of the material in its active or relaxed state is exceeded. In sliding contacts, this can be avoided by reducing the shear stresses by lubricating more efficiently, by promoting the formation of friction-reducing oxide layers, and so on. Furthermore, friction stresses can be reduced by redesigning for lower normal forces or increased load-bearing area.

When *surface cracks* are discovered by tribography, the pattern formed reveals details of the contact situation. Formation of more or less parallel cracks is indicative of excessive shear strains in the direction perpendicular to the cracks. Network patterns are indicative of isotropic strains, usually induced by cyclic thermal expansion.

Abrasive Wear

Joseph H. Tylczak, Albany Oregon

Introduction

ABRASIVE WEAR, as defined by ASTM (Ref 1), is due to hard particles or hard protuberances that are forced against and move along a solid surface. Wear, in turn, is defined as damage to a solid surface that generally involves progressive loss of material and is due to relative motion between that surface and a contacting substance or substances.

The cost of abrasion is high and has been estimated as ranging from 1 to 4% of the gross national product of an industrialized nation. The effect of abrasion is particularly evident in the industrial areas of agriculture, mining, mineral processing, earth moving, and essentially wherever dirt, rock, and minerals are handled. Examples include plows, ore loading/moving buckets, crushers, and dump truck beds.

When two surfaces contact, wear occurs on both surfaces. Individuals and industry tend to focus on th wearing surface that has the greatest potential for their own economic loss, and consider the other surface to be the abrasive. For example, an individual walking up the stairs of a building would be more likely to think that his shoes, rather than the stairs, were experiencing abrasive wear, whereas the maintenance staff would have the opposite opinion. In actually, both surfaces are being subjected to abrasive wear.

The rate at which the surfaces abrade depends on the characteristics of each surface, the presence of abrasives between the first and second surfaces, the speed of contact, and other environmental conditions. In short, loss rates are not inherent to a material. With reference to the above example, changing the material of either the shoes or the steps could, and often would, change the wear on the opposite counter-face. The addition of an abrasive, such as a layer of sand, on the steps would further change the situation, in that the sand would be the second surface that contacts both the shoes and the steps.

Abrasion is typically categorized according to types of contact, as well as contact environment. Types of contact include two-body and three-body wear. The former occurs when an abrasive slides along a surface , and the latter, when an abrasive is caught between one surface and another. Two-body systems typically experience from 10 to 1000 times as much loss as three-body systems for a given load and path length of wear. Contact environments (Fig. 1) are classified as either open (free) or closed (constrained).

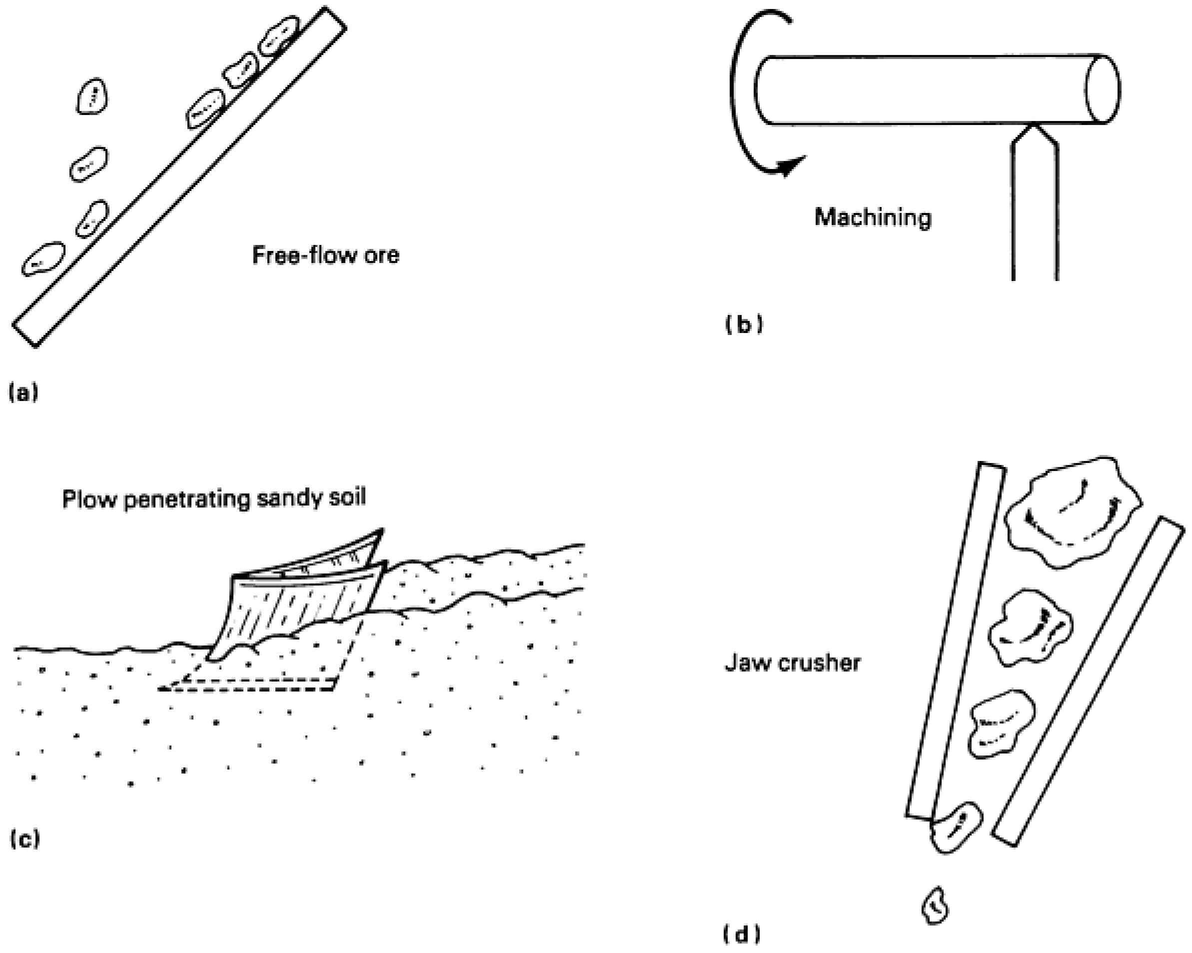

Fig. 1 Types of contact during abrasive wear. (a) Open two-body. (b) Closed two-body. (c) Open three-body. (d) Closed three-body

In several different tests, Blickensderfer *et al.* (Ref 2) showed that for a given load and path length of wear, the wear rate is about the same for both open and closed systems. However, measurements of the loss in closed systems will often appear higher than the loss in open systems. This probably occurs because most closed systems experience higher loads.

Abrasion is often further categorized as being low stress, high stress, or gouging. Low-stress abrasion occurs when the abrasive remains relatively intact, for example, when sanding wood with sandpaper. High-stress abrasion exists when abrasive particles are being crushed, for example, in a ball mill where both the grinding balls and the ore are down. In gouging abrasion, a relatively large abrasive will cut the material that is not fully work hardened by the process from the material of concern, for example, when rocks are crushed in jaw crusher.

Several mechanisms have been proposed to explain how material is removed from a surface during abrasion. These mechanisms include fracture, fatigue, and melting. Because of the complexity of abrasion, no one mechanism completely accounts for all the loss. Figure 2 depicts some of the processes that are possible when a single abrasive tip traverses a surface. They include plowing, wedge formation, cutting, microfatigue, and microcracking.

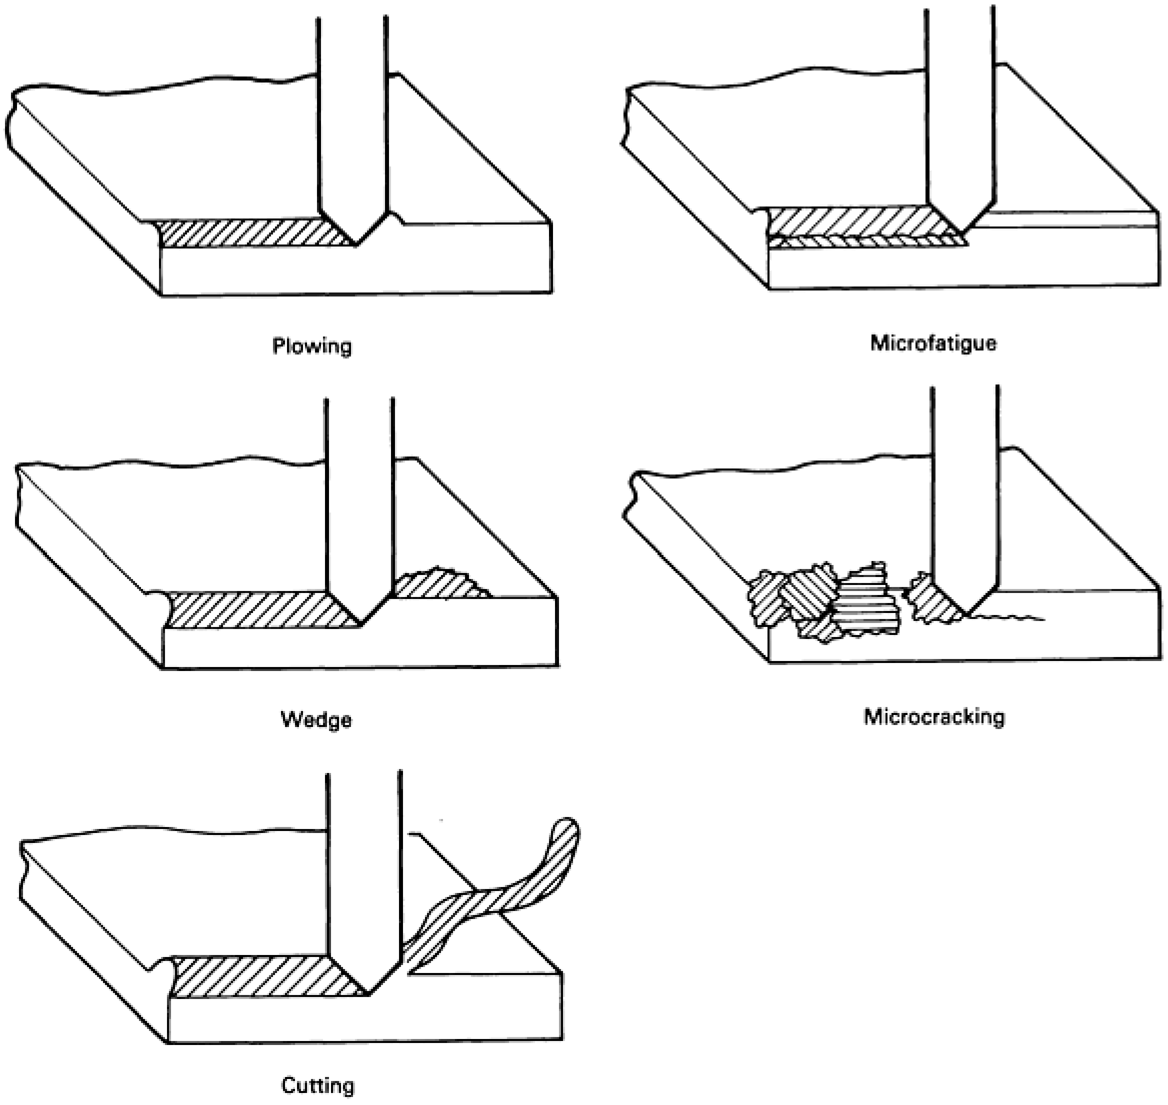

Fig. 2 Five processes of abrasive wear

Plowing is the process of displacing material from a groove to the sides. This occurs under light loads and does not result in any real material loss. Damage occurs to the near surface of the material in the form of a build up of dislocations through cold work. If later scratches occur on this cold-worked surface, then the additional work could result in loss through microfatigue.

When the ratio of shear strength of the contact interface relative to the shear strength of the bulk rises to a high enough level (from 0.5 to 1.0), it has been found that a wedge can develop on the front of an abrasive tip. In this case, the total amount of material displaced from the groove is greater than the material displaced to the sides. This wedge formation is still a fairly mild form of abrasive wear.

The most severe form of wear for ductile material is cutting. During the cutting process, the abrasive tip removes a chip, much like a machine tool does. This results in removed material, but very little displaced material relative to the size of the groove. For a sharp abrasive particle, a critical angle exists, for which there is a transition from plowing to cutting. This angle depends on the material being abraded. Examples of critical angles range from 45° for copper to 85° for aluminum (Ref 3, 4). Abrasion is not dependent on scratches by carefully oriented abrasive grains. Kato (Ref 5) and others have analyzed the effect of a rounded tip pushing through a surface.

For ductile materials, the mechanisms of plowing, wedge formation, and cutting have been observed (Fig. 3). It was found that the degree of penetration was critical to the transition from plowing and wedge formation to cutting. When the degree

of penetration, defined as depth of penetration divided by the contact area, exceeded about 0.2, cutting was the predominant mode of wear.

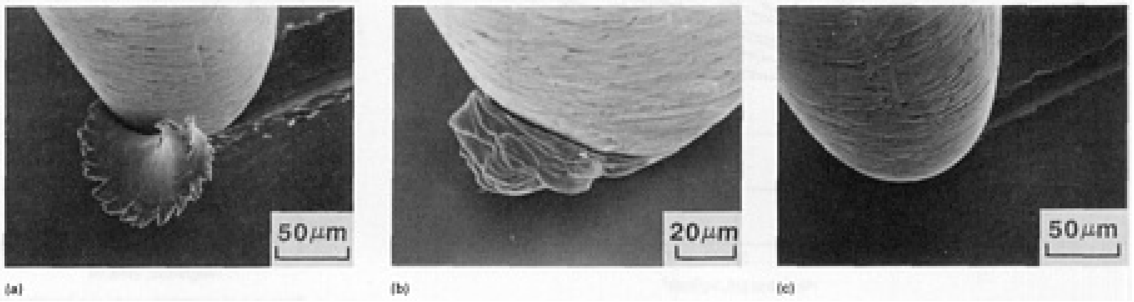

Fig. 3 Examples of three process of abrasive wear, observed using a scanning electron microscope. (a) Cutting. (b) Wedge formation. (c) Plowing. Source: Ref 5

When an abrasive grain abrades while cutting a surface, the maximum volume of wear that can occur is described by:

$$W = Ad \qquad \textbf{(Eq 1)}$$

where W is the volume of material removed, A is the cross-sectional area of the groove, and d is the distance slid. The cross-sectional area of the groove A is dependent on the abrasive grain shape and the depth of penetration, p:

$$A = k_1 p \qquad \textbf{(Eq 2)}$$

where k_1 is constant-dependent on the shape. In turn, the depth of penetration, p, is again dependent on the shape of the grain; the load, L; and the hardness, H, of the material:

$$p = k_2 \frac{L}{H} \qquad \textbf{(Eq 3)}$$

Many factors affect k_1: the possibility of plowing rather than cutting; the abrasive grain may roll and avoid wear; the abrasive grain may break down and not be effective during the latter part of its contact path; and others. Equation 1, 2, and 3 can be combined, forming:

$$W = k_3 \frac{Ld}{H} \qquad \textbf{(Eq 4)}$$

This is commonly known as Archard's equation (Ref 6), which was derived for adhesive wear but has proven very useful in abrasive wear, as well. Factors affecting k_3 are addressed below.

Commonly, materials are described as having good or bad wear resistance, R, which is simply defined as the reciprocal of wear volume:

$$R = \frac{1}{W} \qquad \textbf{(Eq 5)}$$

Brittle materials have an additional mode of abrasive wear, namely, microfracture. This occurs when forces applied by the abrasive grain exceed the fracture toughness of the material. This is often the predominant mode of severe wear for the ceramic materials, and is active in materials such as white cast irons.

Melting or other thermally related mechanisms of loss are also possible. The melting theory depends on small localized areas of strain-induced adiabatic heating. It has been shown that there does seem to be enough temperature rise for recovery to take place near the abraded surface (Ref 7).

Effects of Material Properties on Abrasive Wear

A variety of material characteristics have been shown to either form a correlation with abrasive wear or have some effect on it. These properties include hardness, elastic modulus, yield strength, melting temperature, crystal structure, micro-structure, and composition.

It has been shown experimentally and theoretically that the hardness of a material correlates with its abrasion rate. Khrushchov (Ref 8) performed a large amount of testing and found an inverse relationship between abrasion rate and annealed hardness for pure materials (Fig. 4). He also tested steels of varying hardness. The hardnesses were inverse linearly related to abrasive wear, except that they had a different slope from that of the pure materials.

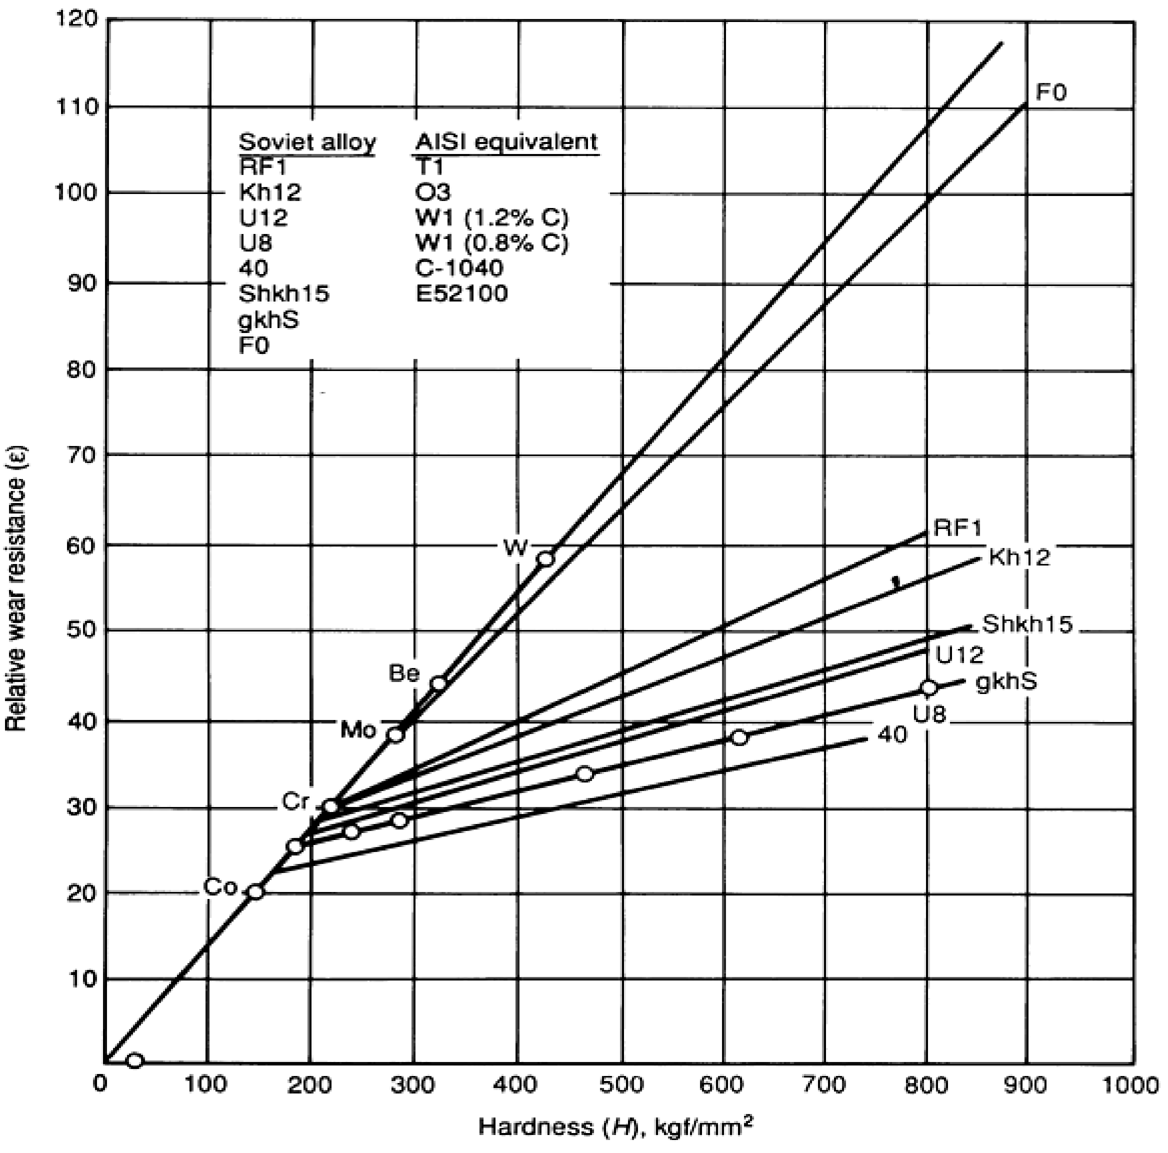

Fig. 4 Wear resistance versus hardness for pure metals and alloys. Source: Ref 8

It is generally thought that the surface of a material is work hardened up to a very high level during the process of abrasion. Richardson (Ref 9) investigated work hardening by plowing during wear on a group of pure metals and steels. He compared the resulting hardness of the surface to surfaces hardened by shot blasting and trepanning, and found that

abrasion produced a high hardness that was nearly the hardness of trepanning. In addition, the wear resistance of the metal was proportional to the hardness of the worn surface.

Abrasive wear has also been found to be dependent on crystal structure and orientation. Alison (Ref 10) showed that cubic metals wear at about twice the rate of hexagonal metals, which was attributed to the lower work-hardening rate of the hexagonal metals. In addition, Steijn (Ref 11) studied the wear of single crystals. Scratching body-centered cubic (bcc) and face-centered cubic (fcc) metals with a prepared surface on the (001) plane, he showed wider scratch width, which implied higher wear, along the <100> than the <110>direction.

Microstructure is also important. Austenite and bainite of equal hardness are more abrasion resistant than ferrite, pearlite, or martensite. This is because of the higher strain-hardening capacity and ductility of austenite.

Additionally, it has been found that fracture toughness, K_{Ic}, of the material is important in determining abrasive wear for ceramics and, to a lesser degree, white cast irons. Fischer (Ref 12) prepared a series of zirconia samples with constant hardness, but varying toughness. He found that the wear decreased with the fourth power of the toughness (Fig. 5). This fourth power law applies to a single case of material and test parameters, but it does show the important effect of toughness on brittle materials.

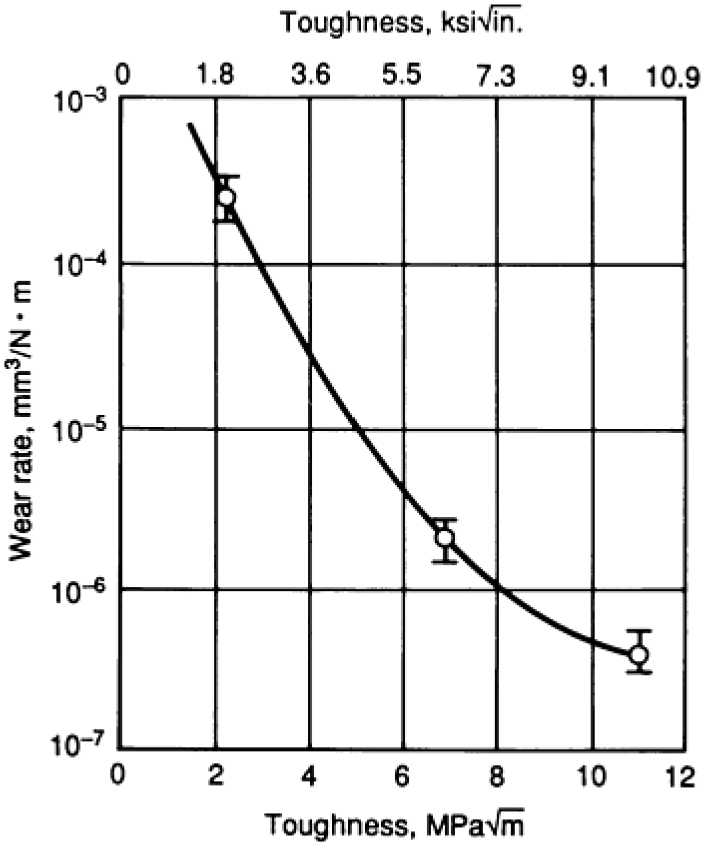

Fig. 5 Wear rate of zirconium oxide as a function of fracture toughness. Source: Ref 12

Alloying is often used to improved the performance of a material. These additions can take either interstitial or substitutional locations. Adding carbon to iron is a good example of an interstitial addition used to improve abrasion resistance. Tylczak (Ref 13) studied the abrasion resistance of Zr and Ti alloys with small interstitial additions of N or O. Like carbon in iron, these alloys also decreases of wear with small increases of interstitial content. For substitutional alloy systems, he also showed that the abrasion of alloys with complete solid solubility, such as Hf-Zr, Cu-Ni, and Cr-V, follows a law of mixing, where the abrasion is proportionate to the amount of each alloy. Abrasion was also found to be somewhat affected by solidus temperature and hardness. For solid-solution mixtures, this indicates that deviations from a law of mixing are separately dependent on strength of the bond and distortion of the crystal lattice.

A common way to modify the properties of a material is to produce a second phase. Treatments that cause the formation of precipitates can result in larger increases in hardness and yield stress. On the basis of the previously developed simple wear model, one would expect this to lead to large decreases in abrasive wear. Unfortunately, the small coherent particles are often sheared during plastic deformation, and the incoherent particles fail to block the dislocations that are generated. As a result, precipitation treatments are not generally a useful way to decrease abrasive wear.

Larger, hard incoherent precipitates or particles such as carbides can be useful in decreasing abrasive wear. Figure 6 shows what happens when the size ratio of the abrasive grains to the hard particles in the matrix is varied. When the incoherent particles are somewhat larger than the abrasive grains abrading the surface, they are generally effective in decreasing the total material wear. Examinations of worn surfaces have revealed that the abrasive grains are lifted over the carbide grains. As the softer matrix is cut away and removed, the load is significantly transferred to hard particles. Incoherent particle wear occurs by two slower processes: abrasion of the hard particles and loss of hard particles by debonding between the matrix and the particles, because of fatigue. For alloyed white cast irons, research indicates that approximately 30 vol% carbides provides the best abrasion resistance.

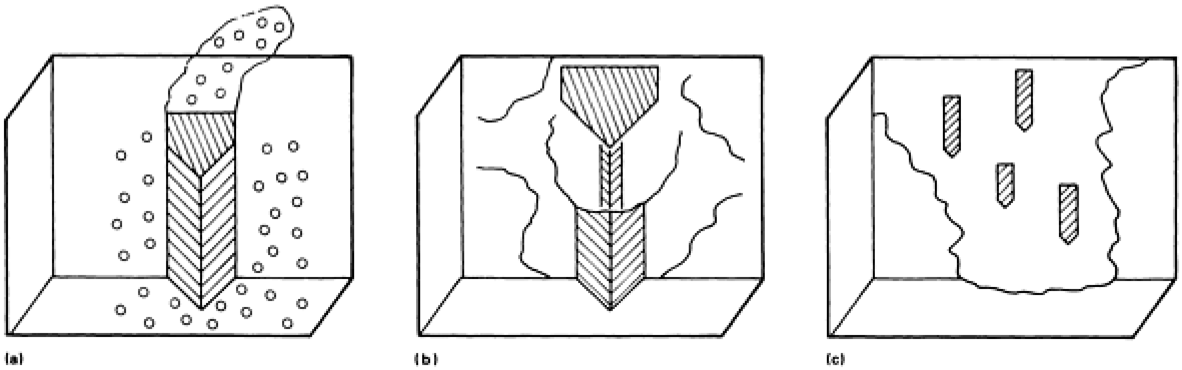

Fig. 6 Effect on abrasive wear when second phase size is varied. (a) Small second phase, easily removed. (b) Large second phase, protection of matrix. (c) Very large second phase, small abrasive channeled to matrix

The relationship between particle size and abrasive grain size is important. Larger abrasive grains tend to create larger wear chips. When incoherent particles are small, relative to the abrasive grains and wear chips, they can be cut out with the matrix, adding little to the abrasion resistance of the material. If the abrasive grains are very small, relative to the hard particles, and the gaps between particles are large, then the grains are able to undermine the hard particles, allowing them to fall out or be dislodged by the occasional large abrasive grain.

The particle characteristics that work best for wear protection are hard, tough, and blocky. A high hardness value makes them harder to cut. Toughness makes them resistant to breakage. Blocky particles, versus those that are plate- or rod-shaped, also reduce crack propagation and breakage.

With the advent of new advanced materials, the use of reinforced composites is becoming more common. These materials are subjected to abrasive wear in many applications. Factors that affect the abrasive wear of these materials include the orientation, size, modulus of elasticity, relative hardness, and brittleness of the second phase. The simplified model of Zum Gahr (Ref 14) (Fig. 7) shows the effects of varying these parameters.

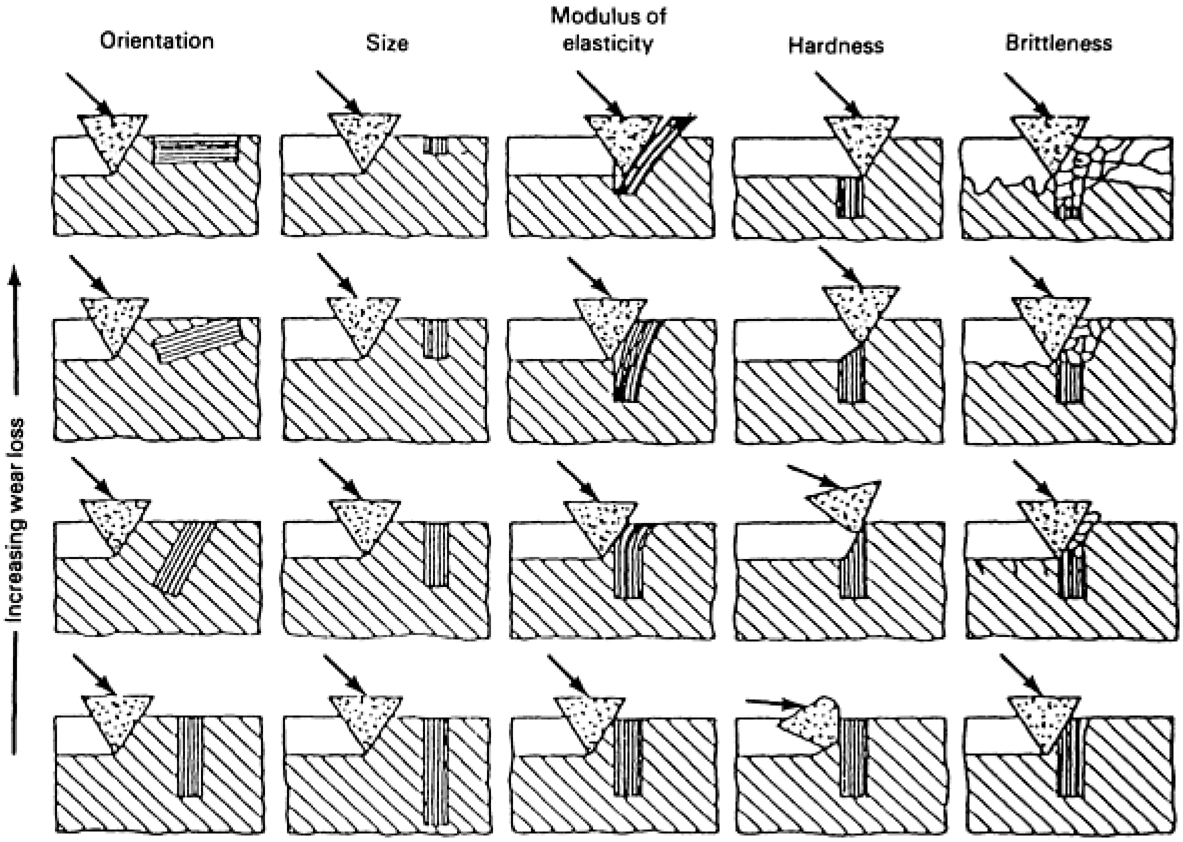

Fig. 7 Effect of orientation, size, elastic modulus, hardness, and brittleness of second phase on abrasive wear. Source: Ref 14

It has been found that a reinforcing second phase lying parallel to the surface is more easily removed than one that is anchored perpendicular to the surface. Also, when the size of the second phase is small relative to the abrasive groove depth, the second phase has little or no beneficial effect. Because most reinforcing additions have a high modulus of elasticity, a matrix with a low modulus will tend to debond at the interfaces and lead to pull-out and abrasive loss. In some metals, such as alloyed white cast irons, if the second phase is harder than the matrix, then the hard phase will protect the matrix. Lastly, brittle materials tend to crack and chip to a larger area than the cross section of the abrasive grain doing the damage. An impressive amount of current research on wear-resistant materials is focusing on advanced composites.

Effect of Environment on Abrasive Wear

In addition to the properties of a material, the environment affects wear. As stated earlier, abrasion loss rates are not intrinsic to a material. Environmental factors that effect abrasive loss include, but are not limited to: the type of abrasive and its characteristics, temperature, speed of contact, unit load of the abrasive on the material, humidity, and corrosive effects, each of which is discussed below.

Abrasive. In the simple model of abrasive wear previously developed, differences in abrasives have been included in the constant and mostly ignored. However, changing the abrasive will change the wear rate. The effect of critical angle has already been discussed, but other abrasive characteristics will also contribute. Among these are hardness, toughness, and size of the abrasive.

The hardness of the abrasive particles is important to the rate of abrasion of the subject material. As the hardness of the abrasive exceeds that of the wear material, abrasive wear typically becomes much worse (Ref 15, 16), as shown in Fig. 8. As the abrasive hardness exceeds the hardness of the material, it is able to penetrate the surface and cut/remove material without having its cutting edges broken or rounded.

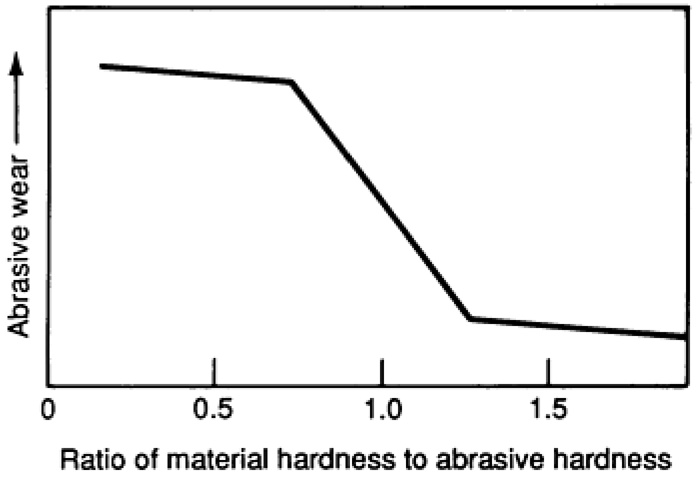

Fig. 8 Effect of abrasive hardness, relative to material hardness, on abrasive wear

Figure 9 shows the hardness of typical minerals and alloy microconstituents. According to the above theory, hematite ore would cut pearlite, but not martensite. This also explains the great advantage of chromium white irons, which have a hardness greater than most common minerals.

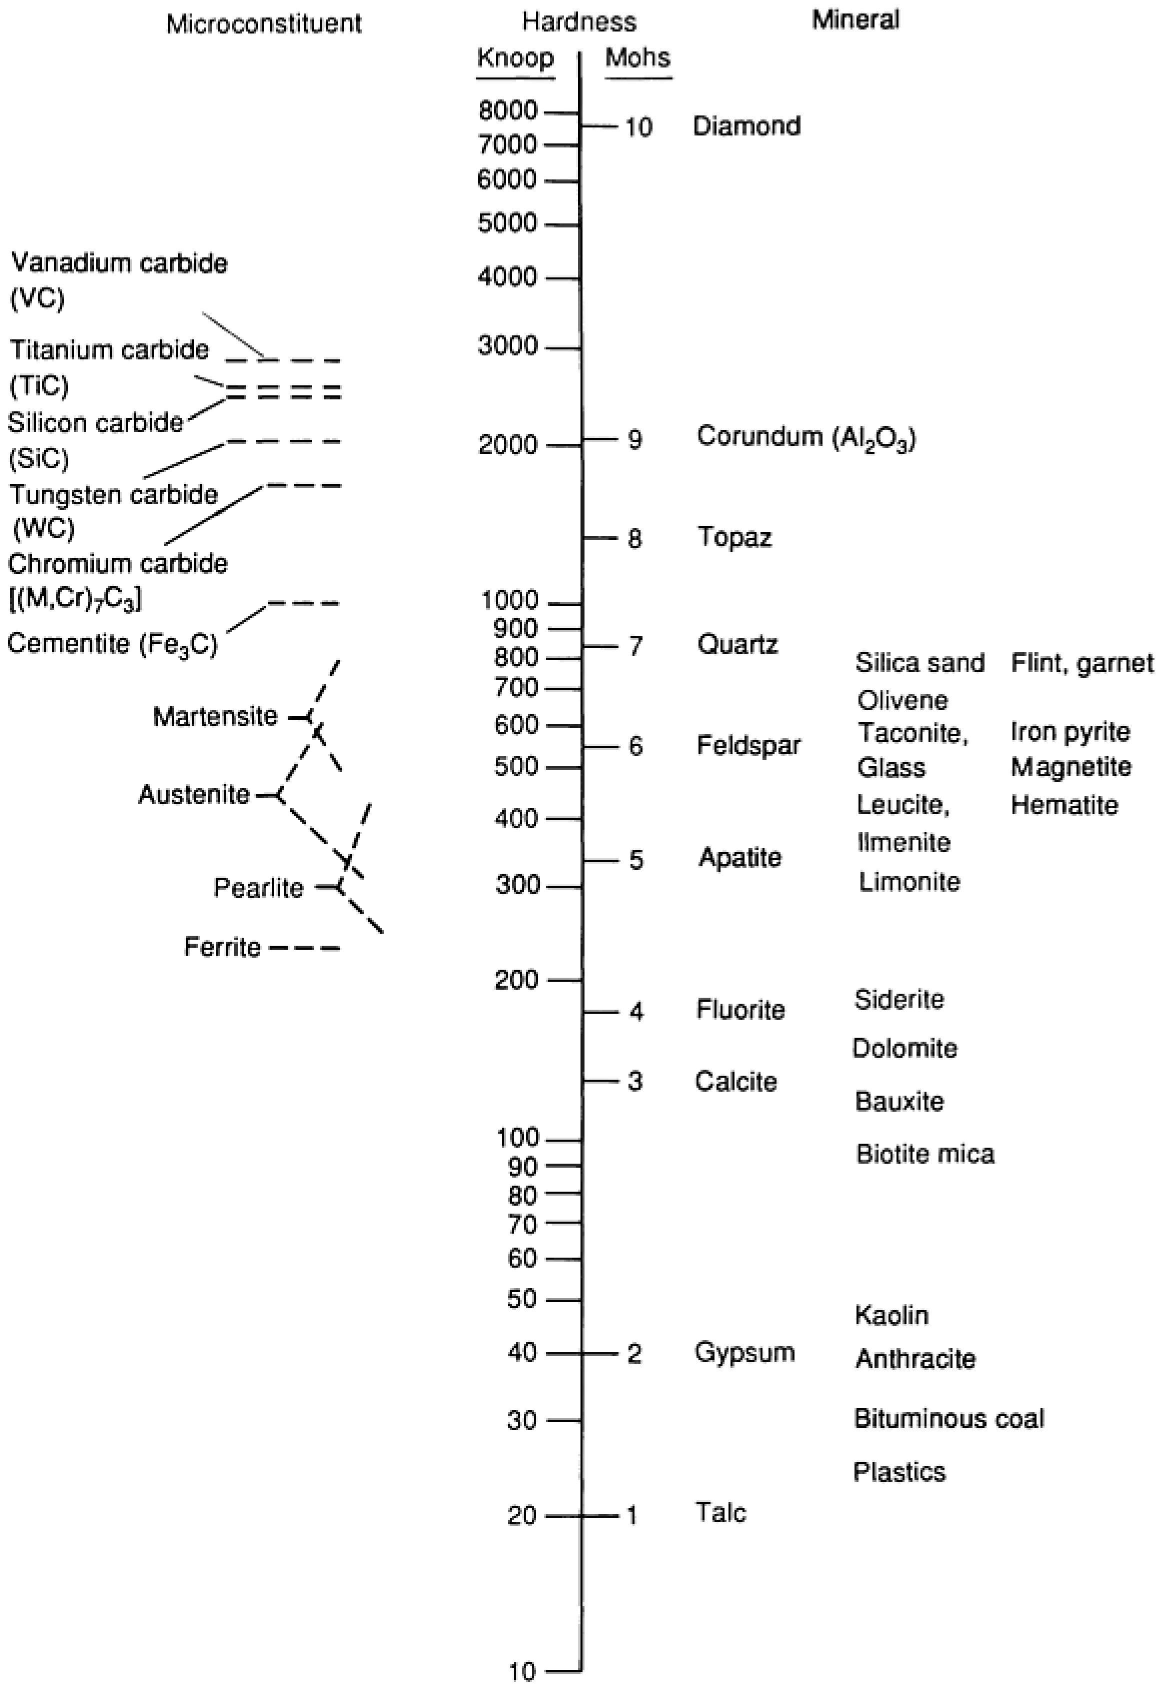

Fig. 9 Hardness of some minerals and alloy microconstituents

The shape of the abrasive particle is important, because it influences the shape of the groove produced in the material. It also influences the contact load and the transition from elastic to plastic contact. Experiments have confirmed that less wear occurs when materials are abraded by rounded, rather than sharp, particles.

The toughness of the abrasive particles is an important factor during abrasion. Material loss will increase when the toughness of the abrasive increases. Avery (Ref 17) gives examples of wear on several white irons and a steel when subjected to two different abrasives of the same hardness (Fig. 10). Although chert and silica both have the same hardness (Mohs 7), the chert, which is the tougher mineral, caused two to three times the wear generated by the silica.

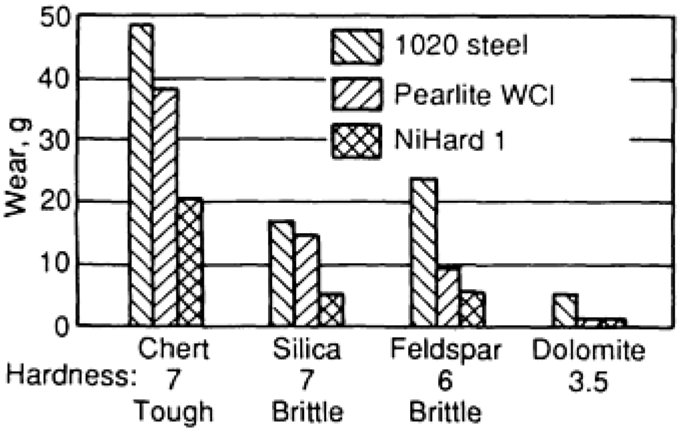

Fig. 10 Effect of toughness of minerals on wear, using ABEX wet abrasion test. Source: Ref 17

Temperature. It might be expected that abrasive wear would increase as the temperature rises, because the hardness and yield strength decrease. Instead, for aluminum and copper (Ref 18), when the temperature was increased from ambient to 673 K, very little change in the abrasive wear rate was observed. It has been proposed that the reason for this small change is that during abrasion, small areas are adiabatically heated. At higher initial temperatures, the metal flow stress is reduced. This results in less heating in the material during the abrasion process. The end result is that areas around the material that is being removed have a similar temperature, independent of starting temperature, and similar abrasion rates.

Speed of Contact. The rate of abrasive wear has been found to slightly increase with increasing speed in the range from 0 to 2.5 m/s (0 to 8.2 ft/s). This increase in wear may be attributable to frictional heating. The effect is small, because all of the abrasion occurs in a near-adiabatic process. This should result in nearly the same peak temperature rise, independent of speed, for the tiny volume of material where the asperities are removing the material.

Load. Abrasive wear has been shown to be proportional to load, following the Archard equation. However, this proportional effect breaks down when the load is high enough to fracture the abrasive particles. If the forces do fracture the abrasive particles and create new sharp points, wear can increase. If the abrasive particle points are rounded, wear will decrease.

Humidity. The effect of atmospheric humidity on abrasive wear is far from clear, and contrary results exist. Larsen-Basse (Ref 19, 20) studied the effect of atmospheric humidity on abrasive wear for a variety of pure metals and steels. When using SiC abrasive, wear usually increased with increasing humidity, up to 65% relative humidity. This increase is attributed to a moisture-assisted fracture of the SiC abrasive particle, which resulted in fresh sharp edges to cut into the surface of the material.

An additional cause for increased wear was the Rehbinder effect (Ref 21). The Rehbinder effect is a chemo-mechanical mechanism in which chemical impurities, such as ions or atomic hydrogen, modify the fracture properties in a crack root, leading to increased wear rates.

Mercer (Ref 22) found a much different result, where, with increasing humidity, abrasive wear decreased for iron and mild steel, stayed constant for titanium, and increased for copper. With contrary results such as these, the effect of humidity is still not clear.

Corrosive Effects. Abrasive wear is often enhanced by corrosive conditions, particularly a low pH. A synergism often occurs between abrasive wear and corrosion. The abrasion creates fresh surfaces that rapidly corrode, and the normally protective corrosion layer is removed by abrasion. Using a laboratory abrasives slurry apparatus. Madsen (Ref 23) demonstrated that the synergism of an abrasive and a corrosive component could be twice that of individual components added together. In a grinding study, Tylczak (Ref 24) showed that grinding in acid waste water increased the wear rate by about twice that of grinding in tap water.

Theory

A number of equations have been used for correlations between wear and other properties. The Archard equation for a relationship of wear with hardness has already been introduced. Khrushchov (Ref 25) demonstrated the correlation with hardness and has proposed an empirical correlation with elastic modulus of the form:

$$W = \frac{k_5}{E^{1.3}} \quad \textbf{(Eq 6)}$$

where E is the elastic modulus.

For pure metals, relationships were found between wear and energy of melting, the combination of atomic weight and Debye temperature, and the combinations of melting points divided by atomic volume. All of these relationships measure interatomic cohesion. However, a fundamental understanding of abrasive wear has not yet been developed from fundamental theories.

Most current theory is based on the concept that abrasion is the process of scratching. Furthermore, most theories simplify the tip of the scratcher as a sharp come. The theories then go on the explain the effect of said come sliding across the surface of a specimen. The Archard equation, with small modifications, is still widely used as a starting point for the development of more complex equations. The more successfully the models deal with "real" complications, the more useful they will be.

One example of an extended Archard mode proposed by Zum Gahr (Ref 26) has a factor that accounts for the proportion of displaced material to removed material. He defines a factor f_{ab} as:

$$f_{ab} = \frac{A_v - (A_1 + A_2)}{A_v} \quad \textbf{(Eq 7)}$$

where A_v is the cross-sectional area of the wear groove, and A_1 and A_2, combined, are the cross-sectional area of the material displaced to the sides of the groove. For perfect cutting, this term is 1, and for pure plowing, with no material removal, the term is 0. The equation for wear, in this case, is:

$$W = f_{ab} A_v d \quad \textbf{(Eq 8)}$$

Factors that will reduce f_{ab} give greater wear resistance without requiring a modification of material hardness. In other words, a material with a greater ability to deform will plow, rather than cut. This follows the results from Khrushchov, where the pure materials, which have a large capacity for deformation, had greater abrasion resistance than alloy steels of a given hardness.

Materials

Material selection for abrasion resistance is not an exact science. Although there seems to be a counter example for every example, there are families of materials that have demonstrated good resistance. They are typically hard materials that resist scratching and include ceramics, carbide materials, alloyed white cast irons, and hardened alloy steels. In addition, these and other materials can be put, or formed, on the surface of many less-abrasion-resistant materials by welding, plasma spraying, flame spraying, electroplating, diffusion, and other techniques.

Ceramics. Many ceramics show outstanding abrasion resistance, because of their high hardness relative to the abrasive particle. One of their weaknesses, however, is an inability to withstand impact, that is, they have a low fracture toughness. At high unit loads, ceramics are also subject to microfracture, which can lead to high wear loss rates. Alumina, zirconia, and silicon nitride, among others, are currently used for wear-resistant applications. Ceramics use will increase as their limitations are further understood and their prices decrease.

Metals, because of their ability to withstand general abuse, will continue to be widely used in abrasive wear applications. As a general guide to metals that will resist abrasive wear, it has been found that:

- High hardness is the primary requirement
- Abrasion resistance tends to increase with additions of carbide-forming metals.
- Carbides are useful additions to metals when they are large in relation to the size of the abrasive.

Alloyed white cast irons are the most abrasion-resistant iron-base alloys. Their resistance to abrasion is due to the formation of carbides during solidification. Unfortunately, they have limited impact resistance compared to steels, are very difficult to machine, and are not weldable, which limits their industrial applications. The families of white irons include high-chromium, chrome-moly, nickel-chrome, and pearlitic white irons. The compositions of typical white cast irons are given at Table 1.

Table 1 Alloy composition of abrasion-resistant white cast irons

Common name	Class	Type	ASTM designation	Composition, wt%						
				C	**Mn**	**Si**	**Ni**	**Cr**	**Mo**	**Cu**
NiHard I	I	A	Ni-Cr-Hc	2.8-3.6	2.0 max	0.8 max	3.3-5.0	1.4-4.0	1.0 max	. . .
NiHard I	I	B	Ni-Cr-Lc	2.4-3.0	2.0 max	0.8 max	3.3-5.0	1.4-4.0	1.0 max	. . .
	I	C	Ni-Cr-GB	2.5-3.7	2.0 max	0.8 max	4.0 max	1.0-2.5	1.0 max	. . .
NiHard IV	I	D	Ni-HiCr	2.5-3.6	2.0 max	2.0 max	4.5-7.0	7.0-11	1.5 max	. . .
	II	A	12% Cr	2.0-3.3	2.0 max	1.5 max	2.5 max	11.0-14.0	3.0 max	1.2 max
Cr-Mo	II	B	15% Cr-Mo	2.0-3.3	2.0 max	1.5 max	2.5 max	14.0-18.0	3.0 max	1.2 max
Cr-Mo	II	D	20% Cr-Mo	2.0-3.3	2.0 max	1.0-2.2	2.5 max	18.0-23.0	3.0 max	1.2 max

The higher-chromium alloys are currently favored over the Ni-Cr or pearlitic white irons, because of their improved resistance to impact in the heat-treated condition. The 25Cr alloy is particularly suited to conditions requiring either extra oxidation or corrosion resistance, whereas the 15Cr3Mo alloys should be used where there is need for thick cross sections, because of their higher hardenability.

Steels. For low-alloy steels, abrasion resistance is basically a function of hardness and carbon content. Other additions can be made to allow for full hardening and other mechanical properties. Tool steels of the M and T (high-speed steel), D (high Cr), and part of the A (air hardening) series often form carbides in the structure for additional abrasion resistance. The American Society of Lubrication Engineers (Ref 27) has developed a chart (Fig. 11) for selecting a replacement tool steel when greater wear resistance, or toughness, is required. Austenitic Mn steels are among the toughest of the available materials. The 12Mn type is known as Hadfield steel. These materials are advantageous where the stresses of use can fully work harden surfaces to help resist further loss.

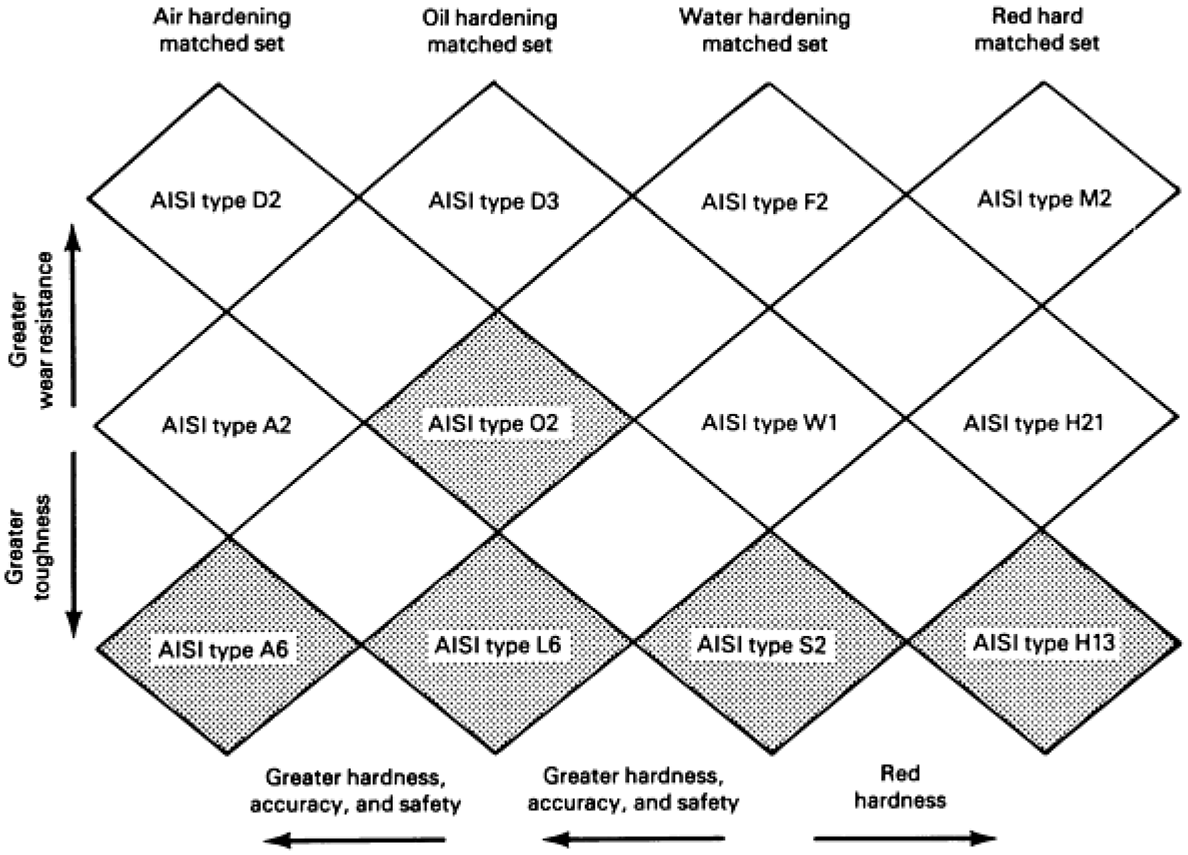

Fig. 11 Basic diagram for matched set method of selecting tool steels. Source: Ref 27

Plastics. It has been observed that plastics have lower wear resistance as the ratio of hardness to elastic modulus decreases (Ref 28). Other work has shown that abrasion resistance increases in both thermoplastics and thermosets, for higher molecular weights of the plastics. These materials are being used for slurry handling because they are able to withstand the abrasion of the small particles of the slurry and are resistant to chemical attack.

Polishing Wear

Leonard E. Samuels, Samuels Consultants

Introduction

THE TERM "POLISHING WEAR" is used to describe interactions between two solids that remove material from, while at the same time producing a polished finish on, the surface of at least one of the two. This definition is not, however, a precise one because the surface condition known as a "polish" cannot be defined quantitatively. The term is, in fact, merely one of common usage describing a surface that reflects light brightly and that produces a clear image of distant objects in the manner expected of a mirror.

The light reflected from real surfaces, which inevitably are rough on a microscopic scale, consists of two components, one known as "specular" or "regular" reflection and the other as "diffuse" reflection. The specular component consists of rays reflected over a narrow range of angles, the same angle as the angle of incidence; these rays are required for the production of sharp reflected images. The diffuse component consists of rays reflected or scattered over a range of angles centered about the angle of specular reflection. Light does not just bounce off a reflecting surface. The incident beam is diffracted from many centers on the surface, and the emergent beam is the net result of the interactions between these diffracted rays. Specular reflection results when the diffracted rays reinforce one another at the appropriate angle and cancel one another at all other angles. For regular parallel grooves in an ideal flat surface, this phenomenon is possible only when the spacing of the centers at which diffraction occurs is less than the wavelength of the incident light (about 500 nm for visible light). The analysis of the reflectivity of actual engineering surfaces, such as abrasive-machined surfaces, however, is complicated by their complex topography, with the spacing, depth, and contour of the roughness grooves varying over a wide range. Theoretical and experimental studies (Ref 1) indicate that the variation in the intensity of specular reflection can best be related to a probability distribution of the heights of these roughness grooves. On the other hand, the spread of the diffusely reflected light depends on the distribution of the slopes of the roughnesses.

A surface has to specularly reflect a large proportion of the incident light before it would be regarded as being "polished," but the degree of reflection and the angle of viewing are very subjective requirements. Thus, there can be no sharp distinction between polished and nonpolished surfaces, as defined by either their reflectivity or their topography. In general, the roughnesses in a reasonably well-polished surface prepared with abrasives consist of grooves spaced ~100 nm apart having a side slope of ≥100° and a length at least several orders of magnitude greater than the width of the grooves.

Because polished surfaces and unpolished surfaces differ only in degree, it may be concluded that polishing wear should only be considered as a special case of certain basic wear processes. This is true only to a degree, and thus this article will concentrate on the circumstances that can generate the required type of finish. Nevertheless, unique wear mechanisms are involved and will have to be considered. Unfortunately, polishing wear encountered in complex engineering systems has not been extensively studied; however, simple systems operated with the deliberate intent of producing a specific polish have been studied, but only to a limited extent. Consequently, the present discussion will necessarily have to be based on these limited studies of deliberate polishing processes, making adjustments as needed to recognize that the objective of these studies of deliberate polishing and of polishing wear have opposing goals; the objective of one is to maximize material removal rate (MRR), and the objective of the other is to minimize the material removal rate. Only materials with high intrinsic reflectivity, the majority of which are metals, need to be considered.

Polishing Wear with Abrasives

Abrasive action is one of the most common causes of polishing wear. It is one of the few types of wear processes that can easily occur on a fine enough scale to generate surfaces with the required topography. Polishing wear under these circumstances can be regarded as a special case of abrasive wear (see the article "Abrasive Wear" in this Section), which typically produces diffuse reflecting surfaces. Consequently, what needs to be discussed here are the conditions under which an abrasive wear system might be expected to generate a surface with a fine topography.

Property Requirements of an Abrasive

Typically, an abrasive is a hard material in the form of small particles (often called grits) bounded by irregularly shaped surfaces that meet at sharp edges and points (Fig. 1). For commercial abrasives, the shape of the grits does not differ greatly, and it is the shape of their points and edges that is of primary importance; the diameter of the particles themselves is of secondary importance. This is demonstrated by the following example. An abrasive with a nominal particle diameter of, say, 10 μm (400 μin.) can be used to produce a good quality polish on many metals. The grooves produced on the workpiece surface with such an abrasive would certainly be <0.5 μm (<20 μin.) wide. Contacting grits can penetrate to only a small fraction of their diameter when producing such groves (Fig. 1), and the penetrating portion must comprise a point or, less likely, an edge. Thus, only the points and edges of abrasive grits actively contribute to a polishing process, and it it the shape of these points or edges that is the determining factor. The primary function of the rest of the individual grit is to support the contacting regions in the same way that the shank of the lathe tool supports the cutting tool. Nevertheless, the dimensions of the particles can have a secondary influence if the maximum number of particles that can be packed together in a given area and, less obviously, the means by which the abrasive particles are held against the workpiece surface can be determined.

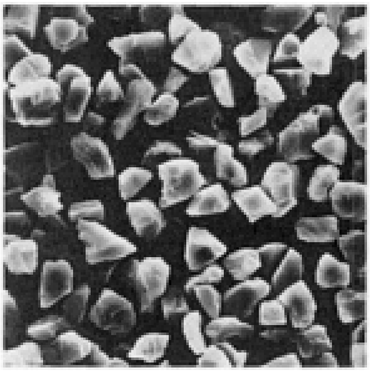

Fig. 1 SEM micrograph of monocrystal diamond polishing abrasive that has a mean particle size of 5 μm (200 μin.). Grit shape is typical of that of most types and grades of abrasives on the market. Width of groove or scratch generated by abrasive is $\approx$0.1 times the grit diameter. 750×

Abrasives are typically considered to be hard materials (for example, silicon carbide, aluminum oxide, and diamond). Nevertheless, the hardnesses of materials conventionally classified as abrasives vary over a considerable range (Table 1), from a value comparable to that of the harder metals (for example, silica, the abrasive most commonly present in natural wear systems) to that of diamond, the hardest material known. In fact, the only requirement of an abrasive from this point of view is that its yield strength be great enough relative to the workpiece to indent the workpiece without the abrasive deforming significantly itself. Strength (that is, hardness) beyond this level of performance is of no benefit.

Table 1 Typical values of hardness and toughness of selected abrasives and metals

Material	Hardness, HV	Fracture toughness[(a)]	
		MPa $\sqrt{m}$	**ksi $\sqrt{in.}$**
Abrasives			
Silica (SiO_2)	850	1.1	1.0
Zirconia (ZrO)	1150	[(b)]	[(b)]
Emery (Al_2O_3·Fe_3O_4)	1400	[(b)]	[(b)]
Alumina (Al_2O_3)	2000	2.2	2.0
Silicon carbide (SiC)	2100	2.5	2.3
Cubic boron nitride (CBN)	2750	5.7	5.2
Diamond (C)	8000	[(b)]	[(b)]
Metals			
Steel			
1.2% C, hardened	950	[(b)]	[(b)]
0.4%			
Hardened and tempered	400	70	64

Normalized	190	50	46
Ferrite phase	75	(b)	(b)
Cementite phase	1100	(b)	(b)
Aluminium alloy, age hardened	135	30	27

(b) No data available

Indentation hardness values, or ordinarily determined, the valid indicators of the relative properties of the abrasive and the workpiece in this respect, and a sample theoretical analysis developed by Tabor (Ref 3) has indicated that the hardness of the abrasive should be two to three times that of the workpiece if the abrasive is not to deform noticeably during indentation. However, an abrasive does not have to be quite that hard to indent the workpiece to some extent. Even if the abrasive itself is deformed a little in the process, it is still capable of removing material with at least a degree of effectiveness that would generate workpiece wear. In fact, one experimental investigation (Ref 4) has suggested that an abrasive need only be slightly harder than the workpiece itself to effect some abrasive wear. The material-removal efficiency was then found to increase rapidly with the increase in the hardness ratio up to a value of 1.5 but leveled off at hardness ratios >1.5. Unfortunately, neither the mechanisms by which the material was being removed nor the effect on surface finish was determined in this investigation. Therefore, these results cannot be precisely interpreted. Nevertheless, the general point has been established that a so-called abrasive does not necessarily require a high hardness top effect wear but only that the hardness of the abrasive must exceed the hardness of workpiece material. Thus, particles of a hard metal could produce abrasive wear in many comparatively soft metals. Protuberances on the surface of a hard metal could also generate abrasive wear. However, hard materials such as the classical abrasives are required to produce wear in the harder alloys used in engineering practice.

A difficulty arises when applying to polishing wear those concepts that were developed with larger-scale processes such as abrasive wear and abrasive machining (grinding). Indentation hardness tests, even the microindentation hardness tests on which the concepts of abrasive wear have been based, are carried out on a much larger scale than the processes occurring during polishing wear. The question arises as to whether these abrasive processes are adequately representative under these circumstances. It was originally believed that the principle of similarity, on which hardness comparisons rely, no longer applied to indentations smaller than a certain size. However, the best evidence currently available indicates that the principle does indeed apply down to the smallest conceivable indentations (Ref 5, 6, 7). The comparisons are still actually valid only if the workpiece material is fairly homogeneous over the entire range of indentation sizes specified. However, many metallic alloys are not homogeneous at the microscopic level at which polishing wear is produced. These metallic alloys can contain phases whose mechanical properties are considerably different from the matrix phase and whose size can vary over a wide range depending on the composition, mechanical properties, and thermal history of the alloy. It is quite possible for such a phase to be small enough relative to the scale of the grinding or abrasion process that it will not have a significant effect but be large enough on the scale of polishing wear to have a major effect on the performance of some types of abrasive grits. In this case, to act as an abrasive, a material would have to be matched to the characteristics of the second phase for polishing wear but not necessarily so for abrasive wear.

It has been recognized in other contexts (Ref 8) that it is convenient to divide abrasion-sensitive materials into two categories:

- All single-phase metals and alloys and those multiphase alloys in which either the properties of the additional phases do not differ significantly from the matrix phase or the particles of the additional phases are small relative to the grooves made by the abrasive particles.
- Multiphase alloys in which one or more of the minor phases is much harder than the matrix phase and is large relative to the grooves made by the abrasive grits

As we have just seen, it is also convenient to categorize materials in the same way as for polishing wear. The difference is the presence of much smaller particles of a hard phase may require that an alloy be included in the second category.

Fracture Toughness. An abrasive may easily meet the hardness ratio criterion mentioned earlier and still not be applicable for a wear system because it fractures easily, either by crushing in compression or by fracturing in tension (due to the bending forces imposed on a contacting grit point as it plows across the workpiece surface). Fracture in bending is

the more likely cause of point fracture because abrasives have poor fracture toughness. That is, abrasives are prone to catastrophic failure when stressed in tension in the presence of stress concentrators. Stress concentrators in the form of notches and cracks inevitably are present in abrasive grits. Fracture toughness can be quantified even in brittle materials. The fracture toughness values for all abrasives are low, but the values differ in a manner that is not necessarily related to hardness. Silica, for example, is the least tough of the common abrasive materials even though it is the softest of them all; diamond, on the other hand, is the hardest of all abrasives and yet probably is the toughest. All common abrasives are significantly less tough than general engineering materials are judged by the values in Table 1, implying that common abrasives would fracture before the workpiece when the two are stressed in contact. The abrasive would then gradually be removed from the system, more so with some abrasives than others. The solution is less clear-cut, however, when brittle phases are present in the workpiece material because the brittleness of some of these phases might approach that of the abrasives. A moderating factor, however, is that small particles of brittle phases are more ductile than expected when supported by a surrounding ductile matrix, but minimal detailed information is available on this phenomenon.

Nevertheless, these comparisons of fracture toughness predict a deterioration in the effectiveness of abrasives in wear systems. The comparison can be expected to be reasonably valid on a large-scale system typical of grinding machining, for example, but it may not be valid on the small-scale system in which polishing wear occurs. This is because small volumes of material are being deformed by an unusual and complex compressive stress system. The work of Bridgman (Ref 9) showed that materials that are brittle in bulk can react in a ductile manner under these circumstances. This certainly appears to be the case for the workpiece material but whether it is also the case for the contacting points of abrasive grits is a matter for conjecture. Under such conditions, it would mean that certain abrasive materials might have a more serious effect on polishing wear than would be expected from their reaction in larger-scale processes.

Melting Point. It has been suggested in the past that the melting point is one physical property that has to be taken into consideration when assessing whether a particular material is likely to act as a polishing abrasive. It was believed that a material had the ability to polish only if its melting point was higher than that of the workpiece material (Ref 10). This conclusion was based on polishing trials with a reasonably wide range of abrasive-workpiece combinations, each of which initially supported this conclusion. However, trials subsequently carried out with a wider range of combinations (Ref 11) unearthed many systems that did not conform to the initial results (Fig. 2). In the combinations investigated in the original experiments of Bowden and Hughes (Ref 10), black dots were found only above the line of equal melting points (Fig. 2). Subsequent experiments by Rabinowicz (Ref 11) produced the combinations that are found below the line. Therefore, the concept of the significance of relative melting points can no longer be regarded as being valid. On the other hand, it is true that hard materials tend to have high melting points. Thus, a general if indirect correlation can be made between polishing ability and the melting point of an abrasive, although no reliance can be placed on the correlation in specific instances.

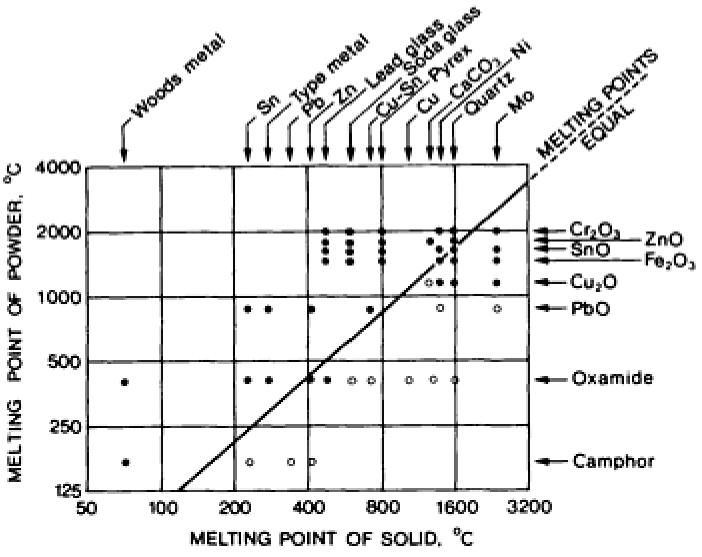

Fig. 2 Correlation between polishing ability and the relative melting points of the polishing powder and the workpiece solid. Solid dots indicate abrasive powder and solid combinations for which polishing does occur, whereas open dots indicate powder-solid combinations that do not generate a polished surface. Source: Ref 10,

Parameters Required to Generate Specularly Reflecting Topographies

Experience indicates that the included angle of potential contacting points of abrasive grits is typically $\geq$100°, and indentations by points as obtuse as this can be taken to be directly analogous to those made by the Vickers-type or Knoop-type indenter, which has an included pyramidal angle of >100° (Ref 12). Consequently the applied force required to produce a static indentation of a particular grit size can be calculated if the true surface hardness of the workpiece is known and the abrasive: workpiece hardness ratio criterion (see the section "Property Requirements of an Abrasive" in this article) has been complied with. The groove produced when an indented grit is then moved across the workpiece surface by a lateral force is known to be narrower than the static indentation but only by ~10% (Ref 13), a difference that can be ignored for the purposes of this discussion. On this basis, an approximate estimate can be made of the largest force that can be applied to contacting grits if they are to produce grooves that are narrow enough to generate a polished appearance (that is, if they are to produce grooves narrower than 50 to 100 nm). A limiting force of ~0.01 N (1 gf) is indicated for a workpiece hardness of 1000 HV and limiting force of 0.002 N (0.2 gf) for a hardness of 100 HV. The next step is to determine under what conditions the applied loads can be limited to this order to magnitude.

In the final analysis, the force applied to an abrasive particle is determined by the elastic constants of the entire system that holds the abrasive grits against the workpiece surface. This system consists of a number of units linked in a closed loop (namely, the grits; the cement, or any other device that holds the grits in place; the mechanical components that connect the workpiece and the abrasive; and the workpiece itself). Grinding machines of the type used in machine shop practice are representative of so-called hard elastic systems (that is, small changes in displacement between the grinding wheel and workpiece cause large changes in the force exerted between the two, principally because the mechanical components of the grinding machine simulate a very stiff spring). Consequently, such a machine can be expected to produce a polished surface if, and only if, the depth of indentation of the contacting grits can be kept appropriately low and if the whole system can be controlled precisely so that the penetration depth is maintained at the low value throughout the machining cycle. This can be done (Fig. 3), but only under special conditions in precision machines (Ref 14). The grinding system required to produce such a highly polished finish must be very rigid and the depth of cut of the grinding passes has to be kept to an unusually small value to ensure that the surface grooves formed are shallow enough and closely spaced enough for specular reflectivity. Even then, a high polish can be obtained only on hard materials. These conditions are not likely to be achieved in an elastically-hard wear system but at least the principle is established that all which is required to produce a "polished" surface is to restrict the width and depth of the grooves generated on the surface. However, it also suggests that wear which yields polished surfaces is not likely to occur in elastically hard systems.

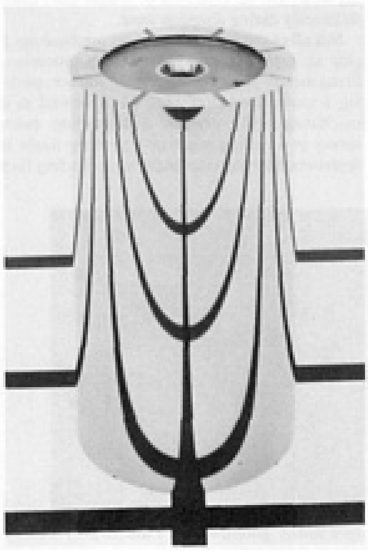

Fig. 3 Hard steel cylinder whose surface was ground to a polish using precision toolroom practices. The cylindrical surface exhibits a high degree of specular reflectivity, as indicated by the clear and sharp reflections of the grid lines ruled on the plane on which the cylinder rests.

Cloth laps charged with a fine abrasive suspended in a liquid, such as those used in metallographic practice, are examples of soft elastic systems. The workpiece surface actually contacts the fibers of the cloth, either individual fibers or groups of fibers incorporated into a thread, and each fiber simulates can elastically soft cantilever spring (Fig. 4). The fibers are typically ~20 μm (~800 μin.) in diameter and made from materials with a low elastic modulus so that they can exert only a very small reactive force when distorted. Moreover, this reactive force would change little with variation in the distortion. Increasing the force applied to a workpiece causes it to sink into the cloth, thus increasing the number of fibers contacted but not markedly increasing the force applied by each component. The local force system is, in effect, self correcting, which permits comparatively easy control of surface finish. The dimensions of the cloth fibers, the method by which they are held or woven together, the elastic modulus of the fiber material, and the number of abrasive grits held in contact by each fiber are consequently the factors that determine surface finish as well as, but usually to a lesser extent than, the force applied to the workpiece. This can be regarded as a more plausible, if perhaps excessively idealized, model of the conditions that are likely to cause polishing wear.

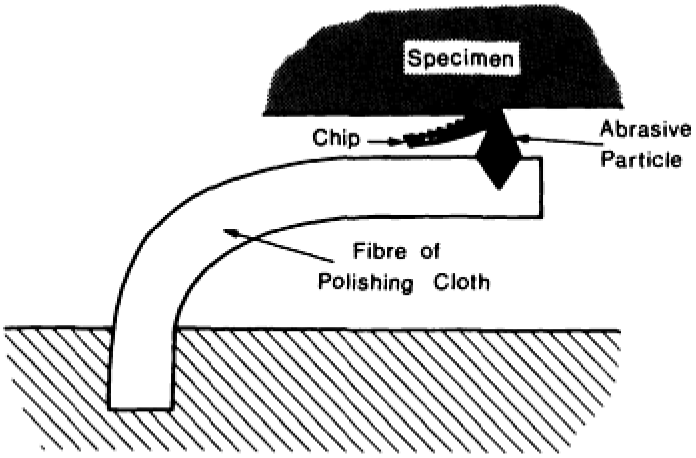

Fig. 4 Schematic showing one method by which an abrasive grit can be held in a fixed position to ensure the application of a very small indenting force. This indenting force is determined by the elastic characteristics of a textile fiber that simulates a very soft cantilever spring. Source: Ref 15, 16

However, extended grooves of the type typically present on specularly reflecting surfaces will be formed only if the grits are held fixed in one orientation in space for a specified duration (Fig. 5). Loose tumbling grits produce angular indentations (Fig. 5b) that are conducive to diffuse the reflectivity. It is difficult to see how grits, initially added as a powder, can be held fixed in this way when the abrasive is present on an elastically soft support such as a cloth, but there are several possibilities (Ref 16, 17):

- Grits can become embedded in the fibers of a cloth (Fig. 6a), provided that their diameter is less than the fiber diameter
- Groups of grits can be attached to the fibers by a viscous liquid or a waxy solid (Fig. 6b); this is likely only when the grits are much smaller than the fiber diameter
- Grits can be snared between tangled fibers (Fig. 6c); this is likely only when the grits are much larger than the fiber diameter

The second arrangement is most likely to result in the highest material removal rate, whereas the third arrangement results in the lowest material removal rate.

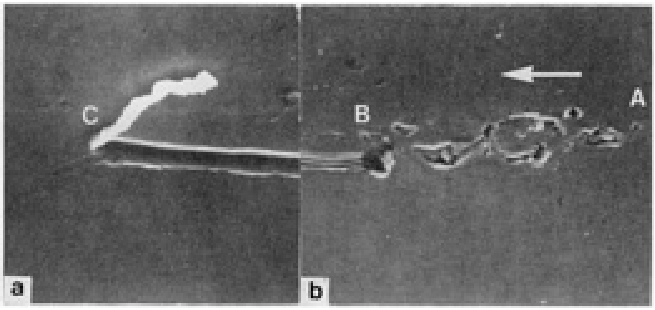

Fig. 5 SEM micrographs of a track on a prepolished copper surface generated by a 1 μm (40 μin.) diamond abrasive grit. (a) 7000×. (b) 5000×. The grit, moving in the direction of the arrow (b) relative to the specimen, first contacted the specimen surface at about point A and made an angular indentation at that location. The grit then tumbled across the specimen surface making additional angular indentations as the numerous edges and corners of the grit successively came into contact. At location B, the grit became fixed in position, perhaps by either one of the methods shown in (a) (b). Thereafter, it formed an extended groove, the end of which is shown in (a). A ribbon of metal that has all the characteristics of a machining chip is attached at the termination of the groove at location C. This groove was clearly machined out of the specimen surface.

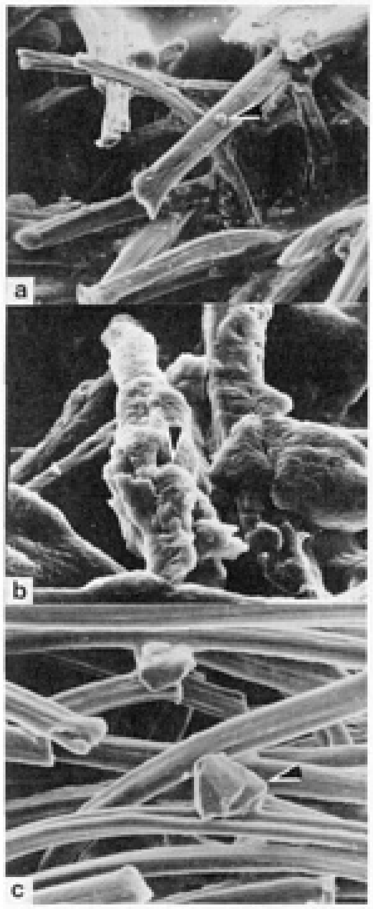

Fig. 6 SEM micrographs showing different methods of holding abrasive grits on a cloth in a fixed position and orientation. (a) Isolated grits (indicated by arrow) embedded in cloth fibers (210×). (b) Numerous grits (indicated by arrow) held to fibers by a pasty material (500×). (c) Isolated grits (indicated by arrow) entangled between the cloth fibers (250×). Grits must be held fixed to form an extended groove in a workpiece surface.

It is also possible that the grits could be circulated by turbulences developed in the liquid in which it is suspended and occasionally whisk across the workpiece surface with sufficient momentum to form an extended groove. In such an event,

polishing wear would become a special case of slurry erosion. There is direct evidence that circulation of the grits does occur by this method (Ref 17), but only inferential evidence that extended grooves can be formed by this phenomenon. Indeed, the indications are that they can most readily be formed on harder materials and less readily on soft materials and phases (Fig. 7). Indentations rather than grooves tend to be formed in the latter case (Fig. 7b).

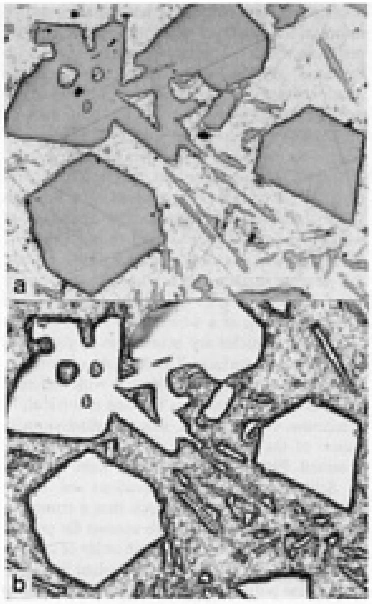

Fig. 7 Optical micrographs of an Al-13Si alloy polished in a dry abrasive and an abrasive entrained in a water slurry. (a) Diamond abrasive applied so that the grits were held fixed to the fibers of a polishing cloth as shown in Fig. 6(b). Alumina abrasive of a grade corresponding to diamond but applied as a water slurry. The fixed diamond grits operated in a cutting mode and cut extended grooves in both the hard silicon phase (angular light gray) and the soft aluminum phase of the matrix. The loose alumina grits, presumably operated in an erosive mode, produced only indentations in the aluminum phase, which consequently has a comparatively poor reflecting matte finish. Both 500×

Mechanisms of Material Removal

The creation of a system of grooves may produce a specularly reflecting surface, but it does not follow that material is removed during the process (that is, that the workpiece actually wears). Little if any information is available on the subject of the material removal mechanisms involved in polishing wear systems. Consequently, it is necessary to make assumptions that are based on the knowledge of other systems, particularly deliberate polishing systems.

Chip Machining Mechanism. The most plausible explanation is that the contacting points of either abrasive-like grits or hard protuberances on another surface simulate tools that produce the grooves by machining out chips. This is the mechanism primarily responsible for the generation of surfaces in ductile materials by abrasive machining processes ranging from industrial grinding to polishing (Ref 15, 16, 18, 19). Evidence of the type illustrated in Fig. 5(a) and Fig. 8(a) indicates conclusively that chip machining is the dominant material removal mechanism in almost all polishing situations. Chip machining is even the dominant mechanism for many materials that are brittle in bulk form (Ref 20, 21). For reasons that are not clearly established and that need not be discussed at this point, these materials are more ductile during indentation when the depth of indentation is less than a critical value, where this critical value can be of the order of magnitude encountered in polishing. Therefore, hard brittle materials or phases may incur wear by the same type of mechanisms as ductile materials during polishing wear, but the materials or phases react quite differently during abrasion wear.

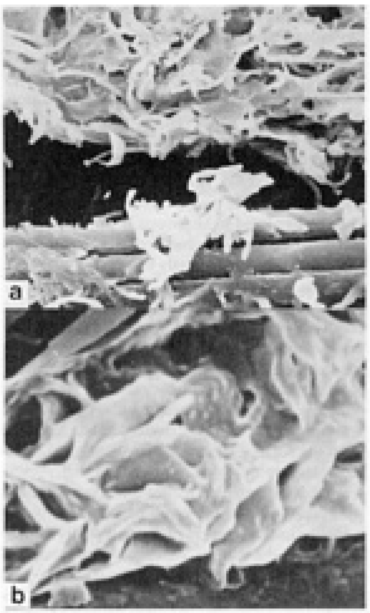

Fig. 8 SEM micrographs of metallic debris remaining on polishing cloths after polishing a Cu-30Zn brass with diamond abrasives. (a) Debris produced during polishing on a comparatively coarse (30 μm, or 1200 μin., mean particle diameter) abrasive. The debris consists almost entirely of threads of metal that have the characteristics of machining chips. 1000×. (b) Platelet-type debris produced during polishing with a very fine abrasive (0.1 μm, or 4 μin., maximum particle diameter). Such platelets are presumed to be generated by a delamination mechanism of material removal and thus are quite different from the debris shown in (a). 5000×. Source: Ref 16

Not all of the contacting points machine out a chip in typical abrasive-machining processes. Some merely plow a groove in the surface, pushing a stem ahead (Ref 18). When viewed as a machining tool, whether a contacting point serves in a cutting mode or a plowing mode is determined by the rake angle of its leading face and the nature of the workpiece material. A point cuts a chip only when its rake angle is more positive than a critical value, a value that is a characteristic principally of the workpiece material (Ref 13, 18). Large numbers of points with a shape suitable for chip cutting are conducive to relatively high rates of material removal, which is desirable for deliberate polishing but clearly undesirable for wear applications. Although it is reasonable to assume that these principles would apply to abrasive polishing, there is no concrete evidence available to confirm this. No information is available on basic parameters (for example, the rake angles of contacting points and the values of critical rake angles) that would be needed for the prediction of wear rates.

The optimum condition from the standpoint of minimizing wear rate is one in which all of the contacting points are operating in a plow mode. Nevertheless, it is still possible that the points would remove material by mechanisms that are of minor importance in abrasive machining but that could be significant in terms of wear. One of these conditions occurs with contacting points that have negative side clearances when serving as machining tools. Contacting points with negative side clearances are commonly encountered in machining practice. Some of the material flowing into the prow established ahead of the contacting point tends to flow towards one side of the groove being produced, thus forming a thin fin at the edge of the groove (Fig. 9). This fin is sure to break off sooner or later. Another potential condition is that the prows themselves sometimes detach by shear fracture at their base (Ref 19). Prows are also likely to detach, partly if not completely, when they reach an external edge of the workpiece. Finally, a prow sometimes may behave as the equivalent of a built-up edge (BUE) on a tool and cause the separation of a small secondary chip when the contacting point itself would not do so (Ref 19). Although each one of these phenomena can be assumed to occur in polishing wear, no information is available about the conditions under which they are likely to occur and, hence, their likely contribution to material removal cannot be quantified.

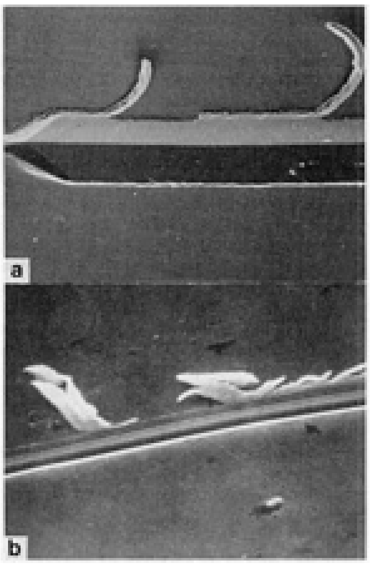

Fig. 9 SEM micrographs of fins formed at the edge of an abrasion groove by a grit having a negative side-clearance angle. (a) End of a groove generated by a model pyramidal point oriented to have a negative side-clearance angle. A portion of the prow formed ahead of the point has flowed into one of the side edges of the groove, developing a fin that periodically separates from the edge. 138×. (b) Abrasion groove formed under actual conditions. An irregular fin has formed at one edge of the groove and is certain to detach, thus constituting a secondary mechanism of material removal. 460×

Delamination Mechanism. An entirely different material removal mechanism from that just described has been observed to occur during certain conditions of deliberate polishing. These conditions involve the use of very fine abrasives (<1 μm, or 40 μin., particle size) and produce surfaces that are brilliantly specular but still composed of systems of parallel grooves. Material removal in this case occurs via the very small labs of material being lifted out of the surface (Fig. 8b), presumably by some form of delamination. Moreover, it seems that this delamination phenomenon is typical, occurring in varying degrees in all abrasive-machining processes from grinding (Ref 22) to polishing (Ref 16); however, this phenomenon is overwhelmed by the chip-cutting mechanisms in the coarser processes. Yet for some as yet unknown reason, the chip-cutting mechanism begins to be phased out at a certain stage of the process as the finish flatness is increased. It eventually ceases, and the delamination mechanism is then left as the sole material removal process. The amount of material removed by the delamination mechanism is likely to be much less than that removed by chip cutting. An adequate explanation for this phenomenon has not yet been developed (Ref 22, 23).

Multiple-Pass Mechanisms. All of the mechanisms discussed to this point assume that the active contacting point is harder than the workpiece (that is, it meets the Tabor criterion); moreover, they assume only a single pass of the contacting point. We have already noted that some commonly occurring abrasive materials cause wear even though they are considered to be comparatively soft by these standards. In addition multiple passes are likely in wear, particularly when material is being removed at a low rate. Kosel and his colleagues (Ref 8, 24, 25) have shown that abrasives can wear harder materials and phases after multiple passes and that material removal can then occur by several mechanisms (for example, delamination and the removal of fragments by fracture). The resultant wear rate is small. The conditions necessary to induce these mechanisms, however, seem to be too severe to be conducive to the generation of specularly reflecting surfaces. Nevertheless, it is expected that multiple passes could enhance the significance of delamination and other secondary processes.

Erosion Mechanisms. It was mentioned in the section "Parameters Required to Generate Specularly Reflecting Topographies" that polishing wear can be caused by an abrasive suspended in a liquid that circulates past the workpiece surface. Normal erosion wear mechanisms can then be expected to operate. The mechanism most likely to occur depends on the momentum of individual grits perhaps being sufficient for the grits to indent into the workpiece surface when they strike the surface and then to sweep across the surface, producing an arc-shaped groove. The grits would either plow or machine out a chip, depending on the shape of their contacting point, typically the same process encountered for fixed abrasives. Small grits and low flow velocities would tend to produce shallow grooves conducive to the generation of a polished finish and comparatively low wear rates. However, it appears that highly reflecting surfaces are likely to be produced by this method only on harder phases; poorly reflecting indented surfaces tend to be produced on soft phases

(Fig. 7b). A further consequence is that adjoining particles or phases of an alloy with differing polishing characteristics are more likely to polish to different levels than when the abrasives operate in a chip-cutting mode. The difference in relief between phases may even be discernible to the naked eye. Moreover, for reasons that are not clear, preferential erosion tends to occur locally at the interface between phases that have markedly different polishing characteristics (Ref 15).

Summary. Assuming that the abrasive material has adequate mechanical properties to withstand undamaged its interaction with the workpiece, it is the shape of the points of the grits and the orientation of the grits as they encounter the workpiece surface that determine their potential to cause wear. The term "shape" refers to the details of the configuration of the small portion of the point that actually contacts the workpiece surface. A perfectly smooth spherical point, for example, might generate a groove in the surface, but it typically would not remove material by machining out a chip because it would present only a highly negative rake angle as a machining tool. On the other hand, a point that contains numerous fracture facets, even if it has a generally spherical form, might be able to do so because some of the fracture facets might have a shape that enables it to act as a machining tool. These facets could be original or they could be the result of fracture in use (Ref 25). However, these cases are contingent on the grit being held in a fixed position in space for a sufficient time to machine a lengthy groove.

Wear Rates

It is a widely accepted belief that polishing wear rates are inversely proportional to workpiece hardness. This view has been implied throughout this article. However, the presumed relationship actually is based on little more than intuition because it has never been supported by quantitative experimental evidence. In addition, theoretical analyses, even the very generalized ones given above, indicate that a simple relationship of this nature is not to be expected.

The width (and hence the volume) of the grooves generated on a polished surface can indeed be expected to be inversely proportional to the local surface hardness of the workpiece. Even this is not necessarily identical to the bulk hardness of the material because it usually would have to be adjusted to account for the effects of surface layer deformation during previous machining and wear and to account for the hardness of individual phases of the microstructure. Even then, a correlation with workpiece hardness would be obtained only if all of the volume of the surface grooves were removed from the surface (that is, if the theoretical limiting wear rate was obtained). An alternative possibility would be that a constant fraction of the grooves was removed for all materials, which is a highly unlikely event. In reality, only a fraction, x, of the groove volume is removed, and this fraction varies considerably $(0 < x < 1)$ with different materials. In fact, the fraction depends on a multitude of factors, many of which are in no way related to workpiece hardness. The fraction cannot be predicted, although experimental determination is sometimes possible. The variation in this fraction is sufficient to negate the possibility of a correlation between wear rate and hardness.

Experimental evidence on the effects of the properties of the workpiece material on polishing rate is scant and confined to metallographic polishing processes. Nevertheless, the evidence that is available confirms the complexity of the matter. Figure 10 explores the possibility of a relationship with workpiece hardness. Figure 10 indicates the existence of an upper boundary for results in which the polishing rate decreases with hardness. Within this boundary, however, the relationship is highly random. A particularly anomalous feature is that the polishing rates of the alloys considered are, with only one exception, higher for their softer base metals.

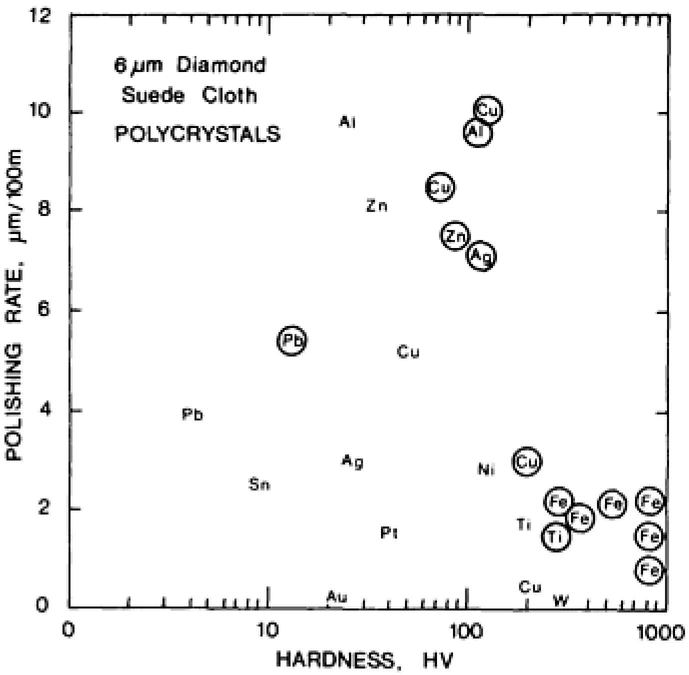

Fig. 10 Variation of polishing wear rate with workpiece hardness. Circled symbols indicate alloys of the base metal, whereas uncircled symbols indicate commercially pure metals. Wear rates were determined under comparable stringent conditions; the abrasive was under conditions that ensured the grits were held to the fibers of a polishing cloth by the method shown in Fig. 6(b). Source: Ref 15

The above considerations are concerned with the efficiency of the wear process. The absolute value of the wear rate depends also on the rate at which the surface grooves are formed; that is, the rate at which abrasive grits actually contact the wearing surface and become active. A very large quantity of grits is usually present in the general vicinity of a wearing surface, but very few of the particles are actually in contact with the workpiece surface. The fraction of contacting points will vary considerably with different types of systems, and this fraction is difficult to determine. Nevertheless, some qualitative indication of the importance of the factor can be obtained. For example, the wear rates obtained in deliberate polishing operations on cloths charged with an abrasive such that a comparatively high proportion of grits contact the polishing surface (as in Fig. 6b) are an order of magnitude higher than those obtained when few grits contact the polishing surface (as in Fig. 6a), even though the grits available per unit surface area of cloth are the same (Ref 15).

The fraction of contacting points available also contributes to the effect of abrasive particle size on the polishing wear rate because, for equal weights, the number per unit area of grits decreases rapidly with the increase in grit diameter. Figure 11 shows that the wear rate decreases markedly when the particle size is >3 μm (>120 μin.). This condition can be at least partially attributed to a decrease in the number of grits present per unit area of the polishing cloth. In this instance probable contributory cause is the fact that the fraction of the grits held in a workpiece-contacting position has also changed because it becomes more difficult to hold grits in a contacting position when the grit diameter approaches or exceeds the diameter of the cloth fibers (Fig. 5c). Under these conditions, the rapid decrease in wear rate when the grit diameter falls to <3 μm (<120 μin.) (Fig. 11) might seem to be paradoxical. However, the decrease in wear rate occurred and added a further complication because the predominant cutting mechanism began to be phased out, leaving only the inefficient delamination mechanism to provide the material removal process (see the section "Mechanisms of Material Removal" in this article).

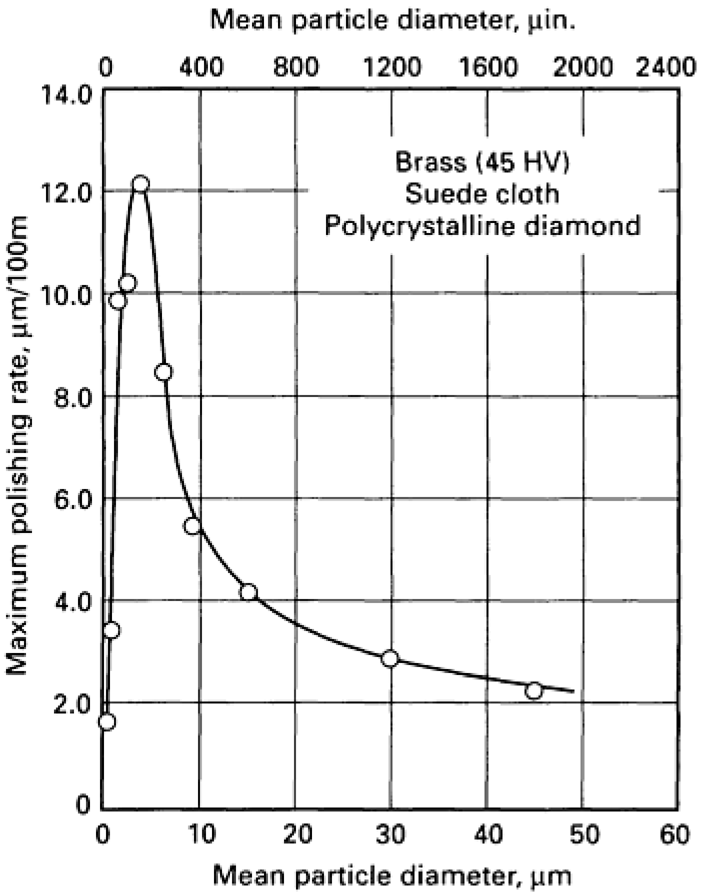

Fig. 11 Variation of the polishing wear rate with the particle size of a diamond abrasive used to machine 30% Zn brass

The polishing systems used in Fig. 10 and Fig. 11 can be regarded only as highly idealized and simplified models of wear systems that are typically encountered in engineering practice. These models certainly indicate, however, that the diagnosis and treatment of practical systems should be logically determined using a step-by-step procedure. The mechanisms of material removal certainly have to be established before rational analysis can commence. Subsequent comparisons with more idealized systems may indicate which methods of controlling the wear rate are feasible.

Polishing Wear without Abrasives

There are several possible mechanisms of polishing wear that do not depend primarily on the physical removal of material by the machining or scraping action of abrasives. Two such methods are discussed in this section:

- Surface flow
- Chemical-mechanical mechanisms

Surface Flow. It was once hypothesized that polishing was a thermally activated process in which a small volume at the crest of an asperity on a solid is heated to a high temperature for a brief period when an asperity on another solid contacts it and rubs past it. It was originally believed that the flash temperature reached the melting point of the solid of the pair that had the lower melting point and that some portion of this solid melted (Ref Ref 26, 27). It was then proposed that the molten material is transported from the asperity crest into an adjoining trough, thus gradually leveling the surface. The realization that the flash temperature might not always quite reach the melting point again altered the proposal for this process to suggest this crest material would be transported by plastic shear at high temperature. In either case, however, it was anticipated that the surface would gradually be made smooth and eventually become specularly reflecting (Ref 26, 27). In the strictest sense, the theory implies that small changes would occur in the dimensions of the surface being

polished but that no material would be removed unless the process were supplemented by a more conventional wear process. (This process would necessarily have to be one that does not destroy the specular reflectivity.) This theory became known as the Beilby theory of polishing; however, there is no need to elaborate on it further because conclusive evidence is now available that confirms it is invalid (Ref 15).

Nevertheless, it is still possible that the asperities on a moderately rough finished surface could be flattened by compression when rubbed by another stronger solid. Even modest localized heating of the workpiece surface during rubbing would increase this possibility. A specularly reflecting finish might then be obtained if the surface finish on the rubbing solid was conformed to specifications. This technique has been applied by jewelers, for example, to burnish precious metals by using tools of a polished hard material such as agate. However, wear in terms of material removal would again occur only if a subsidiary material removal mechanism did not destroy specular reflectivity during the machining process.

Chemical-Mechanical Mechanisms. Valid, if indirect, evidence exists that polishing can generate mechanisms which involve both chemical and mechanical elements in a symbiotic relationship (Ref 15, 28). The general concept is that the corrosion-protective film that normally covers a metal surface is removed from asperities by the rubbing solid. The protective layer is then reformed, consuming a thin layer of workpiece in the process. Repetition of the process gradually removes the crests of surface asperities, and the workpiece surface is leveled (Fig. 12). Only a small wear rate is expected, but a high polish is typically produced.

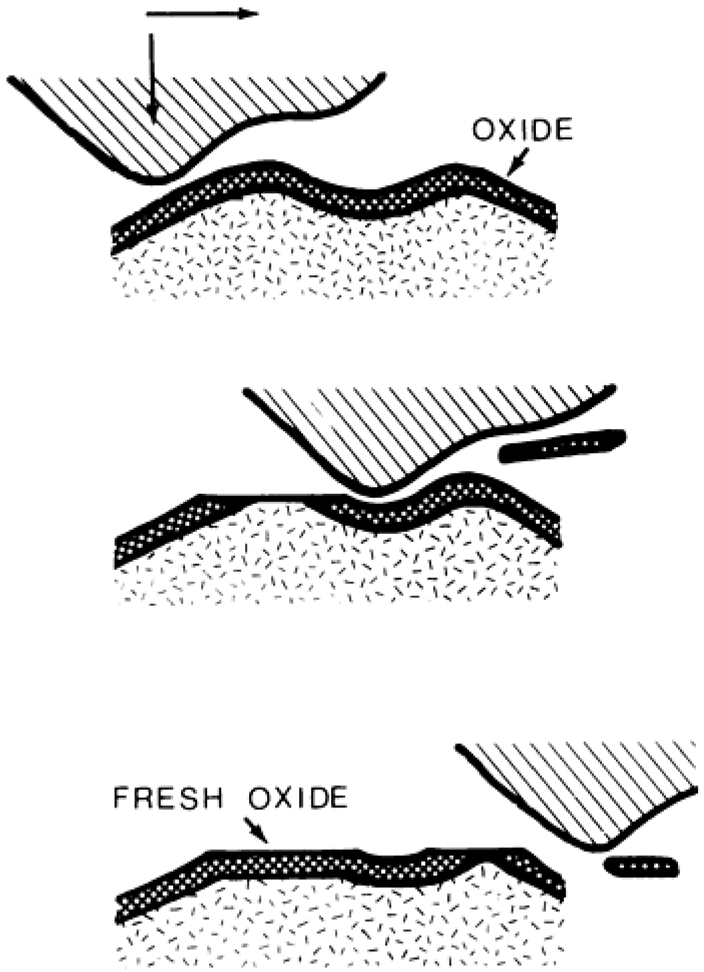

Fig. 12 Schematic of a proposed chemical-mechanical mechanism for the polishing wear process. Repeated removal and reformation of the corrosion-protective layer typically present on metal surfaces causes gradual leveling of the surface. The protective layer is shown to be an oxide and the interacting solid to be an abrasive grit; however, an asperity of any type would be equally effective provided that it was strong enough to break away the protective layer. Source: Ref 29

The rubbing should be, and indeed usually has to be, of a very gentle nature, but the contacting solid can consist of a range of types, including those with well-rounded contacting asperities. For example, rolling abrasives could be effective as could abrasives with well-rounded grits. This is in contrast to mechanisms that depend on abrasive machining. The presence of a medium that is only mildly corrosive would also be adequate. The process could theoretically occur, for example, in air because oxidation takes place the moment the protective film is removed. Nevertheless, the process is more likely to occur when a liquid (water being adequate in most cases) is present. More reactive liquids can, of course, accelerate the process. It is anticipated that metals whose apparent corrosion resistance depends on being covered by a self-healing surface film (that is, the more electronegative metals) would be most responsive to polishing wear by this mechanism, and that truly noble metals would be the least responsive. However, the production of a polish is in all cases dependent on a balance being achieved between the chemical and mechanical elements of the process. Even then, the development of some differences in the level of grains and constituents of the microstructure of the workpiece material is likely.

Solid Particle Erosion

Thomas H. Kosel, Department of Electrical Engineering, University of Notre Dame

Introduction

SOLID PARTICLE EROSION (SPE) is the loss of material that results from repeated impact of small, solid particles. In some cases SPE is a useful phenomenon, as in sandblasting and high-speed abrasive waterjet cutting, but it is a serious problem in many engineering systems, including steam and jet turbines, pipelines and valves carrying particulate matter, and fluidized bed combustion (FBC) systems. Readers faced with problems in particular systems or materials should consult other articles in this Volume that deal with specific components or alloys.

Various design solutions have been developed in which high erosion rates are avoided by reconfiguring the system--such as the blocked tee configuration, in which a tee joint with one end closed is used in place of a gradual bend in a pipeline to prevent low-angle impingement. A good example of the variety of engineering solutions to SPE is provided by the case of power-generating steam turbines, in which exfoliation of iron oxide scale formed on steel heater tubes generates large pieces of scale that are fragmented into approximately 100 μm particles, causing erosion of turbine blades, shrouds, valves, rivets, and other components (Ref 1, 2). Liquid droplet erosion is also present. SPE solutions include minimizing of scale formation by using austenitic steels or chromizing treatments, particle removal with cyclones or screens, application of plasma-sprayed or diffusion coatings to blades, and redesign of turbine configurations.

This article is primarily a review of important SPE variables, their effects for different classes of materials, and the mechanisms and theories proposed to explain SPE. Because there is not general agreement in the literature on every point of practical importance, the reader will be alerted to areas that are less completely understood.

Solid particle erosion is to be expected whenever hard particles are entrained in a gas or liquid medium impinging on a solid at any significant velocity (greater than 1 m/s, or 3.3 ft/s). Manifestations of SPE in service usually include thinning of components, a macroscopic scooping appearance following the gas/particle flow field, surface roughening (ranging from polishing to severe roughening, depending on particle size and velocity), lack of the directional grooving characteristic of abrasion, and, in some but not all cases, the formation of ripple patterns on metals.

Solid particle erosion can occur in a gaseous or liquid medium containing solid particles. In both cases, particles can be accelerated or decelerated, and their directions of motion can be changed by the fluid. This is more significant in liquid media, and slurry erosion is generally treated as a different, though related, subject. In gaseous media, at least for particles larger than about 50 μm, deflection of the particles by the gas stream can often be ignored in erosion tests. However, it should be borne in mind that in an engineering application, such effects can be quite important--as, for example, in the extensive work of Tabakoff (Ref 3) on the spatial distribution and severity of erosion damage within turbines and the effects of particle size and the change of direction and speed when particles rebound from surfaces.

The distinction between erosion and abrasion should be clarified, because the term erosion has often been used in connection with situations that might be better classed as abrasion. Solid particle erosion refers to a series of particles striking and rebounding from the surface, while abrasion results from the sliding of abrasive particles across a surface under the action of an externally applied force. The clearest distinction is that, in erosion, the force exerted by the particles on the material is due to their deceleration, while in abrasion it is externally applied and approximately constant. This serves as a good working definition of the difference between the two phenomena. A clear-cut distinction between erosion and abrasion is difficult in some cases, particularly for very dense particle distributions in liquid or gas media, in which a "pack" of particles can develop and slide across the surface, which would be classed as abrasion according to our distinction. The remainder of this article will concentrate on SPE in dilute particle flows.

In practice, erosion rarely takes place in inert atmosphere or vacuum, but at room temperature the effect of oxidation can generally be ignored, and erosion thought of as "pure." Erosion/corrosion synergistic interactions are considered in the

final section of this article. Following Finnie (Ref 4), variables affecting pure erosion can be broadly separated into three types: impingement variables describing the particle flow, particle variables, and material variables. The primary impingement variables are particle velocity (*v*), angle of incidence (α), and flux (particle concentration). α is defined here and throughout virtually all erosion literature as the angle between the incident particle direction and the particle surface. Particle rotational speed is an additional impingement variable; it is difficult to measure and has not been studied in much detail. Particle variables include particle shape, size, hardness, and friability (ease of fracture). Material variables include all the material properties, such as hardness, work hardening behavior, and microstructure.

In the erosion literature, materials are broadly classified as ductile or brittle, based on the dependence of their erosion rate on α. Ductile materials, such as pure metals, have a maximum erosion rate, *E,* at low angles of incidence (typically 15° to 30°), while for brittle materials, such as ceramics, the maximum is at or near 90°. These two classical extremes are illustrated in Fig. 1. A variety of curves intermediate between these classical extremes exist, as discussed later, and in some cases the same material exhibits behavior that shifts from one extreme to the other, depending on erosion conditions.

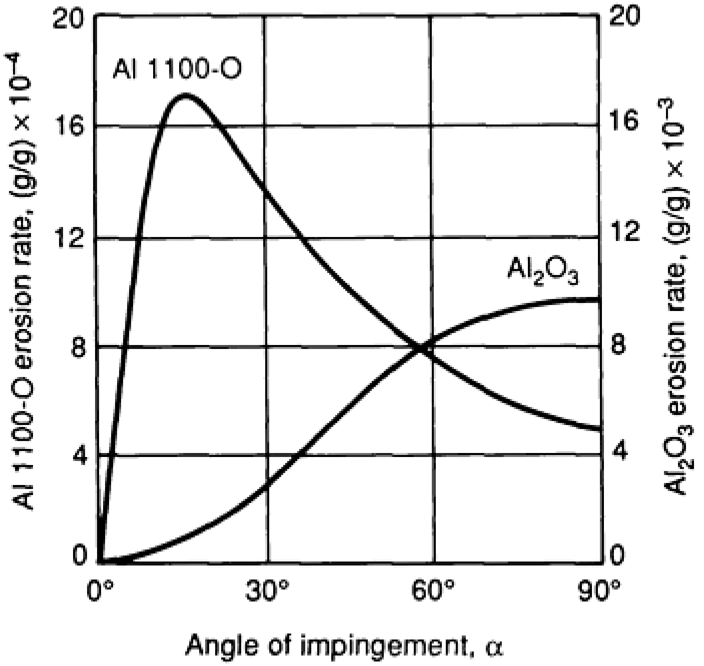

Fig. 1 Erosion of 1100-O aluminum relative to Al_2O_3 when both are eroded by 127 μm SiC particles impinging at a velocity of 152 m/s (499 ft/s). Source: Ref 4

Erosion

The phenomenology of erosion in the absence of corrosion will be briefly reviewed. The erosion rate, *E,* is commonly given in terms of mass or volume of material removed per unit mass of erodent impacted, volume being preferred because it permits thickness loss comparisons between materials of different density. Implicit is the assumption that the dimensions of the eroded area and the particle concentration are unimportant, which is a good approximation for dilute flows. Metals and ceramics differ in the dependence of *E* on α, as mentioned above, and also in their response to velocity and particle size and shape. *E* generally shows a power-law velocity dependence:

$$E = kv^n \quad \textbf{(Eq 1)}$$

where k is a constant and *n* is a velocity exponent that generally depends on material and erosion conditions. The value of *n* usually falls in the range of 2 to 2.5 for metals and 2.5 to 3 for ceramics, although observations exist outside these ranges. Material removal in ductile materials involves considerable plastic flow, while in brittle materials fracture is of primary importance, at least for higher angles of incidence. Theories predict that *E* should be inversely proportional to hardness for metals, while for ceramics there should be a much weaker dependence on hardness, but fracture toughness

should be important. Most theories further predict no effect of particle size for metals, although it is often observed that *E* increases strongly with particle size, at least up to about 100 μm. For ceramics, a particle size exponent is predicted and observed.

Mechanisms of material removal will be considered in more detail later, but it is evident that a division into metals and ceramics is justified. Because of the technological importance of steels and the failure of heat treatments that increase hardness to provide expected improvements in their erosion resistance, erosion of steels is treated in a separate section. A separate section on erosion of alloys containing large, hard second-phase particles, such as Stellites and high-chromium white cast irons, is also included. Such alloys provide excellent abrasion resistance, but under most erosion conditions they provide little or no improvement over plain carbon steels or even pure metals. The conditions under which such materials can provide significantly improved erosion resistance are considered.

Hansen (Ref 5) compared the erosion rates of a large number of alloys, ceramics, and cermets. Although limited to a particular set of conditions, Hansen's study provides the practicing engineer with a good comparison of erosion rates for a very broad range of materials under the same conditions. Estimation of the effects of variables such as velocity on the erosion rates of different classes of materials can be made from the remainder of this article. It should be noted that the order of material rankings would change with any change of variables such as velocity, particle type or size, and angle of incidence. The erosion tests were performed using 27 μm Al_2O_3 particles at normal incidence and 170 m/s (560 ft/s) at 20 and 700 °C (68 and 1300 °F) in nitrogen. As in most other studies, the tests were conducted with a gas-jet erosion apparatus in which particles are fed from a hopper into a nozzle, where they mix with and are accelerated by a flowing gas stream. ASTM has developed a standard test of this type (Ref 6), commonly used in industrial test labs. Hansen (Ref 5) normalized the erosion rates by defining the relative erosion factor (REF) as specimen volume loss divided by that of a standard material, Stellite 6B (Table 1). Figures 2 and 3 show his data for metals and ceramics, respectively. WC-Co cermets gave REFs from about 0.1 to 1.6, and REF was found to increase with binder content. The REFs of most metals were similar at 20 and 700 °C (68 and 1300 °F), typically within about 20% of unity (Fig. 2). The three lowest room-temperature REFs for metals were for tungsten (0.48), molybdenum (0.52), and 1015 steel (0.76), and the highest was for Ti-6Al-4V (1.26). The 700 °C (1300 °F) erosion rate of the standard (Stellite 6B) was 20% higher than the room-temperature value, so that 700 °C (1300 °F) REF values greater than 0.8 represent increases of erosion rate with temperature for a given material.

Table 1 Erosion test results for selected metals and ceramics evaluated at room temperature and at elevated temperature

Test parameters: 90° impingement; 27 μm Al_2O_3 particles; 5 g/min (0.18 oz/min) particle flow; 170 m/s (560 ft/s) particle velocity; 3 min test duration; N_2 atmosphere

These results illustrate the unfortunate fact that alloy-strengthening mechanisms such as solution or precipitation hardening that increase hardness do not significantly improve erosion resistance. According to Hansen (Ref 5), if service experience reveals an erosion problem for a metallic component, substitution of another metallic alloy will generally provide little improvement. Most ceramics tested had REF values in the range 0.3 to 0.6, although a few were much higher, and a few were nearly zero. It is important to note here (as discussed later) that for erodent particles of lower hardness than Al_2O_3 (used in Hansen's study), significant improvements of erosion resistance can be obtained when the ratio of particle to target hardness, H_p/H_t, is less than 1.

Erosion of Metals

Throughout the large body of recent literature on erosion of metals are found the concepts of direct material removal by cutting or micromachining interaction of hard, sharp particles, and of repeated deformation of material leading to eventual removal of a flake or platelet or material. Direct material removal by cutting has been observed experimentally in some cases, as has the platelet mechanism, the latter has recently acquired a significant following. It is probable that both phenomena occur in varying proportions; further experimental and theoretical work is needed to clarify the importance of the two. From a design viewpoint, the distinction is important, because cutting models predict an inverse dependence of E on hardness, while ductility may be of greater importance for the platelet mechanism because it may affect the ease of

platelet removal. This section treats the erosion of single-phase metals and of metals for which the dimension of the impact damage is larger than the dimensions of second-phase particles.

The first theory for erosion of ductile materials was developed by Finnie (Ref 7, 8) and is still widely quoted. The trajectory of the particle was calculated using a number of simplifying assumptions, and the volume removed was equated to the volume swept out by the particle tip. The model predicted a velocity exponent of n = 2, and the predicted dependence of E on α was similar to experimental observations such as that for aluminum in Fig. 1, except for the fact that the model gave a zero erosion rate of 90° (normal) incidence. We will return to this point later. Finnie and McFadden (Ref 9) have discussed the fact that the velocity exponent often increases with increasing angle of impact, and have demonstrated that this can be accounted for by their microcutting analysis of low-angle impingement. E was predicted (Ref 7, 8) to be inversely proportional to the horizontal component of the flow pressure between the particle and surface. Together with the assumption that the particle did not rotate significantly during impact, this implies an inverse dependence on dynamic hardness, P--that is, the mean contact pressure during a high-velocity impact hardness test. Finnie (Ref 4) discussed the fact that P would not be expected to be equal to the static hardness, H, measured in standard hardness tests, because it involves high strain rates (typically 10^4 to 10^7), strains (several hundred percent), and possible temperature rise introduced by plastic deformation.

The observation by Finnie *et al.* (Ref 10) of an inverse dependence of E on H for pure face-centered cubic (fcc) metals and tantalum is illustrated in Fig. 4. The data are plotted as erosion resistance, defined as 1/E in units of g/mm^3, versus H. Finnie (Ref 4) noted that the deviation of points for body-centered (bcc) metals (iron, molybdenum, and tungsten) and steels was not surprising in view of the use of annealed static hardness values. In this regard, Finnie *et al.* (Ref 10) found that increasing H by cold working a metal has essentially no effect on E. It is commonly believed that this is because the surface reaches saturation work hardening during steady-state erosion. A more recent study by Goretta *et al.* (Ref 11) of the effect of cold rolling on erosion of pure copper, nickel, and type 304 stainless steel found that E changed by about 10 to 30% with cold work, but always by an amount significantly les than the change of H. Depending on the metal, α, and the amount of cold work, E either increased or decreased with H. From a practical point of view, cold work is clearly not a reliable method for improving crosion resistance.

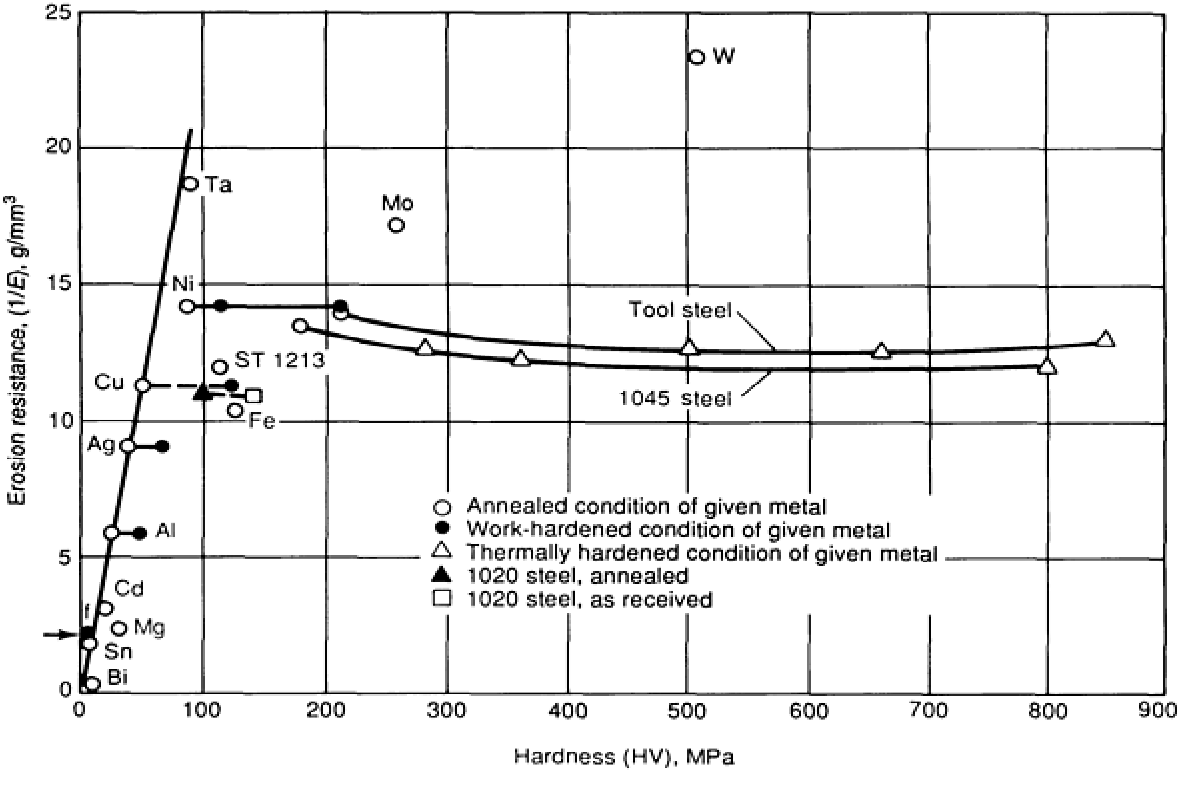

Fig. 4 Plot of erosion resistance versus static hardness for selected materials. Erosion was generated by 60-mesh or 250 μm SiC impinging at the surface at an angle of 20° with a velocity of 76 m/s (250 ft/s). Source: Ref 10

Mechanisms. Solid particles impacting metals form plastic impact craters and displace material. It has been shown that single impacts of spheres remove no material except above a rather high critical velocity (Ref 12) and that single, angular particle impacts remove material only for a small fraction of the possible particle orientations (Ref 13, 14). In the great majority of cases, direct material removal does not occur, but a lip of material remains attached at the end of the crater. Examples of the surfaces of pure nickel specimens eroded to steady state of 20° and 90° are included in Fig. 5; these are typical of the eroded surfaces of metals. Displaced lips of material are clearly visible at the ends of some impact creates on the surface eroded at 20°. As noted by Hutchings (Ref 15) and many other authors, including Finnie *et al.* (Ref 16), such lips are probably vulnerable to later direct removal or to being pushed back into the surface and becoming and extruded platelet that may eventually be removed by ductile fracture or other mechanisms (Ref 16). Finnie (Ref 7, 8) also noted that in order to account for the fact that the actual erosion rate is much lower than that predicted, it is necessary to assume that only a small fraction of the particles cut in the idealized manner, probably because additional impacts are needed to remove the material displaced to the end of the crater (Ref 16).

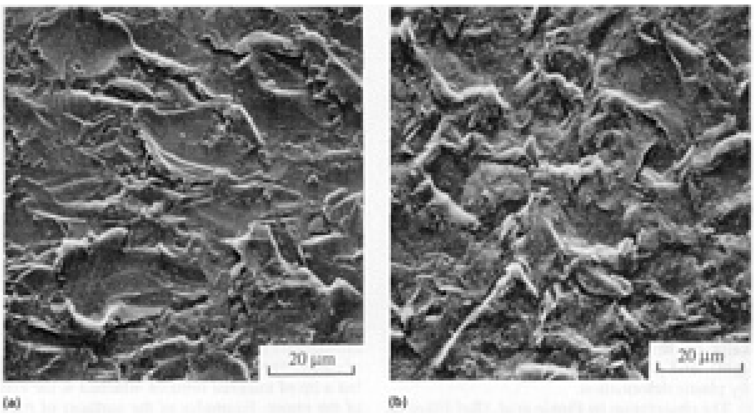

Fig. 5 Typical surfaces of ductile commercial-purity nickel eroded by 130 μm Al_2O_3 at two angles of incidence. (a) 20°. (b) 90°. Erodent velocity was 53.8 m/s (177 ft/s). Source: Ref 40

Finnie (Ref 17) described observations by Mayville (Ref 18) of the same surface area after successive impacts during normal impact erosion of copper and aluminum by SiC. Material removal typically involved the flattening of a protrusion into a platelike particle that was removed by one or two impacts. Typically, the volume removed per particle was smaller than the crater volume by a factor of about 200, emphasizing the multiple-impact nature of normal-impact material removal. Finnie *et al.* (Ref 16) described the mechanism of material removal for normal-incidence erosion of metals by angular particles as "a continuous 'battering' of the surface, leading to removal when extrusion of vulnerable material leads to a ductile fracture."

One of the most widely quoted studies on erosion mechanisms in metals is that of Bellman and Levy (Ref 19), who extended the sequential observation technique to include erosion at glancing angles of incidence. These authors provided convincing experimental evidence that one mechanism of material removal during erosion involves the deformation of surface material into thin platelets by repeated impacts. These eventually become detached and would be expected to form thin platelike debris particles. Figure 6 shows a series of micrographs of erosion of 7075-T6 aluminum at 30° with SiC at 30.5 m/s (100 ft/s) (Ref 19). The initial large crater in Fig. 6(a) is struck by another particle, forming a large platelet that covers the left of the crater in Fig. 6(b) and 6(c). The platelet is finally removed in Fig. 6(d). Platelets observed by Bellman and Levy were generally approximately equiaxed in the plane of the platelets. Many were considerably smaller than the average crater dimensions, although some were comparable to the crater size.

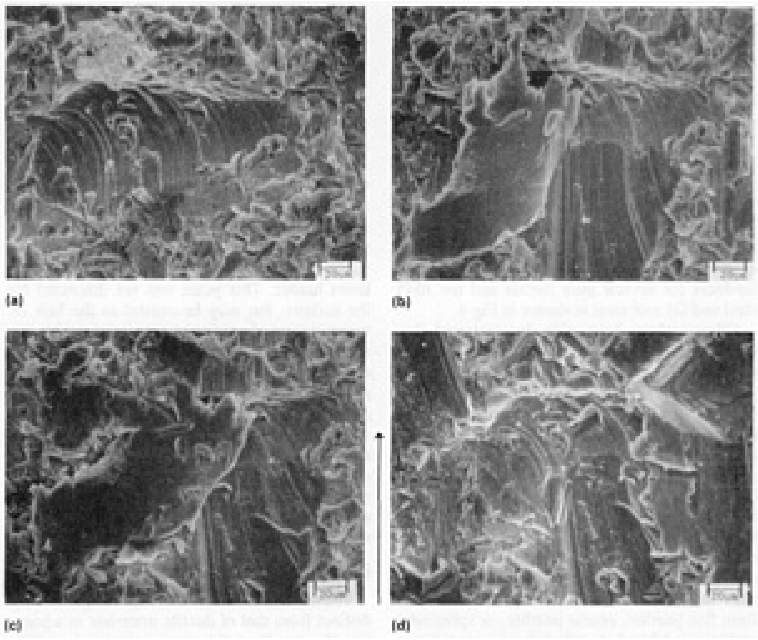

Fig. 6 Micrographs showing sequential erosion of 7075-T6 aluminum by SiC at a 30° angle of incidence with a particle velocity of 30.5 m/s (100 ft/s). The arrow indicates the direction of erodent particles projected onto the surface. See text for details. Source: Ref 19

Bellman and Levy (Ref 19, 20) believed that platelet formation is the primary and probably the only mechanism of material removal. They presented evidence (Ref 19) that part of an evaporated gold film was still present after a glancing impact, and Levy (Ref 20) showed that a glancing impact failed to remove a thin electroplated layer of copper on a steel specimen, suggesting that direct material removal by micromachining does not occur even at low angles of incidence. However, erosion debris particle studies (Ref 21, 22) indicate that micromachining is an operative mechanism at low α, although they do not permit a sufficiently accurate estimation of the relative importance of micromachining and platelet mechanisms.

The platelet mechanism has been summarized by Levy (Ref 23). One aspect of the model that has not been widely accepted is the assertion that surface temperature rise due to erosion leads to softening of the near-surface region, so that a layer of work-hardened material beneath this acts as an anvil against which the softer material is deformed. This aspect of the platelet mechanism was later considered by Hutchings and Levy (Ref 24), who estimated the temperature rise and considered published evidence for and against softening. They concluded that it was not necessary to postulate a thermally softened surface layer as an essential feature of the erosion mechanism under all conditions.

The platelet mechanism of erosion (Ref 23) has not been modeled quantitatively so as to make it possible to predict velocity exponents, the variation of E with α, H, or ductile fracture properties. The simple impact model of Finnie (Ref 7, 8, 9), which quantitative, also has shortcomings, particularly the prediction of zero erosion at 90° and the many observations that E is often not inversely proportional to H. Bitter (Ref 25, 26) offered a model that used the energy per unit volume required to remove material to characterize erosion. This model separated erosion into cutting and deformation wear, with the former peaking at about 20° incidence and the latter at 90°. The shapes of the E versus α curves for cutting and deformation modes are similar to those illustrated in Fig. 1 for ductile and brittle materials, respectively. Neilson and Gilchrist (Ref 27) used the same general approach to show that the E versus α curves of many materials could be fit by assuming the appropriate ratios of deformation and cutting energies per unit volume of material removed. Although these models suggest that different materials removal mechanisms predominate at 20° and 90°, neither theory offers clear mechanisms for either cutting or deformation wear. The platelet mechanism may be the predominant 90° removal mechanism for metals, and micromachining may predominate at low angles of incidence, but there is clearly not general agreement in the literature on these questions. Morrison *et al.* (Ref 28) argue that because velocity exponent, particle size effect, and surface features are similar for all angles of incidence, a single mechanism of erosion is appropriate at all angles of incidence. They consider that indentation, plowing, and cutting types of events, all of which involve similar plastic deformation behavior, occur at all angles, and the variation of the removal and nonremoval events with angle determines E versus α.

Particle Shape. Considerable work has been done on erosion by spherical particles, partly as an idealized case that is easier to analyze than angular particle impact and erosion. Computer models (Ref 12, 29, 30, 31) provide good agreement for rebound velocities and crater dimensions formed by single impacts. Steady-state erosion by spherical particles apparently generally develops a "hill and valley" surface topography, with the "mogul" spacing being significantly greater than single-impact dimensions. This is significantly different from the surface topography produced by angular particles. Brown *et al.* (Ref 32) found that material removal occurred both by plowing deformation on the sides of the hills and by removal of flakes of material from the valleys. Considerable embedding of glass was observed to play a role in material removal in the valleys, with a glass/metal composite layer being formed, and recrystallization also played a role.

As might be expected, angular particles give higher erosion rates than spheres. For example, Maji and Sheldon (Ref 33) observed increases of 70°, 20 m/s (65 ft/s) erosion of 6061-T6 aluminum by about a factor of 5 for 270 μm angular hardened steel grit compared with spherical shot of the same size, and also showed that fragmentation of the spherical shot caused a significant increased of *E*. The degree of angularity of angular particles is also important. Methods of quantifying angularity by means of image analysis, and is effect on *E*, have been discussed by Bahadur and Badruddin (Ref 34), who found that *E* increased by about a factor of 2 to 3 with angularity, which is found to vary with grit size.

Embedding of Erodent Fragments. The influence of embedding of fragments of the erosive particles in the specimen surface is in some cases considerable. Edington and Wright (Ref 35, 36) showed evidence of embedding of particle fragments in Stellite 6B to form a continuous surface layer. Similar observations were made by Ruff *et al.* (Ref 37, 38) for Al_2O_3 erosion of copper and by Kosel *et al.* (Ref 39, 40) for Al_2O_3 erosion of nickel. The work of both Edington and Wright (Ref 35, 36) and Kosel *et al.* (Ref 39, 40) showed that normal-incidence erosion produced a continuous composite surface layer, consisting of particle fragments mixed with the eroded metal, which is actually self supporting when the underlying substrate is electropolished away. The observations of Kosel *et al.* (Ref 39, 40) using Auger spectroscopy showed that the outermost surface contained only about 10% metal for nickel eroded by 400-grit Al_2O_3 at normal incidence and 53 m/s (175 ft/s). Observation by transmission electron microscopy (TEM) showed that the Al_2O_3 particle size was only on the order of 0.1 μm, compared with 23 μm for the incident particles, indicating that embedded fragments were subsequently refragmented by further impacts. 100-grit Al_2O_3 produced a discontinuous composite layer at normal incidence and 53 m/s (175 ft/s), but generated a continuous layer when the velocity was reduced to reduce the initial crater size. Both Kosel *et al.* (Ref 39, 40) and Ives and Ruff (Ref 37) described qualitative models for material removal under conditions giving rise to a continuous embedded layer in which incident particles never impinge directly on the substrate metal.

Particle Size. The size of erodent particles has little or no effect on the erosion rate of ductile materials as long as the particle size is above about 100 μm, but the erosion rate decreases rapidly with decreasing particle size below 100 μm. This fact, known as the size effect, is also found in abrasive wear. Misra and Finnie (Ref 41) discussed the many theories that have been suggested to explain this effect and concluded that it is probably due to an actual increase in the flow stress with decreasing indentation size. Evidence for this has been presented by Gane and Cox (Ref 42, 43), who performed microhardness indentation tests. Some recent studies have found that *E* is not always constant for particle sizes above approximately 100 μm. For instance, Liebhard and Levy (Ref 44) found that *E* became constant for SiC sizes above 200 μm at 20 m/s (65 ft/s) on 1018 steel, but continued to rise even up to 850 μm particle sizes for 60 m/s (195 ft/s) erosion of the same material.

Particle Hardness. The hardness of the erodent particles relative to the material being eroded is an important, often overlooked, factor in erosion. As in the case of abrasive wear (Ref 45, 46), it was found by Wellinger and Uetz (Ref 47) that the erosion rate drops dramatically when particle hardness decreases below that of the material being eroded. This and other similarities between erosive and abrasive wear have been discussed by Misra and Finnie (Ref 41). As noted by Finnie (Ref 17), it is quite possible that the observation that (as will be discussed later) heat treatment of steels appears to have almost no effect on their erosion resistance may be partially due to the use of hard particles such as SiC and Al_2O_3 in most previous work.

Particle Flux. Impact models predict no effect of erodent particle flux on erosion, because only one particle is considered. Anand *et al.* (Ref 48) have demonstrated that because of interference of rebounding particles with incident particles, the surface is effectively shielded--the result being that *E* decreases exponentially with increasing flux. For example, in the case of 1018 steel eroded with 63 μm Al_2O_3 at 90° and 50 m/s (165 ft/s), the erosion rate with a feed rate of 5 g/min (0.18 oz/min) in a 3.2 mm ($\frac{1}{8}$ in.) diam nozzle is reduced by 10% due to this effect. The effect increases with decreasing velocity or particle size and depends on material through the effect of rebound velocity, which affects the time during which the rebounding particles shield the surface.

Temperature. The influence of temperature on erosion (in the absence of complications caused by corrosion) is not as simple as might be expected on the basis of decreasing yield strength with increasing temperature. Sundararajan (Ref 49) has reviewed this area; in some cases *E* increases with temperature, while in others it decreases. Some data are included in Fig. 2 and 3.

Erosion of Steels

Erosion of steels is treated separately, because although the hardness of steels can be dramatically increased by heat treatment, there is no evidence that this improves erosion resistance. The accompanying decrease of tensile ductility might also be expected to cause a shift to more brittle behavior. Finnie (Ref 50) found that the erosion rate of 1055 steel by 250 μm SiC peaks at about 25° in the ferrite plus pearlite condition, but at 90° for the same steel in the martensitic condition, using 250 μm SiC at 107 m/s (350 ft/s). Other authors (Ref 51, 52) have found no effect of heat treatment on the shape of the *E* versus α curve for 36 μm Al_2O_3. This could possibly be due to the use of larger particles in Finnie's study (Ref 50), since Sheldon and Finnie (Ref 53) showed that the *E* versus α curve of a hardened tool steel shifted from a shape intermediate between brittle and ductile materials with approximately 125 μm SiC to a clearly ductile shape with a maximum at 20° with approximately 9 μm SiC. Similar behavior was also found for MgO and plate glass, and with 9 μm particles the surface ripple pattern characteristic of ductile metals (Ref 54) occurs at low α even for MgO and glass. The ductile behavior of brittle materials with small particles is probably directly connected to the fact that below a critical load and indentation depth, cracks are not formed in Vickers microhardness tests on ceramics. This effect is known to occur in abrasion as well. It is not clear whether the 30 μm Al_2O_3 used by Sargent *et al.* (Ref 51) and Peterson *et al.* (Ref 52) should be small enough to cause the transition to ductile behavior, but the latter authors searched for and found no evidence of brittle behavior of martensite.

The most important theoretical and technological aspect of erosion of steels is that several authors have demonstrated that the erosion rate at fixed α is nearly independent of hardness in individual steels, contrary to Finnie's theory (Ref 7, 8, 9). For example, the plot given by Finnie *et al.* (Ref 10) for 20° erosion resistance versus hardness for several pure metals and for 1045 steel and O1 tool steel is shown in Fig. 4.

Other authors have also demonstrated that hardness has little effect on erosion resistance in a given steel and that *E* sometimes increases slightly with *H.* The results of Sargent *et al.* (Ref 51) indicated very little effect of hardness at any impact angle. Salik and Buckley (Ref 55) found almost no effect of hardness on erosion for 1045 steel eroded by fine ($\sim$100 μm) crushed glass at 90° incidence. These authors did find a very substantial increase in erosion resistance at the highest hardness level, using 15 μm glass beads, but not with crushed glass. This may be an affect unique to spherical particles. Levy and Jahanmir (Ref 56) found that 1075 steel heat treated to form fine pearlite, coarse pearlite, or spheroidal carbides exhibited ductile behavior and that a slight increase in erosion occured with increasing hardness.

Zhu and Mao (Ref 57) studied erosion of steels and three WC cemented carbides by particles with hardnesses in the range of 90 to 2500 HV. A steel equivalent to 4140 was tested in the annealed condition (254 HV) and two quenched and tempered conditions (464 and 642 HV), and a high-speed tool steel was tested in the annealed (289 HV) and quenched (923 HV) conditions. In general, soft erodents produced maximum erosion rates at or near 90°, while erodents significantly harder than the target produced maximum erosion at low angles. The 4140 and tool steels showed only about 10% variation in *E* with hardness for SiC ($\sim$2500 HV), Al_2O_3 ($\sim$2200 HV), and SiO_2 ($\sim$1350 HV). However, with angular glass ($\sim$500 HV) erodent, the 15°, 65 m/s (210 ft/s) erosion rate of the 4140 steel decreased from about 0.41 to 0.25 mg/g due to hardening, and for the tool steel *E* decreased from about 0.28 to 0.08 mg/g upon hardening. The hard erodents produced typical features suggesting micromachining at low α, while the soft erodents produced surface deformation without clearly defined grooves.

Peterson *et al.* (Ref 52) studied erosion of 1078 and 10105 steels in spheroidized, pearlitic, tempered, and untempered martensitic conditions, with *H* ranging from 163 to 775 HV. Velocities from 40 to 100 m/s (130 to 330 ft/s) and angles from 15° to 90° were used, with 240-grit (36 μm) Al_2O_3. The peak erosion rate was about 40° at 40 m/s (130 ft/s), but increased to near 90° at 100 m/s (330 ft/s). *E* was essentially independent of *H* at 40° and increased somewhat with *H* at 90°. Surface features indicated ductile displacement of material for all microstructures, including untempered martensite, and no evidence of subsurface cracking was found in cross sections. There was remarkably little difference between micrographs of spheroidized and untempered martensitic 10105 steel at 90° incidence, either in general appearance or in mean crater dimensions. The latter is consistent with the observation of similar erosion rates (0.14 and 0.24 mg/g, respectively), but is clearly not consistent with impact theories, which would predict much smaller crater dimensions for the martensitic microstructure because it was 4.4 times harder. This point was not discussed by the authors, but may be central to the lack of improvement of erosion resistance of steels with *H.* Because there is no evidence of different

response in terms of brittle versus ductile fracture, the material removal rate would be expected to be essentially proportional to crater volume. Some unpublished work by Liang and Kosel (Ref 58) has shown that the dynamic hardness of 1080 steel does not increase as rapidly as static hardness, but that the difference is not sufficient to explain the lack of change of erosion rate.

Erosion of Ceramics

The erosion of brittle materials is significantly distinct from that of ductile materials in a number of ways. First, the erosion rate peaks at 90°, as indicated in Fig. 1. The mechanism of material removal is also markedly different, involving cracks initiated by brittle fracture, at least for normal-incidence erosion. The influence of erodent particle size on erosion is also different in brittle materials.

The erosion behavior of ceramic materials has been reviewed by Ruff and Wiederhorn (Ref 59), Wiederhorn (Ref 60), Evans (Ref 61), and, most recently, Routbort and Scattergood (Ref 62). A book on the subject is also in press (Ref 63). It is well established that erosion of ceramics involves formation and propagation of cracks to generate chips of material. Most authors quote the work of Lawn and Wilshaw (Ref 64), who showed that during static indentations, radial ("penny") cracks and/or conical (Hertzian) cracks form during loading, whereas lateral vent cracks form during unloading. Hertzian cone cracks, in which the cone vertex lies at or near the surface, are the only cracks formed by spherical or blunt particles at low impact velocities (Ref 59). Erosion of glass by spherical glass beads was studied by Mehrotra *et al.* (Ref 65), who found that material removal proceeds initially by interaction of cone cracks and later by chipping. Sharp or angular particles generally produce radial cracks, which lie perpendicular to the surface and are semicircular in shape, and which form during loading. Upon unloading, the stresses generated by the plastically compressed zone cause the formation of lateral vent cracks approximately parallel to the surface. These initiate beneath the indentation and travel upward to the surface, resulting in material removal from the surface. In contrast, radial cracks alone cannot result in material removal, although they are often intersected by subsurface lateral vents, giving rise to removal of pie-shaped wedges of material. Such behavior was observed in MgO, for instance, by Rickerby and Macmillan (Ref 29). Radial cracks, being approximately perpendicular to the surface, reduce the strength of the ceramic by acting as preexisting flaws. Figure 7 shows an example of a single impact crater on sapphire in which material removal by a large semicircular lateral vent crack is evident.

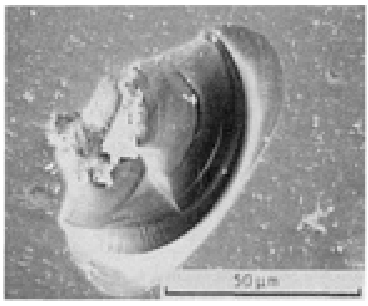

Fig. 7 Surface damage in sapphire (Al_2O_3) produced by 90° impact of 405 μm SiC particles traveling at a velocity of 90/ms (300 ft/s). Note material removed by the extension of a large semicircular lateral vent crack. Source: Ref 73

Considerable evidence for plastic deformation in nominally brittle ceramics has been presented by Hockey *et al.* (Ref 66), who used TEM to observe the dislocation structures beneath impact craters in MgO, silicon, SiC, and Al_2O_3. Such plasticity is probably due largely to the compressive component of the stress field below the impacting particle. High dislocation densities were observed in all cases, although the relative extents of the dislocation damage and crack propagation compared with the indentation size varied with the material.

At low angles of incidence, angular particles still produce high dislocation densities, and surface observations show that plastic displacement of material occurs in a similar manner to that in ductile materials (Ref 59). The extent of cracking is greatly reduced, and it may be that plastic deformation is of primary importance in erosion at glancing in incidence. In some instances, TEM observations (Ref 66) showed dislocation tangles without evidence of cracking for 15° incidence of single particles. Steady-state surfaces showed considerable evidence of plowing, with only minor cracking along the edges of the furrows. It is interesting to note in this context that Shetty *et al.* (Ref 67) observed the formation of

continuous micromachining chips from large M_7C_3 carbides in Stellite alloys during scratch tests with hard particles, again indicating the role of plasticity in wear of brittle phases.

Two major elastic-plastic theories of erosion have been developed. The theory by Evans *et al.* (Ref 61, 68) includes the effects of elastic waves generated by the impacting particle, as well as plastic waves. The theory of Wiederhorn *et al.* (Ref 59, 60, 69) assumes that dynamic effects may be neglected and that the particle penetration depth is determined by equating the plastic work done to the incident kinetic energy of the particle. The erosion rate predicted by Evans *et al.* is given by:

$$E \propto v_0^{3.2} d^{2/3} \rho^{1.3} K_{\mathrm{Ic}}^{-4.3} H^{-0.25} \quad \textbf{(Eq 2)}$$

while that predicted by Wiederhorn *et al.* is:

$$E \propto v_0^{2.4} d^{2/3} \rho^{1.2} K_{\mathrm{Ic}}^{-4.3} H^{0.11} \quad \textbf{(Eq 3)}$$

where v_0, d, and ρ are particle velocity, diameter, and density, respectively, H is material hardness, and K_{Ic} is material toughness (Ref 59, 60). It should be noted that the above expressions are valid when E is in units of mass or volume loss per unit mass impacted, as most experimental data are given in this form. The original theories were formulated in terms of material loss per impact, and because the mass per particle is proportional to d^3. the particle size dependence in these units is $d^{1\ 1/3}$ (Ref 62). The models can be used to predict E for $\alpha \neq 90°$ by using the normal component of velocity, $v \cdot \sin \alpha$ (Ref 66), and particle size and velocity thresholds can be included by replacing d by ($d - d_0$) and v by ($v - v_0$) (Ref 70).

Studies of single crystals or glass permit assessment of the theories without microstructural complications (Ref 62). Routbort *et al.* (Ref 70) studied erosion of silicon single crystals and found that, as shown in Fig. 8, E versus $v \cdot \sin \alpha$ gives the same value and velocity exponent except for low α. Similar results were observed for other ceramics in other studies. This effect was attributed to plasticity at low α, but Srinivasan and Scattergood (Ref 71) showed that it could be accounted for by greater crack extension at low α due to changes in stress distribution. Velocity exponent is found to decrease with increasing particle size, as indicated by the data points in Fig. 9. This is not explained by existing erosion models (Ref 62), whose predictions are indicated by the dotted lines, but may be due to greater temperature rise for larger particles (Ref 72) or to particle blunting and fragmentation (Ref 73, 74). Little work has been done to test the prediction that E is proportional to $d^{2/3}$, but work on silicon is in agreement with this (Ref 70).

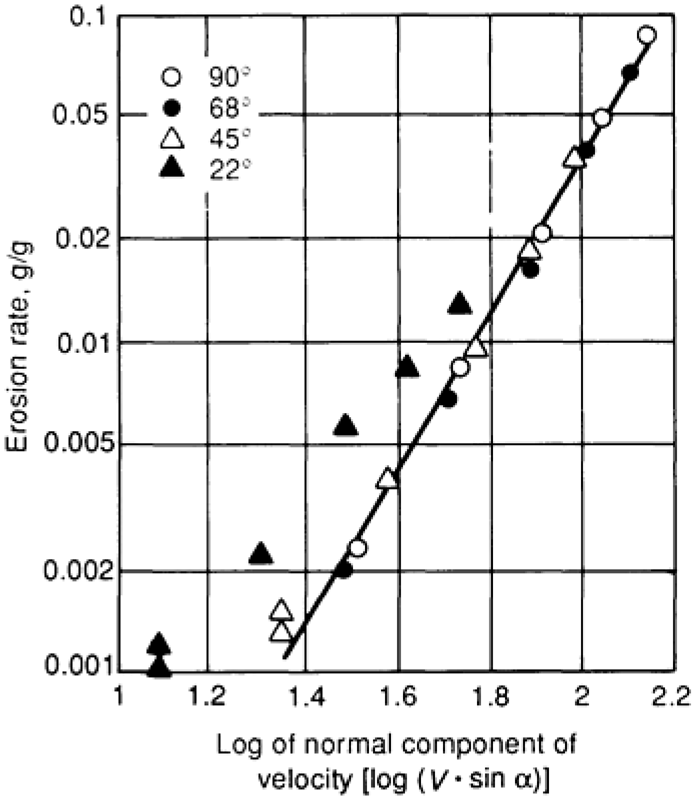

Fig. 8 Plot of erosion rate versus the normal component of velocity ($v \cdot \sin \alpha$) for a (111) silicon single crystal as a function of angles of incidence. Al_2O_3 erodent particle size was 390 μm. Source: Ref 62

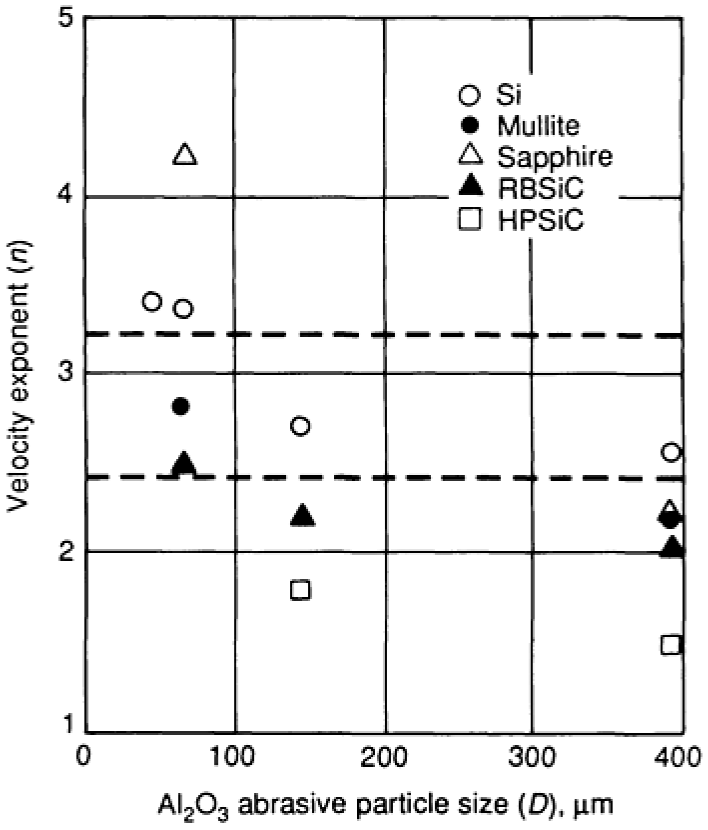

Fig. 9 Plot of velocity exponent versus Al_2O_3 particle size for selected ceramics. Source: Ref 62

Erosion of conventional ceramics (Al_2O_3, SiC, Si_3N_4) is also in general agreement with the models in most cases. The velocity exponent is lower for softer Al_2O_3 erodent than SiC because of the low particle-to-target hardness ratio; no cracks form in these ceramics when eroded by Al_2O_3 (Ref 75). Studies of Al_2O_3 by Ritter *et al.* (Ref 76, 77, 78, 79, 80) reveal that for large-grained material, grain ejection can occur with very irregular radial crack patterns. Although it might be expected that toughened partially stabilized zirconia (PSZ) would give improved erosion resistance, after an initial improvement E saturates and becomes nearly independent of K_{Ic} (Ref 81). A number of studies of ceramics toughened by addition of ceramic whiskers have been reviewed by Routbort and Scattergood (Ref 62). Improvements of erosion resistance have been obtained, but are not always in agreement with the $K_{Ic}^{-4/3}$ prediction of the models. Additional factors suggested as important in erosion of ceramics are (Ref 62) erodent fragmentation and *R*-curve effects (the dependence of crack growth resistance on crack size).

Particle Hardness. For quartz (~1100 HV), which is the hardest constituent of most minerals, the erosion rates of ceramics can be much lower than for Al_2O_3 (~2000 HV). Gulden (Ref 82, 83) studied erosion of reaction-bonded (RB) and hot-pressed (HP) Si_3N_4, glass-bonded Al_2O_3, and MgF_2. Hot-pressed Si_3N_4 was eroded by both SiC (~2500 HV) and quartz, and for a given combination of particle size and velocity, E was two orders of magnitude lower for the softer quartz erodent. Scanning electron microscopy (SEM) studies of single impacts also showed very small indentation for quartz, with none of the material removal by lateral fracture which occurred for SiC particles, so that the impact damage dimensions shown for comparable velocity and particle size was about 100 times smaller for quartz. Routbort *et al.* (Ref 84) compared erosion rates of three whisker-reinforced ceramic-matrix composites with matrices of Al_2O_3, Si_3N_4, and stabilized ZrO_2 by four erodents. Increases of E by factors of 10 to 20 were observed for SiC erodent (~2500 HV) compared with Al_2O_3/ZrO_2 (~1500 HV). In simple terms, erosion by particles softer than a ceramic target is expected to deform the particle as well as the target. Murugesh and Scattergood (Ref 73) recently studied erosion of several grades of Al_2O_3, including sapphire, by SiC and Al_2O_3. The harder erodent typically gave higher erosion r0ates by factors of only 2 to 4, and there was not a major increase of erosion rate for $H_p/H_t > 1$, although values much less than 1 were not investigated. The results were interpreted in terms of a model for erodent fragmentation, which can reduce E by particle blunting.

From a design standpoint, the important point is that particles encountered in practice are often significantly softer than ceramics, and if this is the case in a particular application, use of ceramics could be very beneficial if permitted by other design requirement such as toughness and conductivity. Ceramic coatings applied by various techniques can also offer significant advantages, provided they are thick enough to survive the service life of the component and to confine impact damage within the coating. Thermal expansion mismatch problems must also be avoided.

Erosion of Coarse Two-Phase Microstructure

This section will discuss erosion of alloys with coarse, nominally two-phase microstructures in which the second-phase particles (SPPs) are typically large compared with the dimensions of the damage zone created by the impact of one particle. Many other alloys that have multiple phases, such as steels and precipitation-hardened alloys, can be treated as though they were homogeneous, because the impact damage occurs over dimensions large compared with the microstructure.

Given the many similarities between erosion and abrasion (Ref 85), highly abrasion-resistant materials, such as white cast irons and the Stellite alloys, might be expected to exhibit high erosion resistance. Ideally, one might hope to combine the relatively good erosion resistance of a hard ceramic phase with the desirable ductility and toughness of a metal by choosing an alloy with a ductile metallic matrix and hard SPPs, such as carbides. However, as discussed recently by Kosel and Ahmed (Ref 86), this is rarely the case, due to the synergistic increase of the erosion rate of a hard, brittle phase by its presence as a dispersed phase in a relatively soft matrix.

Aptekar and Kosel (Ref 87) studied erosion of high-Cr/Mo white cast irons and Stellite alloys by angular Al_2O_3 and by both angular and rounded quartz particles. Because quartz is softer than the carbides in the alloys, while Al_2O_3 is of comparable hardness, quartz does not cut the carbides directly during abrasion (Ref 88, 89, 90), while Al_2O_3 does so quite readily, leading to a reduction of abrasion rate by a factor of about 25 for quartz compared with Al_2O_3 on Stellite. However, the reduction of erosion rate for quartz compared with Al_2O_3 was only about a factor of two at most (Ref 87). E also increased with second-phase volume fraction (SPVF) for both Al_2O_3 and crushed quartz, demonstrating that the SPPs

could actually be detrimental to erosion resistance. The erosion rate of white cast iron by crushed quartz was a higher than that of annealed 1020 steel, and the large primary carbides were deeply depressed below the surface.

The failure of large carbides to improve erosion resistance led to a study by Kosel and Aptekar (Ref 91) of erosion of model alloys consisting of Al_2O_3 or WC/W_2 CSPPs dispersed in a matrix of pure copper. *E* typically increased rather than decreased with SPVF, even when *E* was 20 to 80 times lower for a flat plate of the ceramic phase than pure copper. Variations of *E* and SPP protrusion with SPP size and with erodent particle velocity and size were consistent with the edge-effect concept described more fully below.

The edge effects refers to the increase of *E* for a ceramic due to easy fracture at SPP edges. If a large, flat plate of ceramic is eroded, its edges become rounded to a steady-state width, *W,* from the original edge, but the removal rate of the interior of the plate is unaffected. However, if the width of the plate is less than 2*W,* the entire surface of the plate is subject to easy chipping, and erosion rate increases over that for an infinite plate by an amount that increases with decreasing plate width or increasing *W.* Figure 10 illustrates a narrow plate of width *d,* or a rod of diameter d_r, eroded from the top at α= 90°. The two curves show the superposition of a hypothetical shape of steady-state rounding to a width *W* for a semi-infinite plate eroded under the same erosion conditions. When the material attempts to round to width *W,* a sharp cusp will result if $d < 2W$, but the cusp will be subject to easy fracture, with the result that no steady-state shape exists and *E* is increased. If *W* increases or *d* decreases, *E* increases further. For SPPs larger than $d_{SPP} = 2W$, the edge effect should vanish and the second phase should retain its high inherent erosion resistance. *W* increases with the size of chips generated by impacting particles and therefore with the kinetic energy of the particles, and as *W* increases, the magnitude of the edge effect increases.

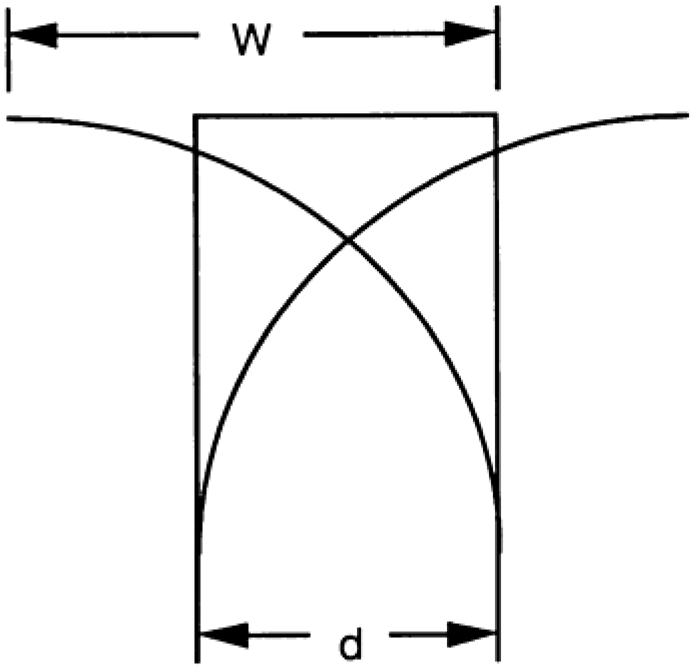

Fig. 10 Schematic showing square edge of a plate, *d,* or end of a rod of diameter d_r, being eroded from the top. Curves show superposition of a steady-state shape of rounding of width *W,* which would occur for the edge of a thick, semi-infinite plate.

Direct evidence for the edge effect was obtained by Ahmed (Ref 92) and Kosel (Ref 93), who eroded glass of a range of diameters with crushed quartz particles of varying size and velocity incident parallel to the rod axis. Flat plates of the same glass were also eroded at normal incidence under the same conditions; in the absence of the edge effect, the ratio of rod to plate erosion rate, E_r/E_p, would be unity. E_r, E_p, and *W* were measured, and it was found that E_r/E_p decreased from values as high as 70 to close to unity as rod diameter increased to about 2*W.* The E_r/E_p results for four velocities and particle sizes also fell on a single curve with a correlation coefficient of 0.93 when plotted against the ratio d_r/W, which characterizes the geometry in Fig. 10.

Related studies were also reviewed by Kosel and Ahmed (Ref 86). According to Ninham and Levy (Ref 94), smaller SPPs are often rendered ineffective by through-thickness fracture rather than the edge effect, and the subsurface SPP fracture is observed (Ref 94, 95, 96) and in some cases produces void nucleation. Kosel and Ahmed (Ref 86) argued that these phenomena are related to the edge effect by the lack of sufficient support offered by a relatively soft matrix.

A study by Rossing and Rocazella (Ref 97) of slurry erosion of alloys with a high volume fraction of large SiC SPPs in a matrix of Al/Al_2O_3 demonstrated that the edge effect is absent for sufficiently mild erosion conditions (Ref 86, 97), so that such materials can approach the erosion resistance of a monolithic ceramic. This is a particularly important result, because it demonstrates that there are erosion condition under which the edge effect can be avoided. The conditions under which the edge effect disappears are predicated by the edge-effect concepts given above. The key is that low-velocity erosion, such as occurs in slurry erosion, generates such small chip dimension at SPP edges that with sufficiently large SPPs, the condition $d_{SPP} > 2W$ can be obtained. Relatively ductile alloys with dispersed ceramic phases can then approach the much higher inherent erosion resistance of ceramics, provided the distance between SPPs is sufficient to prevent their undermining and direct removal.

The edge is also a significant factor in abrasion (Ref 98). However, it is of lower magnitude than in erosion, probably because abrasive particles approach the SPPs tangent to the surface.

WC-Co cermets represent an important class of materials in which the edge effect is not applicable. Erosion of such materials has been studied extensively (Ref 94, 99, 100) because of their generally very high erosion resistance relative to other alloys. These materials typically have very high SPVFs and very small SPPs, and the lack of SPP support by the adjacent matrix is complicated by several factors. The matrix yield strength is significantly higher due to the constraint of adjacent carbides and very small mean free path in the matrix. The carbides are so close that they often touch, creating a carbide "skeleton" that can transmit forces to adjacent carbides, and the carbides in WC-Co cermets are typically so small (1 to 3 μm) that an impacting particle will often contact more than one carbide. The combination of support from the constrained matrix and the carbide network, together with the very high SPVF, is probably responsible for the high erosion resistance of such materials.

Ninham and Levy (Ref 94) found a clear decrease of E with increasing SPVF for quartz erosion of WC-Co, WC-Ni, and related cermets. Anand and Conrad (Ref 100, 101) studied Al_2O_3 erosion of WC-Co and found a transition of the peak erosion angle from 90° to low angles as the scaling of the impact damage zone increased in size from one comparable to the WC grain size to one much larger. This was explained as a transition from brittle to ductile behavior, with brittle fracture of WC in the former case and deformation of the matrix controlling the latter. The erosion rate in the ductile regime was found to be proportional to the square root of the matrix mean free path; for constant WC grain size, this would imply a decrease of E with increasing SPVF. The lateral crack dimensions in pure WC (grain size, 1000 to 3000 μm) was significantly greater than the dimensions of the impact damage site of even the least erosion-resistant cermet under the same impact conditions (Ref 100), suggesting that crack length is limited by the ductile matrix, with impact energy being absorbed more by plastic deformation of cobalt than by fracture of WC.

Erosion / Corrosion

Erosion/corrosion (E/C) refers to the simultaneous, synergistic interactions between SPE and corrosion. In this general sense, discussion should logically include E/C synergism in slurry, cavitation, and liquid erosion, as well as gas-borne particle erosion. The present discussion is limited to the latter area, in which thick scales (oxides, sulfides, and so forth) can develop on metallic substrates, unlike slurry, cavitation, and liquid erosion. The discussion is further limited to E/C of metals.

Much progress has been made on the subject of gas-borne particle E/C of metals within the past several years, and a reasonably complete and generally accepted picture of the important features of the problem is emerging. Many of the details remain under intensive investigation, and the reader is encouraged to consult the current literature to keep abreast of rapid developments in the field. A number of papers on E/C were presented at a recent conference (Ref 102). Although quantitative prediction of E/C rates is impractical, progress has been made toward predicting and understanding divisions between E/C regimes.

Erosion/corrosion is of considerable technical importance in several types of applications, including coal gasification or liquefaction, steam turbines, jet turbines, and in the in-bed evaporator tubes, waterwalls, and convention pass surfaces of FBC systems.

An extensive program on E/C in the high-temperature, high-pressure conditions is coal gasification systems was surveyed by Sorrel (Ref 103). Affected components include cyclones, piping, valves, and heat exchangers. It was found that chromium was the most beneficial alloying element and the E/C rates were typically about two orders of magnitude higher than simple corrosion. Iron, nickel, and their oxides are thermodynamically unstable in the sulfidizing atmosphere, resulting in the formation of nonprotective sulfides that tend to become molten and accelerate attack at the necessary operating temperatures. This situation is the antithesis of the protective oxide scales that appear to offer some promise for other, less sulfidizing applications. The E/C problem in coal gasification pressure vessels is treated by lining the vessels with refractory brick (Ref 104). Much recent E/C research has investigated oxidizing atmospheres in which sulfides are not dominant in the scales, such as coal-fired boilers and gas turbines.

Types of Erosion/Corrosion

In the simplest terms, E/C can be separated into two regimes--dominated by erosion or corrosion, depending on which process occurs at the greater rate under the conditions of interest. For very low corrosion rates and/or highly erosive conditions, erosion dominates and basically pure erosion is expected. For high corrosion rates or mild erosion conditions, corrosion dominates. Between these extremes, important synergistic interactions can increase the metal thickness loss rate significantly beyond that due to either erosion or corrosion alone. It is important to point out that a number of studies (Ref 105, 106, 107, 108, 109, 110, 111) have shown the existence of a maximum E/C rate at an intermediate temperature within the synergistic regime between pure erosion and pure corrosion, while others have shown a rapid rise followed by a leveling, which may indicate that a maximum would exist at a temperature beyond the range investigated. Some examples are given in Fig. 11.

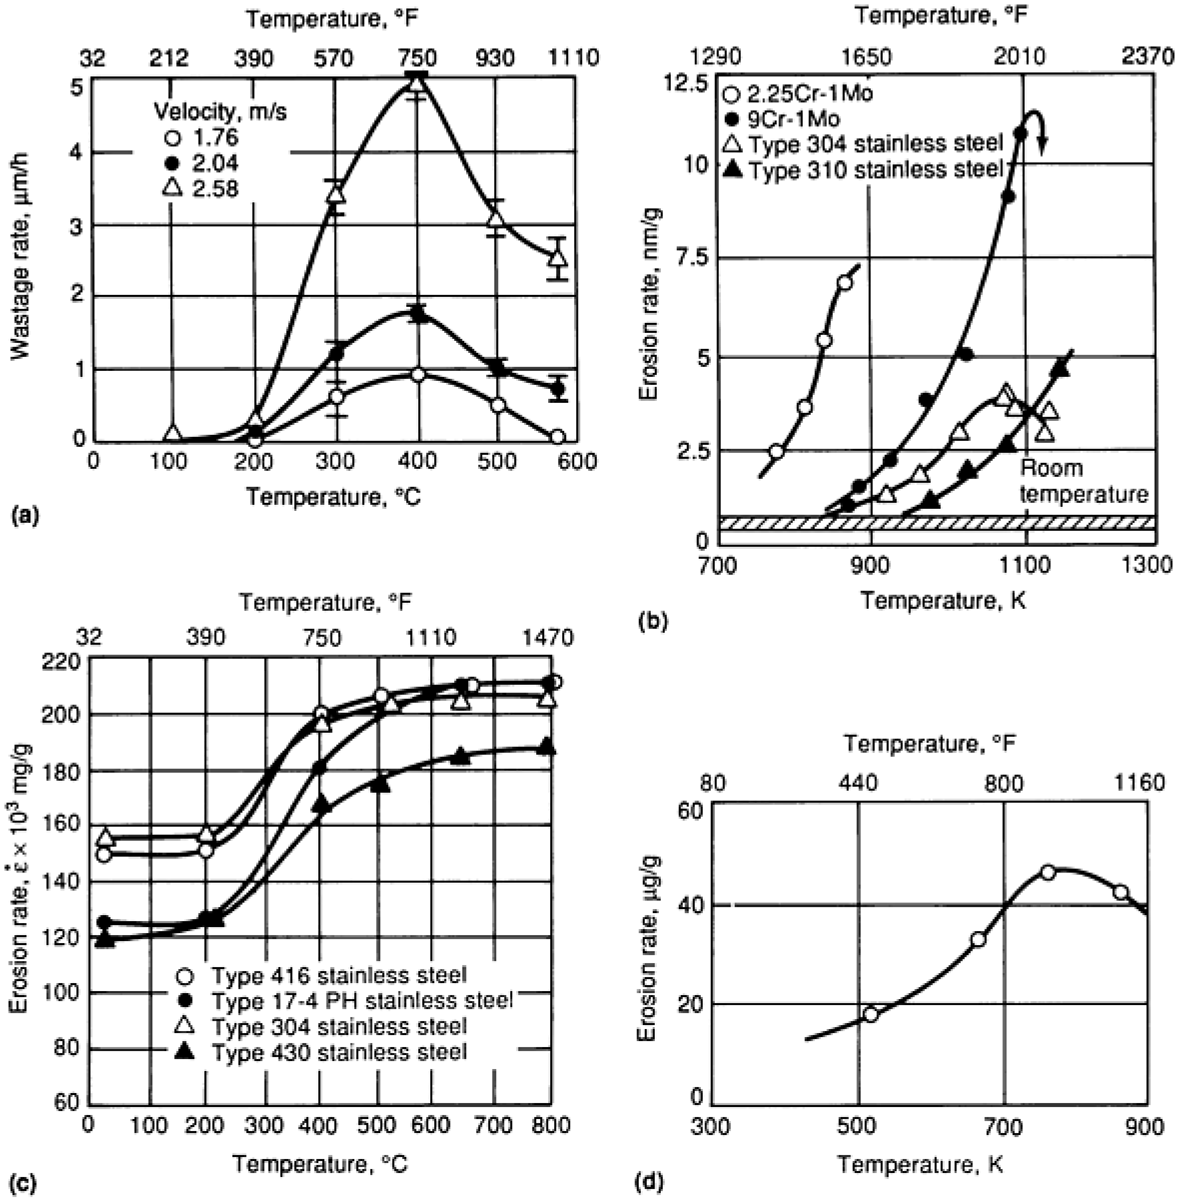

Fig. 11 Typical observed temperatures for maximum E/C rates of selected materials. (a) Fluidized bed combustion E/C of untempered martensitic type 401 stainless steel with 80-mesh alumina as a function of abrasive velocity. (b) Erosion/corrosion of four selected alloys by 1 mm Al_2O_3 particles at 30° angle of incidence and 2.7 m/s (8.9 ft/s) velocity. (c) Erosion/corrosion of selected stainless steels by 120-grit SiC at 30° angle of incidence and 65 m/s (215 ft/s) velocity. (d) Erosion/corrosion of 9Cr-1Mo at an incident angle of 30° and a velocity of 30 m/s (100 ft/s) with 250 μm SiC. Source: Ref 105, 107, 108, 129.

Most authors separate the synergistic regime between pure erosion and pure corrosion into two broad categories: (1) erosion-enhanced corrosion (EEC), in which the dimension of the impact damage zone is confined within a thick scale, and (2) corrosion-affected erosion (CAE), in which the damage zone includes both scale and metal. Erosion-enhanced corrosion causes increased metal thickness loss rates because erosion reduces the scale thickness and therefore increases the corrosion rate, which is controlled by transport of metal or corrosive elements (oxygen, sulfur, and so on). Scale spallation can also be involved. Corrosion-affected erosion often produces a surface composite consisting of intimately intermixed metal, scale, and embedded erodent particle fragments. Although it appears to produce the highest loss rates, the mechanisms of CAE have not yet been fully elucidated. A more detailed discussion of mechanisms and the effects of important variables follows. Note that the concern is always with the *relative* rates of erosion and corrosion, although the erosion component may refer either to erosion of the scale or of the metal substrate. The most logical sequence of increasing severity of corrosion relative to erosion is as follows: (1) erosion, (2) CAE, (3) EEC, and (4) corrosion. An important fact for applications involving E/C is that as temperature increases, the corrosion rate increases, resulting in

progression through the series just described. There is considerable evidence to suggest that the maximum E/C rate (Fig. 11) occurs at the transition between CAE and EEC, with the loss rate decreasing after this because of protection of the metal by the scale.

Rishel *et al.* (Ref 112) extended a previous E/C classification by Kang *et al.* (Ref 113, 114) to include scale spalling. They described the following four categories of E/C, which have been rearranged here in order of increasing corrosion rate. Figure 12 schematically illustrates the different regimes.

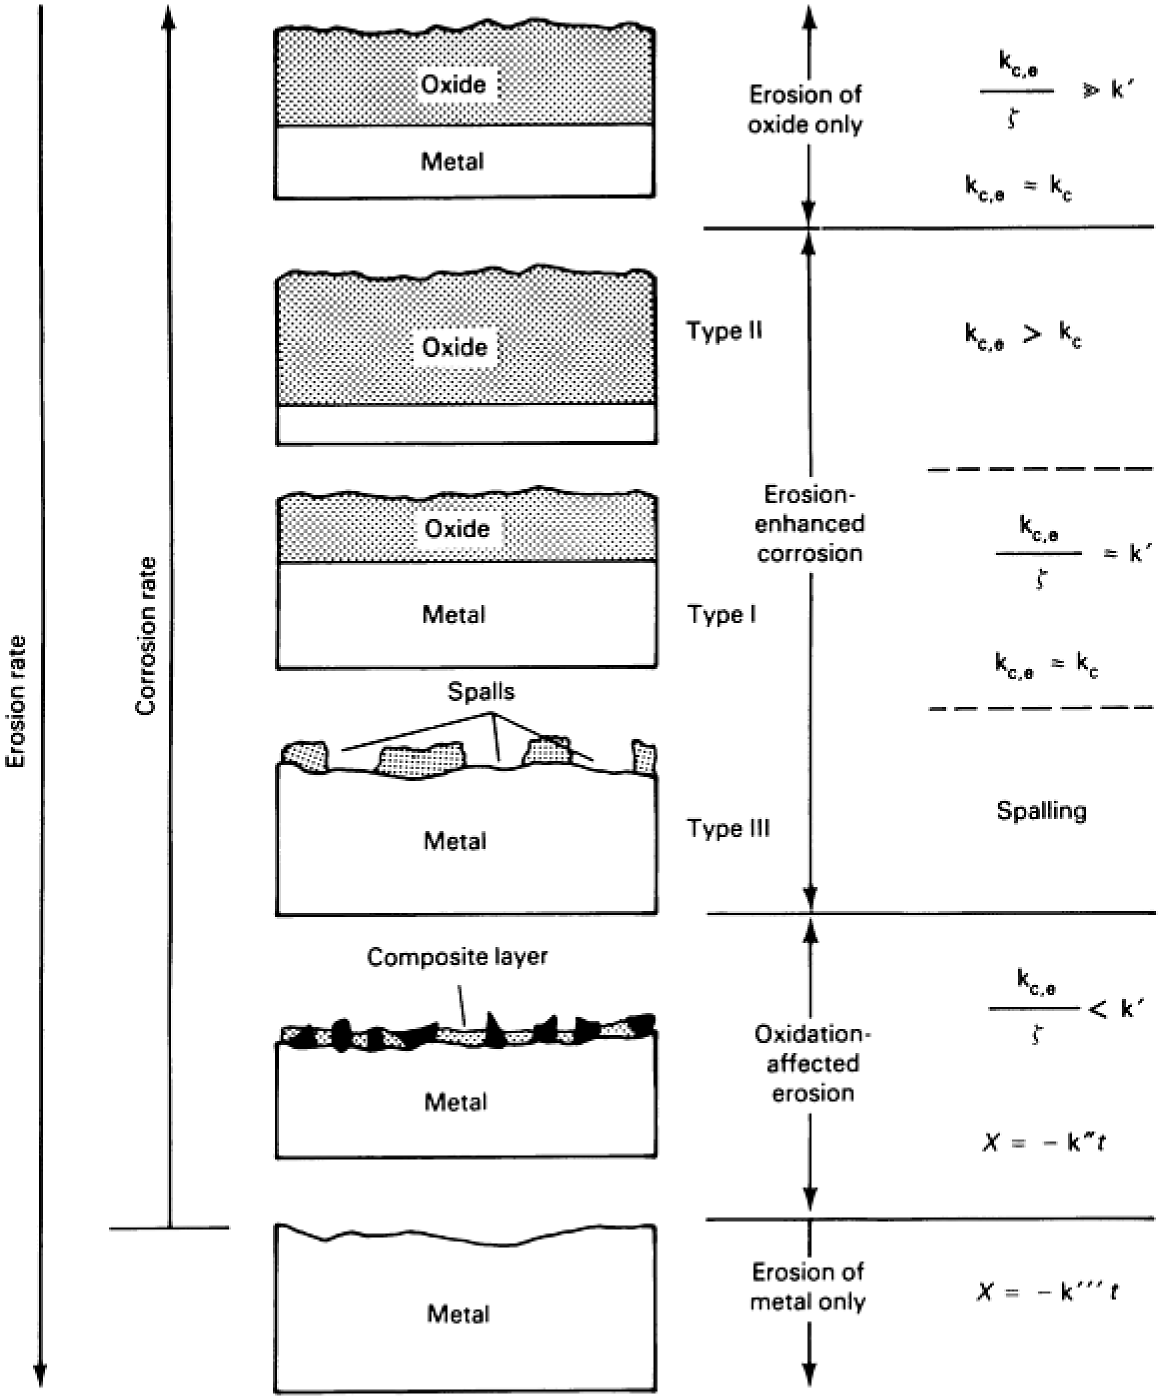

Fig. 12 Erosion/corrosion interaction regimes shown in order of increasing severity of corrosion relative to erosion. Types I, II and III regimes are subdivisions of EEC.

Pure erosion occurs when the corrosion rate is negligible compared with the erosion rate, as in severe erosion conditions (high-velocity, angular particles) or in noncorroding conditions such as an inert gas. In a corrosive gas, this regime would be confined to relatively low temperatures. The mechanisms and phenomenology of erosion of metals discussed earlier apply.

Corrosion-Affected Erosion. With an increased corrosion component, a thin scale is developed, but the dimensions of the stress field introduced by the particles are greater than the scale thickness, so that both scale and metal are deformed. The metal loss rate is increased over that for pure erosion, and a surface composite of metal, scale, and erodent particle fragments is typically produced. The mechanisms by which the E/C synergism increases the metal los rate in this regime appear to be the least fully understood, as discussed later. One likely explanation is that bare metal is repeatedly exposed to corrosion. A parabolic rate equation would predict an infinite initial corrosion rate, but is only applicable after the early stage of scale growth, which is controlled by other mechanisms (Ref 115).

Erosion-enhanced corrosion was broken into three categories. The first two categories involve a steady-state scale thickness, ζ_{ss}, determined by the relative erosion and corrosion rates, and the third involves spalling of the scale.

Metals likely to be of use in high-temperature applications in air or other corrosive atmospheres are those that form protective scales that grow naturally in a state of compression, because the volume of scale formed from a given amount of metal exceeds that of the metal consumed (Ref 115). The compressive stress combats fracture, resulting in a protective scale free of cracks and pores. Scales that form in tension generally crack and are nonprotective. After a short initial stage, protective scale growth is limited by the diffusion of either metal outward or of the oxidant (oxygen, sulfur, halogen) inward through the scale thickness. Because the diffusion gradient is inversely proportional to ζ, scale thickness ζ is often proportional to $t^{0.5}$, referred to as parabolic oxidation. The protective scale growth rate, $d\zeta/dt$, during free corrosion is given by:

$$\frac{d\zeta}{dt} = \frac{k_p}{\zeta} \qquad \textbf{(Eq 4)}$$

where k_p is the parabolic rate constant.

During EEC, if a continuous protective scale is maintained without spalling, scale is removed from the outer surface at a rate k' (which will depend on erosion conditions). The net scale growth rate will then be (Ref 112, 113, 114):

$$\frac{d\zeta}{dt} = \frac{k_{c,e}}{\zeta} - k' \qquad \textbf{(Eq 5)}$$

where k_p has been replaced by $k_{c,e}$, the applicable parabolic rate constant during E/C. A steady-state scale thickness, ζ_{ss}, is possible when $d\zeta/dt = 0$, which gives:

$$\zeta_{ss} = \frac{k_{c,e}}{k'} \qquad \textbf{(Eq 6)}$$

If a specimen is exposed to simultaneous E/C, scale builds up to thickness ζ_{ss}, while if it is preoxidized to a thickness $\zeta > \zeta_{ss}$ and then erosion begins, $d\zeta/dt$ is initially negative and ζ decreases until ζ_{ss} is reached (Ref 112).

Type I EEC was defined by Rishel *et al.* (Ref 112) as the case just described, with $k_{c,e} = k_p$, that is with the scaling rate essentially unaffected by the presence of erosion. Good agreement was found (Ref 112, 116) between literature values of k_p and those calculated from measured values of ζ_{ss} and k', for E/C of Co.

Type II EEC was defined (Ref 112) by $k_{c,e} > k_p$, that is, the case in which the presence of erosion actually increases the scaling rate. This was observed by Rishel *et al.* (Ref 117) for commercial-purity nickel (Ni 270) in air + SO_2/SO_3, in which the scale thickness after E/C was about 50% greater than for free corrosion, and by Levy *et al.* (Ref 118) for low-chromium steels in methane/air mixtures. In the case of Ni 270, the effect $k_{c,e} > k_p$ was attributed to a redistribution of the

nickel sulfide network, which aids transport through the mixed oxide/sulfide scale. In general, $k_{c,e} > k_p$ could occur through mechanisms by which erosion alters the type or distribution of phases within the scale or introduces fast transport paths, such as dislocations or cracks.

Type III EEC was described (Ref 112) as the case in which erosion-induced spalling of the scale enters as an additional scale loss mechanism, resulting in a very thin or absent scale and a high corrosion rate. Spalling was included within the EEC regime (Ref 112) because it is a mechanism of discontinuous scale thinning that leads to an enhanced corrosion rate. The metal loss rate can be very sensitive to particle loading rate (in $g/cm^2 \cdot s$); a threefold increase of loading rate produced a 13-fold increase of type III EEC rate for nickel. (In the absence of spallation, the metal loss rate was simply proportional to loading rate.) In the absence of erosion, protective scales tend to spall above a certain thickness due to buckling induced by the natural compressive stresses, but this requires separation at the scale/metal interface.

Rishel *et al.* (Ref 112) discussed work by van der Zwaag and Field (Ref 110) that showed that indentation on a coating can significantly increase the maximum shear stress at the coating/substrate interface, promoting separation that could lead to spalling by buckling. Levy (Ref 120) suggested that spalling of scale in E/C of 9Cr-1Mo steel could be attributed to consolidation of the scale due to hot pressing action caused by particle impact. This was believed to eliminate nodule boundaries, forming a continuous scale susceptible to buildup of stresses and thus spalling. Other work by Rishel *et al.* (Ref 117) showed spalls on Ni 270 of sizes comparable to the impact dimension; this may be due to stress wave effects (Ref 112).

Pure Corrosion. Rishel *et al.* (Ref 112) describe this regime as one in which the ratio of corrosion to (scale) erosion rate is very high, resulting in pure corrosion and parabolic scale thickening. However, for a thick scale in the presence of a flux of erodent particles, it is important to realize that unless the scale erosion rate k', is actually zero, there must always be a steady-state scale thickness ζ_{ss} as described earlier. Even though this thickness may be large, a *constant* rate of metal thickness loss would be expected with a constant scale thickness, whereas for free corrosion (k' = 0) the rate of metal thickness loss decreases continuously unless scale buckling and spalling occur above a critical thickness. Certain, if the metal loss rate is sufficiently low, the distinction is of little practical significance.

Time- Versus Mass-Based E/C Rates

Sethi and Wright (Ref 111, 121) discussed the importance of flux in E/C, and based on a simple model in which the entire scale thickness is removed down to bare metal within the "footprint" of each impact, they demonstrated the different behavior expected when *E* is expressed in units of mass loss per unit time (time-based) as opposed to mass loss per unit mass impacted (mass-based). Because the erosion rate varies with flux while the corrosion rate does not (except for synergistic interactions, such as effects of erosion on scale properties), flux should be important through its effect on relative erosion and corrosion rates, regardless of the model assumed for E/C synergism.

Figure 13 illustrates how a steady-state E/C rate would occur based on the model assumed for simplicity by Sethi and Wright (Ref 121), for fluxes $F_1 = 4F_3 = 16F_5$. For higher fluxes, less time elapses between scale-removal events, and even though the amount (thickness) of scale removed per impact is less, the overall time-based E/C rate increases as $F^{0.5}$ due to the higher average parabolic corrosion rate at short times. In contrast, the mass-based E/C rate would be proportional to $F^{-0.5}$, as was observed by Sethi and Corey (Ref 108) for 2.25Cr-1Mo steel. Raising the temperature increases the E/C rate because of the increase of corrosion rate. The authors observed that this mechanism is not always applicable, but that time- and mass-based units will also give different flux effects for other mechanisms. The authors noted that if the oxide thickness grown in the fixed time between impacts exceeds a critical value at a higher temperature, the system will enter the scale erosion regime, and the E/C rate will be expected to decrease. They noted several studies in which a maximum E/C rate has been observed at some temperature.

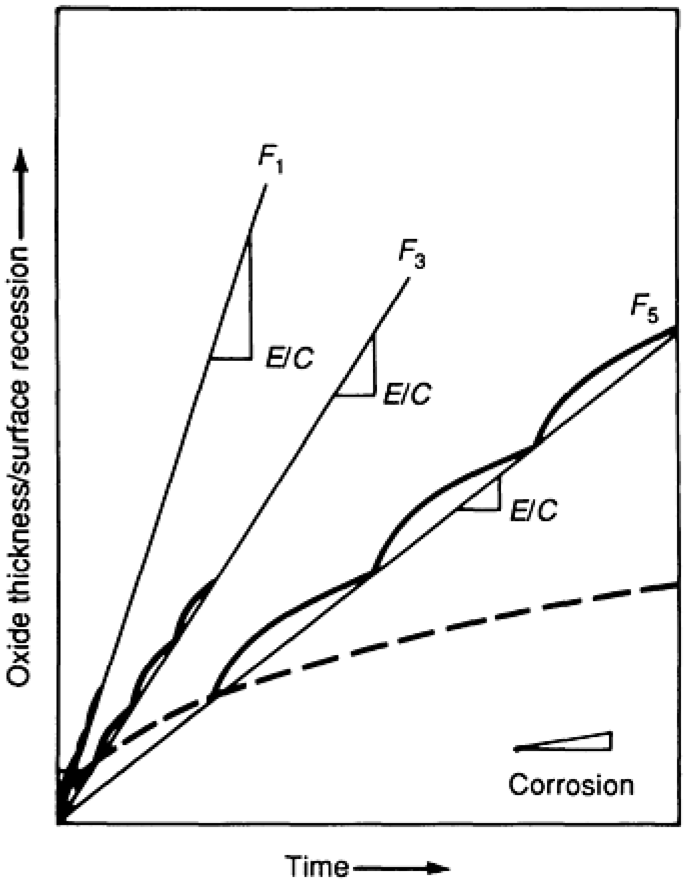

Fig. 13 Plot of oxide thickness versus time as a function of flux, *F*, at temperature T_3. The assumed parabolic corrosion curve is also shown. Source: Ref 111

Comparison With Other E/C Classifications

An earlier study by Hogmark *et al.* (Ref 122) discussed a classification scheme similar to that of Rishel *et al.* (Ref 112) as originated by Kang *et al.* (Ref 114). In order of increasing relative corrosion rate, they listed (1) pure erosion, (2) simultaneous damage of metal and scale (equivalent to CAE), (3) flaking (spalling) of scale at individual impacts, (4) erosion of scale without flaking, (5) erosion-affected corrosion, and (6) pure corrosion. Pure corrosion was treated as involving periodic flaking due to stress buildup, and erosion-affected corrosion was attributed to effects of erosion on the critical thickness for flaking or spalling. The regime of erosion of scale without flaking was not treated in terms of a steady-state scale thickness as in the work of Rishel *et al.* (Ref 112).

Sundararajan (Ref 49, 123) has classified E/C in a manner similar in most respect to that of Rishel *et al.* (Ref 122). One difference is that he separates what Rishel *et al.* termed type III EEC (scale spalling) into two separate cases of "oxidation-controlled" erosion: (1) continuous oxide removal, in which all oxide is removed down to bare metal within each impact site, and (2) intermittent spalling of oxide when the scale builds up to a critical thickness, ζ_c, only after several impacts. Sundararajan's treatment of the effects of the several important variables in the various regimes and his application of wear maps to their interpretation is quite useful. He also discussed the role of increased plasticity of scale along with the effect of increasing scale thickness with temperature. A ductile-to-brittle transition (DBT) occurs in many protective oxide scales; Stephenson *et al.* (Ref 124) observe that single impacts on oxide scales on nickel-base superalloys gave brittle behavior below a critical temperature for a fixed scale thickness and that, at high temperature, impacts went from ductile to brittle behavior with increasing scale thickness. Thus, Sundararajan (Ref 49) defined a critical scale thickness above scale behavior became brittle. Hutchings *et al.* (Ref 105) also attributed the decreasing E/C rate above the maximum temperature to the combined effects of increasing scale growth rate and scale plasticity with increasing temperature.

Erosion-Enhanced Corrosion Regime

If the picture presented by Rishel *et al.* (Ref 112) of a steady-state scale thickness being achieved by equal scale growth and loss rates in types I and II EEC is valid, as it appears to be from the published results, a simple point should be made with regard to the implications for the temperature dependence of the metal thickness loss rate. Because it is postulated that $k_{c,e}/\zeta = k'$, the scale growth rate $k_{c,e}/\zeta$ is directly controlled by the scale erosion rate k', because erosion controls ζ_{ss} at a given temperature and therefore controls the rate of diffusion through the scale. The metal thickness loss rate is proportional to the scale growth rate through appropriate density factors. This being true, even though $k_{c,e}$ varies significantly with temperature, the condition that growth and loss rates are equal implies that the temperature dependence of the metal thickness loss is controlled by k', not $k_{c,e}$. This point does not seem to have been made by other authors. It also follows that if the scale erosion rate were independent of temperature in the EEC temperature regime, the metal thickness loss rate would remain constant. As described above, other authors have alluded to the effect of increasing scale ductility with temperature as decreasing its erosion rate, and it appears that this may be responsible for the fact that the E/C rate is observed to reach a maximum and then decrease with temperature.

Scale Flaking or Spalling

Scale spalling is included by most authors as an important mechanism, but there is lack of general agreement as to whether it belongs in the CAE or EEC regime, or where it falls with respect to the often observed maximum E/C temperature. Sethi and Wright (Ref 111, 121) discussed intermittent parabolic growth between spalling events, which they considered a mechanism of CAE associated with rising E/C rate with increasing temperature. Rishel *et al.* (Ref 112) included it as type III EEC and presented an extensive discussion of spalling mechanisms. Sundararajan (Ref 49) included spalling as the oxidation-controlled erosion regime.

Levy *et al.* (Ref 118, 125, 126, 127, 128) showed the importance of erosion-induced changes of scale morphology on spalling. Segmented scales were found to give lower E/C rates compared with consolidated scales. Segmented scales formed on 9Cr-1Mo steel by growth of nodules that impinged (Ref 120); nodule growth is rare in free oxidation and was attributed to initiation of nodules by damage to thin scale at impact sites. Scale consolidation occurred at higher velocity and was attributed to compressive stresses generated by the normal component of velocity, which leads to a process similar to hot isostatic pressing at high enough E/C temperatures. The E/C rate increased suddenly by a factor of eight at 30 m/s (100 ft/s) when consolidated scale was formed, apparently because the area that spalls is limited to the original crystallite size in segmented but not in consolidated scales. The consolidation process is found to be more effective for round Al_2O_3 particles than for angular SiC particles. Also, higher chromium content promotes the segmented scale morphology (Ref 125, 128) and therefore gives lower E/C rates.

Corrosion-Affected Erosion Regime

There is lack of general agreement on the mechanisms of CAE, and the process appears difficult to model. Sethi and Wright's model of periodic scale-removal events with intervening periods of scale growth (Ref 111, 121) differs significantly from the description of Rishel *et al.* (Ref 112) of a continuous removal of a composite layer consisting of deformed metal, corrosion products, and embedded erodent particle fragments. In the model of Rishel *et al.*, the removal rate of the composite is the controlling factor, while in Sethi and Wright's model, the E/C rate is controlled entirely by the rapid mean corrosion rate for the thin scale that builds up between impact events. Rishel *et al.* also discuss the importance of including transient oxidation characteristics, since the scale is thin or absent. For Sethi and Wright's simplified assumptions, the rate of CAE should be close to the mean oxidation rate for the time between impacts, but this has not been established. As Sethi and Wright point out, some metal may be removed along with oxidation products, as would be expected when the depth of particle penetration exceeds the thickness of scale built up between impacts. It has been established that the majority of material removal in erosion of pure metals involves multiple impact phenomena, and it is likely that this would also be true in the CAE regime, unless scale adherence is weak and spalling is easy in a particular case. A composite layer such as that discussed by Rishel *et al.* might thus be expected. Because there are no satisfactory quantitative models for the aspects of material removal involving multiple impacts in pure erosion, quantitative modeling of the removal rate of the composite metal/scale layer appears very difficult.

Sundararajan (Ref 49) also refers to composite layer formation, and in addition notes that if the scale is ductile enough, it can partially shield the metal. Ductile response of scales to impact has been observed by Zhou and Bahadur (Ref 106, 129) and by Stephenson *et al.* (Ref 124). Oxide plasticity is expected at higher temperatures, and more brittle behavior may be expected in low-temperature CAE.

Despite the difficulty of quantitatively modeling CAE, it is worth discussing some of the factors that could be involved. Enhancements of the corrosion rate could occur by pipe diffusion along dislocations introduced by plastic deformation of

the metal or scale, or by short-circuit diffusion along metal/scale fragment and metal/embedded erodent fragment interfaces produced within a composite layer. One way in which corrosion could significantly increase the metal erosion rate is by penetration of corrosion through the highly deformed, thin platelets or displaced lips of metal, so that they are more easily detached. This would be particularly effective at lower temperatures, where corrosion products are brittle. However, this mechanism depends on whether displaced metal lips are formed, which may occur infrequently in a composite layer. Also, a thin scale overlying the metal might prevent rewelding of extruded platelets to the surface, increasing the metal erosion rate due to the presence of oxidation.

Sundararajan (Ref 49) estimates the range of conditions over which CAE should dominate. He assumes that if the scale thickness is greater than one-tenth of the depth of penetration in the metal, the scale will begin to influence the process promoting CAE, while if the scale thickness is greater than twice the depth of penetration in the scale, EEC will prevail. This leads to the conclusion that there should be only a very narrow range of velocity in which ζ_{ss} is in the correct range to produce CAE. His estimates also give a narrow range of temperature (about 100 °C, or 210 °F) over which a particular velocity would produce CAE. Experiments are in general agreement with this, often showing strong increases in E/C rates over a range of 100 to 200 °C (210 to 390 °F) (Ref 107, 108, 110, 111) before a maximum is reached, although in some cases the temperature range between pure erosion and the maximum is closer to 300 °C (570 °F) (Ref 105, 106, 109).

Cavitation Erosion

Carolyn M. Hansson, Queen's University, Canada; Inge L.H. Hansson, Alcan International Ltd., Canada

Introduction

CAVITATION is defined as the repeated nucleation, growth, and violent collapse of cavities, or bubbles, in a liquid. The term has been used in this context by the fluid mechanics and physics communities for centuries. It should not be confused with the metallurgical use of the term, which describes the growth of voids within a solid material, usually as a result of creep.

When a liquid is subjected to sufficiently high tensile stresses, vapor-filled voids, or cavities, are formed at weak regions within the liquid and usually grow under tensile conditions. In practice, all liquids contain gaseous, liquid, and solid impurities, which act as nucleation sites for the cavities. When the liquid that contains cavities is subsequently subjected to compressive stresses, that is, to higher hydrostatic pressures, these cavities will collapse. This collapse is directly responsible for the erosion process.

In practice, cavitation can occur in any liquid in which the pressure fluctuates either because of flow patterns or vibrations in the system. If, in a particular location in a liquid flow system, the local pressure falls below the vapor pressure of the liquid, then cavities may be nucleated, grow to a stable size, and be transported down-stream with the flow. When they reach a higher-pressure region, they become unstable and collapse, usually violently. This form of cavitation commonly occurs in hydrofoils, pipelines, hydraulic pumps, and valves. The pressures produced by the collapse may cause localized deformation and/or removal of material (erosion) from the surface of any solid in the vicinity of the cavities.

Similarly, when a stationary liquid is subjected to vibrational pressure fluctuations, the fluctuations may be sufficient to nucleate, grow, and collapse cavities, again resulting in erosion of any solid in the vicinity of the cavity cluster. Such cavities can produce the type of erosion that is typically observed on the coolant side of a diesel engine cylinder liner.

The collapse velocity, v, of a cavity is a function of the hydrostatic pressure, P, under which the cavity collapses, the volume, V, of the initial cavity, and the density, ρ, of the liquid (Ref 1):

$$v \propto \left(\frac{P\,V}{\rho}\right)^{1/2} \qquad \textbf{(Eq 1)}$$

Cavity radii for flow cavitation are typically from ~0.25 to 1.0 mm (~0.01 to 0.04 in.), and for vibratory cavitation, ~50 μm (~2 mils). P is of the order of a few atmospheres. For a cavity of 1 mm (0.04 in.) radius collapsing at 0.1 MPa (1 atm) overpressure in water, the cavity collapse velocity typically ranges from 100 to 150 m/s (330 to 490 ft/s).

Furthermore, the collapse time, t, of the cavity is related to the initial radius, R_0, of the cavity, the liquid density, ρ, and the hydrostatic pressure at collapse, P, as follows (Ref 1):

$$t \propto R_0\left(\frac{\rho}{P}\right)^{1/2} \qquad \textbf{(Eq 2)}$$

For the above case, the time is ~100 ns.

The effects of surface tension and viscosity on the collapse of a cavity are relatively insignificant. However, the compressibility of the liquid, vapor, and any trapped gases has a profound effect on the final stages of the collapse and will cushion the erosive effect of the single cavities (Ref 2). It is important to note that the driving force for the cavity collapse is the difference between the hydrostatic pressure and the vapor pressure of the liquid. A more detailed description of cavity dynamics and the parameters influencing the cavitation process is given by Mørch (Ref 3).

The mechanism by which cavitation causes erosion is briefly described below. When a cavity collapses within the body of the liquid, away from any solid boundary, it does so symmetrically and emits a shock wave into the surrounding liquid. On the other hand, those cavities that are either in contact with or very close to a solid surface will collapse asymmetrically, forming a microjet of liquid directed toward the solid, as shown in Fig. 1 (Ref 4).

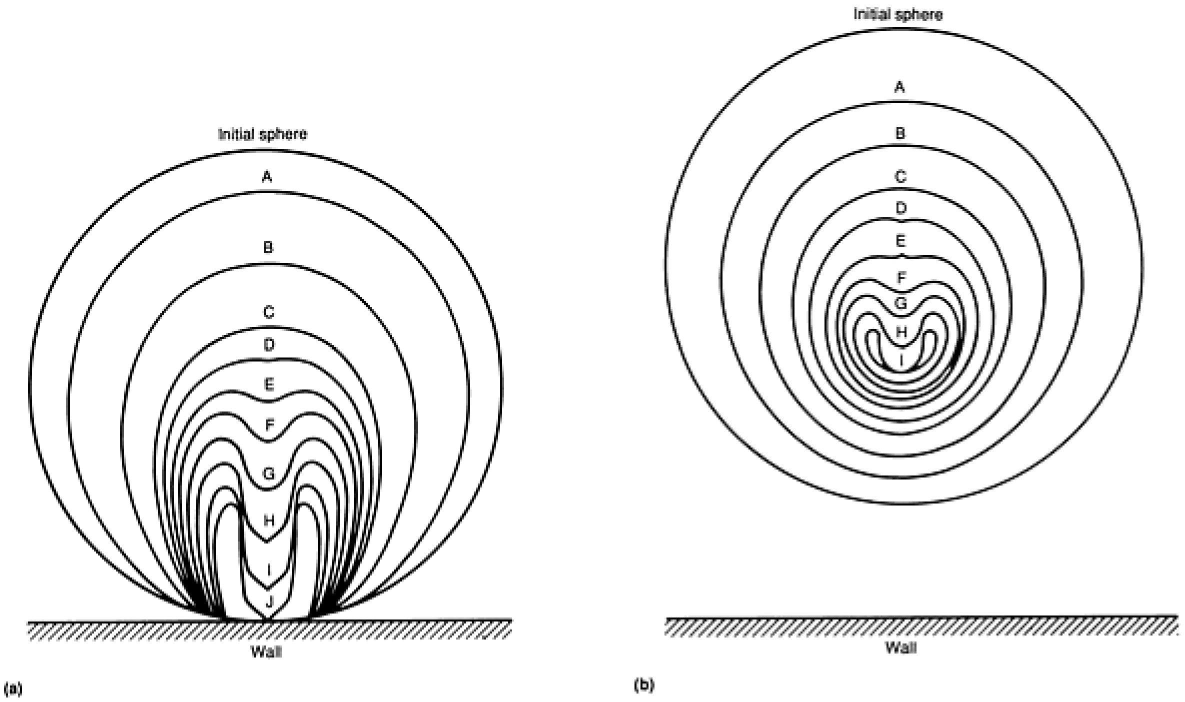

Fig. 1 Asymmetrical collapse of cavity. (a) In contact with solid surface. (b) Adjacent to solid surface. Source: Ref 4

The shock wave from spherical collapse and the jet impact from asymmetrical collapse have earlier been regarded as the most likely causes of erosion. However, each has features that do not permit a ready explanation of the observed erosion phenomena (Ref 5, 6). For example, the shock wave attenuates too rapidly, and the microjet diameters are typically too small to account for the degree and extent of the overall erosion damage. The discrepancies are now attributed (Ref 6, 7) to the fact that single cavities do not act independently but instead collapse in concert. The collapse of the cavity cluster enhances the effects of the cavities adjacent to, or in contact with, the solid.

In all practical situations involving cavitation, large numbers of cavities are generated at the same time and constitute what can be described as cavity clusters (Ref 2). When these clusters are subjected to an increased external hydrostatic pressure, they collapse in a concerted manner, stating with the cavities at the outer perimeter of the cluster and proceeding inward toward the central cavities (Ref 8). In this sequence, much of the energy generated by the collapse of the outer cavities is transferred to the cavities in the inner part of the cluster through an increased local hydrostatic pressure at the individual collapse. This results in a significant increase in the intensity of collapse of the central cavities (Ref 9). This concerted collapse mechanism has been demonstrated for flow cavitation as well as for vibratory cavitation (Ref 8, 10).

Because of the localized nature of the cavitation process, the energy dissipation has a significant temperature increase associated with the collapse. Local temperatures up to 5000 K have been reported (Ref 11).

Cavitation Erosion

Cavitation erosion is the mechanical degradation of materials caused by cavitation in liquids. The mechanical loading of a solid surface that is due to a cavitating liquid is caused by asymmetrical collapse of cavities either at or near the surface. These asymmetrical collapses result in liquid microjets that are directed toward the solid surface. The mechanical loads are very localized and, because of the concerted collapse of the cavity cluster, can be extremely severe, resulting in deformation of the surface. The repeated loading eventually leads to removal of material from the surface, that is, erosion.

The erosive effect of a cavity cluster is dependent on a number of factors, including hydrostatic pressure, cavity cluster size, distance of the individual cavities from the solid surface, cavity size distribution, and the temperature and density of the liquid. The total inherent energy of the cavity cluster is transferred to the solid material and must be either absorbed or dissipated by the solid or reflected as shock waves in the liquid. The solid material will absorb the impact energy as elastic deformation, plastic deformation, or fracture; the latter two processes lead to erosion of the material. The more elastic or plastic deformation energy that the material can absorb, the greater will be the cavitation erosion resistance of the material.

Erosion is generally regarded as mass loss from the surface and, for most materials under most forms of cavitation, is preceded by an incubation period, during which the material will deform either elastically or plastically (Ref 5). However, it should be noted that for some applications, a roughening of the surface by plastic deformation without actual loss of mass can render the part unusable for that application. Thus, cavitation damage without mass loss can be regarded as "erosion" for those applications. At the other extreme, material losses of >10 mm/year (0.4 in./year) from tough construction materials are observed in such applications as hydraulic turbines (Ref 12).

After the initiation of material loss from the surface, the rate of erosion as a function of continued exposure to cavitation is usually nonlinear (Ref 5). The observed time dependencies of the erosion rates are similar to those described in the article "Liquid Impingement Erosion" in this Volume.

Materials Factors

Localized Nature of Material Deformation and Removal. As described above, the loading that a material experiences during exposure to a cavitating liquid is localized, dynamic, and, at least initially, compressive in nature. However, the localized nature of the loading and the fact that it occurs at a free surface means that the deformation is not under the constraints normally imposed under bulk compressive or shock stressing. Therefore, the material is free to deform, both on a local and an extended level, in a manner that is unlike that of any other, more common, form of stressing. Because the material is not deformed as a whole, the deformation of one grain or one phase within a grain is not influenced by the behavior of the surrounding grains of phases, as it would be under bulk deformation conditions. Thus, the theoretical and empirical "rules" that have been developed to describe and explain the various strengthening mechanisms in different materials do not always apply to the resistance of the material to cavitation erosion.

Added to this localized loading factor is the dynamic, shocklike nature of the loading. It is not surprising, therefore, that no universal correlation with quasistatic mechanical properties has been observed. Consequently, the approach to materials selection and/or materials development for cavitation erosion resistance cannot be based on general experience in the selection and/or development of materials for resistance to bulk deformation and has, therefore, been almost exclusively empirical.

Until very recently, structural components have been predominantly fabricated of metallic alloys. A search of the literature has revealed very little information concerning cavitation erosion of either bulk ceramics of polymers. The only data concerning cavitation erosion of nonmetallic structures in practice has been of concrete (Ref 13), which, as a structural member of dams and sluices, is often exposed to cavitating liquids. Consequently, the discussion of the materials aspects of cavitation erosion will concentrate on metallic alloys and on the coatings and surface treatments that have been employed to minimize the erosion rates. There is little discussion of the very limited data on laboratory studies of nonmetallic bulk materials.

Erosion of Metals and Alloys. The deformation and failure mechanisms of both metals and alloys are markedly influenced by strain-rate sensitivity (and, therefore, the crystal structure) and the ability to absorb the energy of the shock loading without macroscopic deformation (which is related to the stacking fault energy). In multiphase alloys, the volume fraction, size, and dispersion of a second phase generally have a different and usually less significant influence on erosion rates than they do on the quasistatic mechanical properties.

Face-centered metals and alloys are isotropic and are the least sensitive to strain rate of the three common metallic structures. Consequently, their response to cavitation is similar to their quasistatic mechanical behavior in that they are highly ductile and fail by a void growth and coalescence mechanism (Ref 7) or by a ductile rupture (Ref 14) mechanism. Very early damage in the face-centered cubic (fcc) metals and single-phase fcc alloys consists of isolated depressions (Ref 15), Fig. 2, which can be attributed to the jet impact of individual cavities collapsing close to the surface. Also during this early stage, the grain boundaries become delineated, coarse slip bands develop across the width of the grains, and the grains become increasingly undulated. Eventually, the undulations develop into craters and material is lost by necking of the rims of the craters.

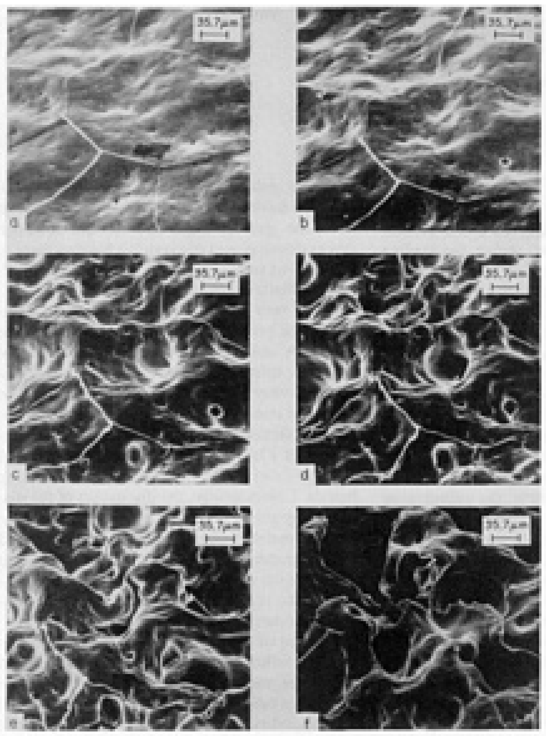

Fig. 2 Scanning electron micrographs of polycrystalline aluminum exposed to vibratory cavitation at varying lengths of time. (a) 12 s. (b) 24 s. (c) 40 s. (d) 60 s. (e) 75 s. (f) 90 s. Source: Ref 7

Body-centered cubic (bcc) metals and alloys are usually also isotropic, but their deformation is highly strain-rate sensitive. Their response to an applied stress is always a competition between flow and fracture. As the temperature decreases or the strain rate increases, flow becomes more difficult, and there is an increased tendency to brittle fracture. When pure iron is subjected to vibratory cavitation, it exhibits both brittle and ductile failure mechanisms. The brittle failure mode is illustrated in Fig. 3.

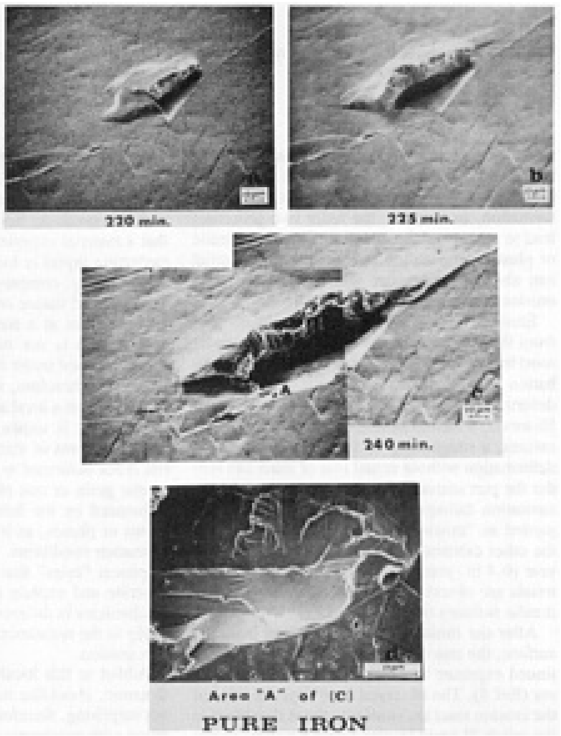

Fig. 3 Brittle fracture of pure iron exposed to vibratory cavitation. Source: Ref 16

Hexagonal close-packed (hcp) metals are anisotropic to varying degrees and can be either strain-rate sensitive or not, depending on the axial ratio of the unit cell. Two hcp metals that behave quite differently are zinc and cobalt. Zinc is highly anisotropic, highly strain-rate sensitive, and exhibits poor resistance to cavitation (Ref 17). Cobalt, on the other hand, is the most erosion-resistant pure metal of all those studied to date. Cobalt also has an almost ideal axial ratio and, unlike zinc, does not undergo a ductile-to-brittle transition with decreasing temperature or increasing strain rate. Its excellent erosion resistance is attributed to its extensive twinning mechanisms, which can effectively allow absorption of the cavitation energy without any major distortion of the metal (Ref 18).

Studies of multiphase alloys have shown that the size and dispersion of the second phase(s) determine whether or not these phases influence the cavitation erosion behavior. For example, the erosion rates and mechanism of material removal of precipitation-hardenable aluminum alloys exposed to cavitation are strongly dependent on the heat treatment, whereas the incubation period is little affected (Ref 19). Al-Mg alloys generally exhibit superior erosion resistance than do Al-Cu alloys because of the greater propensity for strain aging in the former. With both increasing solute content and degree of hardening, the mode of failure changes from ductile rupture, similar to that of the pure fcc metals, to the development of flat-bottomed pits that grow parallel to the surface and exhibit striated surfaces reminiscent of fatigue fracture surfaces. This effect appears to be related to the work hardenability of the surface layers and the depth of the work-hardened layers.

In steels, the ferrite phase controls the resistance to cavitation, because it erodes in a manner similar to pure iron. Thus, the microstructures with a continuous ferrite phase, for example, a spheroidized or normalized alloy, offer the least resistance because the ferrite can be eroded away from around the carbides, which then drop out (Ref 16, 20). It is necessary to strengthen the matrix phase, such as by heat treating to produce martensite or bainite, in order to impart greater erosion resistance.

In practical applications where intense cavitation is unavoidable, cobalt-base alloys (Ref 21) and, to a lesser extent, austenitic stainless steels (Ref 12) have been found to be the most erosion-resistant alloys available to date, despite their fairly low strength and hardness characteristics. Unlike most high-strength alloys, neither exhibits any significant strain-rate-sensitive behavior. More importantly, both have low stacking-fault energies and are readily able to develop stacking faults, twins, and/or martensitically transformed regions (Ref 18, 21, 22, 23). Thus, these alloys have the ability to absorb the impact energy with a lower distortion of the crystal lattice than do other alloys, which deform by normal multiple slip mechanisms.

The cavitation erosion resistance of cobalt alloys is superior to that of the stainless steels, but their cost is considerably higher. The economic factors, together with a better understanding of the factors responsible for the high erosion resistance of the cobalt alloys, have simulated the recent development (Ref 12) of new cavitation-resistant iron-base alloys. The success of this development is evidenced by the erosion data given in Fig. 4 for the new alloys designated IRECA and several iron- and cobalt-base commercial alloys. More comparative data on the erosion rates of various materials are given in the article "Liquid Impingement Erosion" in this Volume.

Surface Coatings and Treatments. The recent trend in materials development has been to specify a component for bulk property requirements and subsequently coat or treat the surface to provide the required environmental resistance. Welded overlays of stainless steels or cobalt alloys are commonly used to provide resistance to cavitation erosion. Several alternative coating techniques that have been investigated in the laboratory in recent years include: arc-sprayed coatings (Ref 24), plasma-sprayed coatings (Ref 25, 26), laser hardening, cladding and alloying (Ref 10, 27), ion implantation (Ref 28, 29), and electroless nickel coatings (Ref 30). Plasma-sprayed coatings and laser treatments are beginning to be applied in practice for this purpose.

Of these techniques, plasma spraying (Ref 31) is probably the most commercially well developed and offers flexibility in terms of the types of materials that can be sprayed. In addition, the technique can be carried out in air, in inert gas atmospheres, or in a reduced-pressure environment.

There are two major disadvantages of plasma-sprayed coatings. One is that the coating is generally only mechanically bonded to the substrate and therefore does not exhibit very good adhesion. The other disadvantage is the inherent porosity

of the coatings. One of the more erosion-resistant coatings produced by plasma spraying is of the "shape memory" alloy, NiTi (Ref 24). Like cobalt and the IRECA stainless steel, NiTi owes its superior properties to a stress-induced phase transformation.

Laser surface treatments appear to offer the most possibilities and advantages. By rapidly heating (but not melting) and quenching the surface of a finished component, an extremely hard and resistant surface layer can be induced without requiring any further surface finishing and with little effect on the bulk properties of the part. Alternatively, the composition and properties of the surface can be tailored specifically to the requirements either by melting the surface layers and adding additional alloy components to the base alloy or by depositing a cladding material onto the surface.

The advantages of this process are that the clad, alloyed, or heat-treated surface layer is an integral part of the component, which precludes any adhesion problems, and the process can be carried out in the atmosphere, rather than in vacuum. Its major disadvantages are that the processing equipment (laser and manipulation stations) is expensive and the technique cannot readily be executed on internal surfaces, because it is a line-of-sight process.

Laser cladding is now being used to provide erosion resistance to marine engine diesel cylinder liners (Ref 32). To the best of the authors' knowledge, the other laser techniques have not yet been applied for the purpose of cavitation erosion resistance.

Combined Effects of Cavitation Erosion and Corrosion

As described above, cavitation erosion leads to mechanical degradation of engineering materials, whereas corrosion is an electrochemical oxidation, or dissolution, of the material. Because cavitation always takes place in a liquid medium, there is always the possibility of an interaction between mechanical and electrochemical processes, which can produce diverse and complex effects on the materials. The interaction may be synergistic and can lead to increased damage. Alternatively, one mechanism may inhibit or reduce the harmful effects of the other, leading to a reduction in the overall damage.

Effect of Cavitation on the Corrosion Process. Cavitation can have a variety of effects on corrosion processes, including:

- Removing any protective passive film from the metal surface
- Increasing the diffusion rates of reactive dissolved gases to the metal surface
- Increasing the rate of removal of the corrosion reaction products from the vicinity of the surface

The net effect of cavitation is dependent on the type of corrosion. For example, it has been shown that cavitation can increase the ability of solution-treated stainless steel to become passive, whereas, for the same steel in the sensitized condition, the degree of intergranular corrosion is increased by cavitation (Ref 33).

Effect of Corrosion on the Cavitation Process. The corrosion process is electrochemical and can be described by two reactions: the anodic reaction, which involves the dissolution, or oxidation, of the metal, and the cathodic reaction, which usually involves the evolution of hydrogen. As mentioned above, dissolved gases can cushion the implosion of the cavities and reduce their damaging effects. In a situation that involves both corrosion and cavitation, the evolution of hydrogen can therefore have the effect of reducing the mechanical stressing of the metal. Similarly, it is possible (although no evidence has been reported) that solid particles produced by the corrosion process could act as nuclei for cavities, and thereby enhance the onset of cavitation.

Cavitation Erosion Testing

When testing materials for their cavitation erosion resistance, there is *no* laboratory experimental equipment that simulates the total situation for a real structural component exposed to cavitating liquids. However, there are a number of laboratory techniques and procedures that can be used to, at least reasonably, rank a series of selected materials on the basis of cavitation erosion resistance. The most commonly used techniques today are flow channels, vibratory (ultrasonic) systems, and cavitating jets, all of which can simulate accelerated cavitation erosion in most materials. However, it is important to note that most real situations involving cavitation also involve corrosion attack (for example, salt water on ship propellers) and other mechanical loading of the materials (for example, the structural load on valve seats or in concrete water channels).

Flow Channels. Typical flow channel equipment consists of a closed-loop circulating liquid flow channel with either a test section for scaled components, such as ship propellers, or a venturi restriction with a specimen holder designed to generate cavitation at specific locations near the specimen. This test simulates a flow cavitation situation very well. However, it is difficult to conduct accelerated cavitation erosion testing without changing the cavitation parameters relative to the service envelope of the simulated application. There are several different cavitation and specimen section designs (Ref 5) with the common feature that they are an integral part of the flow channel, which makes specimen changes difficult and more time consuming relative to the other techniques.

Vibratory (ultrasonic) equipment consists of an ultrasonic horn that is partly submerged in the liquid, which is contained in a beaker (Fig. 5). The vibration, typically at 20 kHz frequency, generates negative pressure for cavitation nucleation and growth, and positive pressure for cavity collapse in a small, stationary volume of the liquid. The specimen is either mounted on the horn tip (moving specimen) or at a fixed distance (a few millimeters) below the horn tip (stationary specimen).

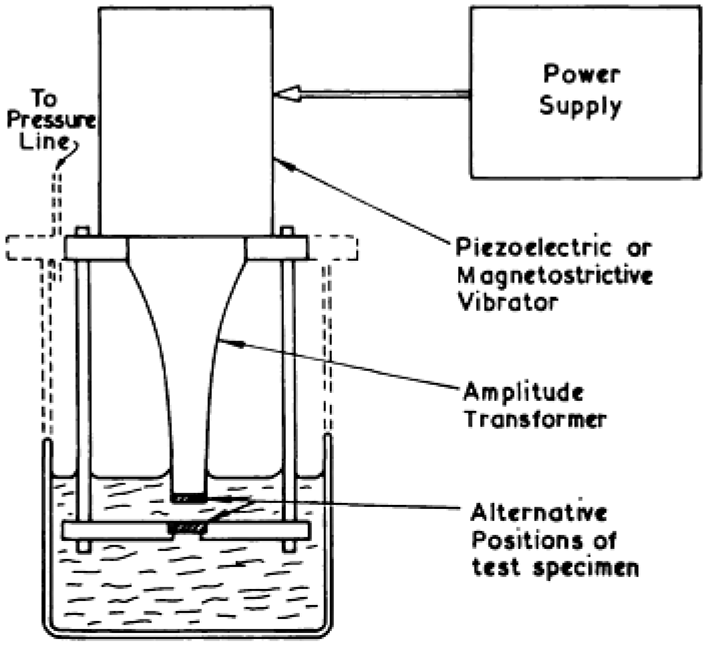

Fig. 5 Vibratory cavitation device in which specimen is either attached to or held below a horn oscillating in the lower kilohertz frequency range. Source: Ref 5

This test device is used for accelerated testing and lends itself to the study of interaction mechanisms with corrosion. Because the cavity size distribution is not the same as in the flow channel equipment, direct comparisons are not advisable. However, because the equipment is easy to use, it is widely applied to cavitation erosion resistance screening. Furthermore, ASTM G 32 describes the equipment and procedures for this test.

Cavitating Jet. Two variations of this technique have been described. In type I, a hydraulic pump with an accumulator delivers the test liquid through a sharp-entry parallel-bore nozzle, which discharges a jet of liquid into a chamber at a controlled pressure (Ref 34). In type II, a high-pressure nozzle with an internal center body is used to create the low pressure to initiate the cavitation (Ref 35, 36). Cavitation starts in the *vena contracta* region of the jet within the nozzle (type I) or at the end of the center body (type II) before ejecting as a cloud of cavities around the emerging jet (type I) or in the center of the jet (type II). The specimen is placed in the path of the jet at a specific stand-off distance from the nozzle tip. The cavities collapse on the specimen, thereby causing erosion of the test material.

The advantage of this technique is that it is an accelerated test method that offers the possibility of control and, thereby, allows the possibility of changing most of the cavitation parameters. Furthermore, the cavity size distribution resembles that of a real flow situation more than does that produced in the vibratory system. The technique is currently under consideration by ASTM as a standard test method.

Other Techniques. Rotating disk test equipment has been used in earlier cavitation studies (Ref 37, 38, 39, 40). Such equipment consists of a rotating disk with specimen holder and cavitation sites (that is, holes in the disk) submerged in the liquid. The liquid is kept relatively stable in a chamber where the disk is rotated. This technique is no longer in common use; however, it can be used, for example, to simulate cavitation occurring in pump impellers.

Means of Combating Erosion

Materials Selection and Development. It is clear from the current understanding of deformation mechanisms in metals and alloys, and from the dynamic and localized nature of cavitation loading, that materials selection for erosion resistance should be based on the ability of alloys to absorb the impact energy by a nondestructive strain mechanism, such as twinning, stacking-fault formation, or a stress-induced martensitic-type phase transformation. Unfortunately, most standard mechanical testing is quasistatic in nature, and most cavitation erosion testing comprises weight loss measurements without any determination of the mechanism of material loss. Consequently, mechanical property databases do not usually contain the type of information necessary for appropriate materials selection.

Similarly, there has been little effort to develop materials specifically for their erosion-resistant properties. However, the success of the initial research into the development of the iron-base IRECA alloys, which was based on a knowledge of the required deformation mechanisms and understanding of the compositional factors necessary to ensure that the alloy could deform in the appropriate manner, suggests that this is indeed a feasible approach and should be pursued.

Coatings and Surface Treatments. Coating technology is one of the more rapidly growing technologies in the field of materials. It is clear that the selection of the base material for its bulk properties and a coating/surface treatment for its resistance to environmental factors is the wave of the future. A combination of the development of materials specifically designed for erosion resistance and the appropriate technique for the application of these materials as a coating would be the optimum solution. Suitable coating techniques also allow for regeneration of parts that have been rendered unusable by erosion.

Other measures described below include design, air injection, and control of the operating temperature or pressure.

System design represents the best way to either reduce or eliminate cavitation erosion. Therefore, fluid flow systems should be designed to minimize the changes in flow pressure that occur when the velocity is either increased or decreased, usually as a result of constrictions or changes in the direction of the flow. Similarly, the elimination of vibrations or the reduction in their amplitude would reduce the problems of cavitation erosion in many types of machinery. If cavitation cannot be eliminated, the cavitating regions should be designed to allow the cavities to collapse as far away from a solid surface as possible or to decrease the concerted collapse mode of the cavity cluster (Ref 9).

Air injection into a cavitating fluid has been shown to be an effective method of reducing the intensity of erosion. The air creates bubbles and partly fills the cavities as they are formed, which prevents their complete collapse, thereby significantly reducing the magnitude of the shock wave emitted or the impact pressure of the microjets. The air also significantly changes the dynamic properties of the liquid, that is, the shock-wave velocity and its attenuation.

Control of Operating Temperature or Pressure. It is more difficult to nucleate cavities at temperatures that approach the freezing temperature, T_F, of the liquid and more difficult to collapse them at temperatures that approach the boiling temperature, T_B. Therefore, cavitation erosion intensity is at a maximum at temperatures in the middle range between freezing and boiling. Consequently, a change in temperature that is close to either T_F or T_B will reduce the cavitation intensity and, thus, the degree of erosion. Similarly, increasing the hydrostatic pressure makes nucleation of cavities more difficult, but increases the erosive power of the cavities, whereas decreasing the collapse pressure makes collapse less intense.

More comprehensive discussions of the influence of various cavitation parameters on the resulting erosion are given in a number of reviews (Ref 5, 41, 42).

The salient conclusions that can be made about cavitation erosion are:

- No materials are immune to cavitation erosion, as some are to corrosion; all will eventually erode
- Metallic materials that exhibit stress-induced phase transformations have the highest erosion resistance. Further development of alloys specifically for their erosion resistance is to be encouraged

- The combination of erosion and corrosion can be either synergistic or less harmful than either process alone. Unfortunately, there do not appear to be any general rules; therefore, each combination of material, environment, and erosion conditions must be evaluated
- Coating technologies, particularly laser processing, offer great potential both in providing tailor-made erosion resistance to structures that are selected for their bulk properties and in repairing and regenerating eroded surfaces

Liquid Impingement Erosion

Frank J. Heymann (retired), Westinghouse Electric Corporation

Introduction

LIQUID IMPINGEMENT EROSION has been defined as "progressive loss of original material from a solid surface due to continued exposure to impacts by liquid drops or jets" (Ref 1). The operative words in this definition are "*impacts* by liquid drops or jets": liquid impingement erosion connotes repeated impacts or collisions between the surface being eroded and small discrete liquid bodies.

Excluded from this definition are erosion mechanisms due to the impingement of a continuous jet, due to the flow of a single-phase liquid over or against a surface, due to a cavitating flow, or due to a jet or flow containing solid particles--although all these can produce erosion (progressive loss of solid material) at least under some conditions. Some of these mechanisms will, however, be discussed briefly in order to distinguish them clearly from the primary subject.

The significance of the discrete impacts is that they generate impulsive contact pressures on the solid target, far higher than those produced by steady flows (see the discussion "Liquid/Solid Interaction--Impact Pressures" later in this article). Thus, the endurance limit and even the yield strength of the target material can easily be exceeded, thereby causing damage by purely mechanical interactions. In some circumstances the damage can also be accelerated by conjoint chemical action.

At sufficiently high impact velocities, solid material can be removed even by a single droplet (or other small liquid body). Much of what is currently known about the liquid/solid interactions in liquid impingement has been determined through laboratory experiments and analytical modeling involving single impacts.

Liquid impingement erosion in its advanced stages is characterized by a surface that appears jagged, composed of sharp peaks and pits (Fig. 1). A possible reason for this will be given later.

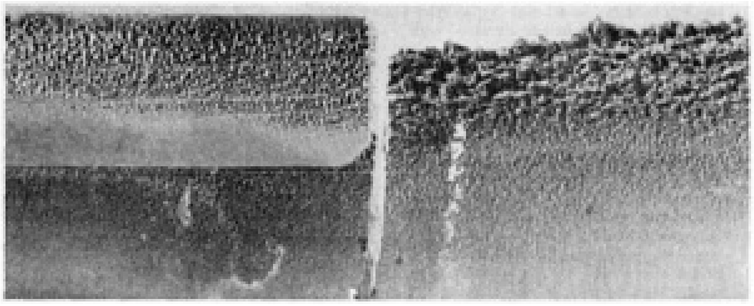

Fig. 1 Two portions of a steam turbine blade that has experienced liquid impingement erosion. The portion on the left was protected by a shield of rolled Stellite 6B brazed onto the leading edge of the blade; the portion on the right is unprotected type 403 stainless steel. Note the difference in degree of erosion. Normally such erosion does not impair the blade's function. Both at 2.5×

A very comprehensive treatment and review of liquid impact erosion can be found in Ref 2; in particular the chapters therein by Adler (Ref 3) and by Brunton and Rochester (Ref 4). Reference 5 contains some now classic studies that provided the foundation for subsequent work. Many other contributions to this field are found in several ASTM symposium volumes (Ref 6, 7, 8, 9, 10) and in the proceedings of the international "Rain Erosion" and "Erosion by Liquid and Solid Impact" (or "ELSI") conferences (Ref 11, 12, 13, 14, 15, 16, 17). Individual papers from some will be cited in context.

Acknowledgements

The author would like to thank John E. Field of Cambridge University, George F. Schmitt, Jr. of the Air Force Materials Laboratory and Westinghouse Electric Corporation for supplying photographs. Additional thanks are due to George Schmitt for also supplying information on the current state of rain erosion protection and providing valuable suggestions for improving this article.

Occurrences in Practice

It is quite difficult to propel liquid droplets to high velocities without breaking them up, and liquid impingement erosion haas become a practical problem primarily where the target body moves at high speeds and collides with liquid drops that are moving much more slowly. Almost all the work done in this subject has been in connection with just two major problems: "moisture erosion" of low-pressure steam turbine blades operating with wet steam, and "rain erosion" of aircraft or missile surfaces and helicopter rotors.

Whenever vapor or gas flows carrying liquid droplets impinge upon solid surfaces--as in nuclear power plant pipes and heat exchangers, for example--erosion can also occur. However, the probable impact velocities and impact angles are such as to make "pure" liquid impingement erosion an unlikely mechanism. It is much more likely that an "erosion-corrosion" mechanism is then involved (see the discussion of "Impingement Attack and Erosion-Corrosion" later in this article).

Steam Turbine Blade Erosion. Moisture erosion of low-pressure blades has been a problem throughout steam turbine history, and remains a concern today. In the last stages of the low-pressure turbine, the steam expands to well below saturation conditions, and a portion of the vapor condenses into liquid. Although the condensation droplets are very small, some of them are deposited onto surfaces of the stationary blades (guide vanes), where they coalesce into films or rivulets and migrate to the trailing edge. Here they are torn off by the steam flow, in the form of much larger droplets.

These large droplets slowly accelerate under the forces of the steam acting on them, and when they are carried into the plane of rotation of the rotating blades, they have reached only a fraction of the steam velocity. As a result, the blades hit them with a velocity that is almost equal to the circumferential velocity (wheel speed) of the blades, which can be as high as 650 m/s (2100 ft/s) in a modern 3600 rpm turbine. References 18 and 19 describe these processes in detail. The same basic phenomenon can, of course, occur in wet vapor turbines operating with other working fluids, such as sodium or mercury.

The principal remedies in modern turbines include extracting moisture between blade rows, increasing axial spacing between stator and rotor to permit droplets to be accelerated and broken up, and making the leading edge of the blade more resistant to erosion. This last remedy has been accomplished by local flame hardening of the blade material, by brazed-on "shields" of Stellite (Fig. 1), or in some cases by shields of tool steel or weld-deposited hardfacing. Tests on many blade and shield materials are reported in Ref 20 and 21. The base material for present-day low-pressure blades is usually a 12% Cr martensitic stainless steel, a 17Cr-4Ni precipitation-hardening stainless steel, or, more rarely, a titanium alloy.

Recently, success has been claimed for new "self-shielding" blade alloys that harden under the action of the impacts. One such alloy is Jethete M152, a martensitic steel containing about 11% Cr, 2.9% Ni, 1.6% Mo, and 0.3% V. Other new approaches that have been investigated include plasma-deposited Stellite and an ion-plated chromium-tin multilayer coating; however, it is doubtful that relatively thin coatings can provide long-term protection.

The evaluation and prediction of steam turbine blade erosion is very complex; recent contributions include Ref 22 and 23.

Aircraft Rain Erosion. Rain erosion became a major problem in the 1950s, when military aircraft reached transonic and supersonic speeds. The impact of rain drops, 2 mm (0.08 in.) or more in size, on unprotected aluminum alloy surfaces, optical and infrared windows, and radomes caused severe erosion which seriously limited operational time in rain storms. This resulted in many government-funded research projects into erosion mechanisms as well as development and evaluation of protective coatings. Reference 24 gives an overview of the rain erosion problem, with special reference to radomes. The current status concerning remedies has been summarized as follows by Schmitt (Ref 25):

Protection of aircraft radomes and composite surfaces is accomplished with two classes of elastomeric coatings--polyurethanes for widespread lower temperature applications, and fluorocarbons where elevated temperatures (above 177 °C, 350 °F) or special requirements (camouflage colors, thermal flash protection) are involved.

For applications where supersonic rain erosion is a concern, the inherent erosion resistance of the base materials combined with streamline geometry to reduce impact angles is the most often used approach. Another aerodynamic technique is to utilize the shock waves to shatter and fragment the raindrops into very small pieces that produce less damage. For hemispherical domes where impact angles must be large (near normal), protective coatings of boron phosphide, germanium carbon and diamond are being pursued, but they are restricted to velocities less than Mach 2. At extremely high velocities, protection at high impact angles may require metal tips or sacrificial layers even though a performance penalty must be paid. In many cases, lack of adequate materials and potential catastrophic failure simply precludes operation at high supersonic speed in rainy environments.

References 8, 9, 10, 11, 12, 13, 14, 15, 16, and 17 contain numerous papers on evaluation of materials and coatings for rain erosion applications. Among the most recent are investigations of infrared window materials, slip-cast fused silica, and hard carbon-coated germanium in Ref 17; polyurethane and fluoroelastomer coated composite constructions, composite materials for radomes, new materials for radomes, and infrared windows (including polyethersulfone, polyetherimide, polyetherketone, and germanium) in Ref 16; and slip-cast fused silica, boron-aluminum composites, composite and honeycomb structures, polytetrafluoroethylene (PTFE) and polymethylmethacrylate (PMM) in Ref 15.

As mentioned earlier, rain erosion also poses a threat to missile surfaces and helicopter rotors. Figure 2 shows the catastrophic failure of a missile dome due to rain erosion effects.

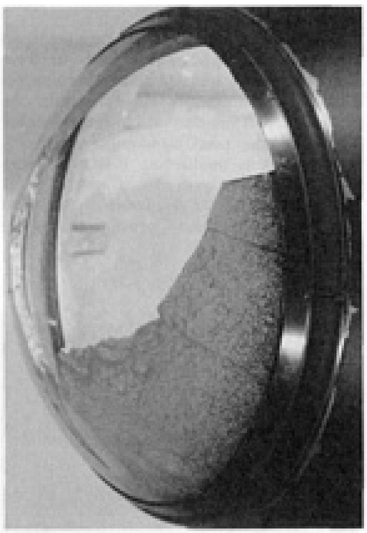

Fig. 2 Rain erosion effects on a Maverick missile dome made of coated zinc sulfide that was exposed for 10 s at a speed of about 210 m/s (690 ft/s). The dome itself suffered catastrophic damage, and erosion is also seen on the filled elastomeric mounting ring. Courtesy of G.F. Schmitt, Jr., Materials Laboratory, Wright Research and Development Center, Department of the Air Force

Relationship to Other Erosion Processes

Continuous Jet Impingement. Impingement of a high-velocity continuous jet can cause material removal, and that fact has led to the development of jet-cutting technology used in quarrying, mining, and material cutting. While there is some overlapping with erosion research, much of the literature is found in the "American Water Jet Conferences" and the "International Conferences on Jet Cutting Technology."

Steady continuous jet impingement produces only stagnation pressure on the target, whereas discrete impacts produce much higher shock-wave or "water-hammer" pressures. Thus, high supply pressures are needed to achieve material removal with truly continuous jets. This has led jet-cutting research to develop techniques for producing moving and oscillating jets, pulsating jets, and cavitating jets, all of which serve to introduce something akin to discrete impact conditions (also, jets laden with abrasive particles are used). References 26 and 27 describe these techniques.

Rough comparisons of test data suggest that the erosion rate due to a continuous jet can be from one to five orders of magnitude lower than that due to the same quantity of liquid impinging at the same velocity but in the form of droplets.

Cavitation Erosion. Whereas liquid impingement connotes a continuous vaporous or gaseous phase containing discrete liquid droplets, cavitation connotes a continuous liquid phase containing discrete vaporous or gaseous bubbles or cavities. Despite this seeming antithesis, the nature of cavitation damage and liquid impingement damage has many similarities. Both, in fact, are due to small-scale liquid/solid impacts. In cavitation, micro-jet impacts have been shown to occur in the asymmetrical collapse of cavitation bubbles adjacent to a solid surface, although shock waves generated by collapsing cavity clusters may also contribute to damage.

The relative resistance of materials to the two types of erosion is much the same, the damage appearance is similar, the complicated time dependence of the erosion rate is similar (see the section "Time Dependence of Erosion Rate" in this article), and historically cavitation tests have been used to screen materials for service in liquid impingement environments, and vice versa. In some practical cases, it is not clear whether the mechanism causing erosion was impingement or cavitation erosion. One such example is the heavily eroded dynamometer stator shown in Fig. 3. Erosion in such machines has often been characterized as cavitation erosion; however, the author believes it to be liquid impact erosion caused by the discrete streams of water issuing from the rotor pockets and sweeping across the stator vanes. This is supported by dynamic pressure transducer spectra which were dominated by discrete spikes at the rotor vane passing frequency, but did not show the characteristic signature of cavitation. In addition, injection of air bubbles, which can inhibit cavitation, had no influence on the signals or on the erosion.

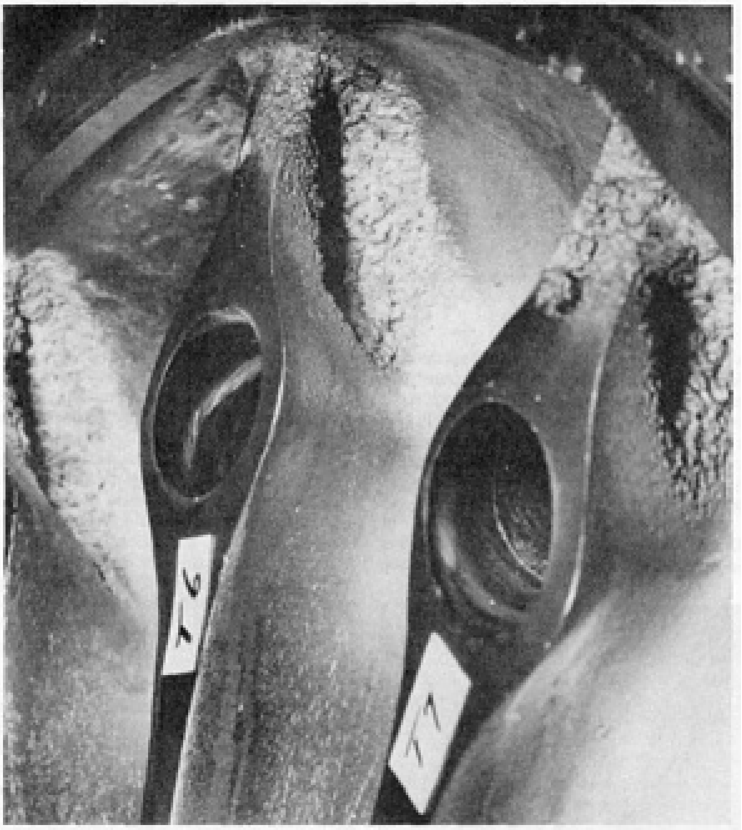

Fig. 3 Severe erosion of copper-manganese-aluminum stator vanes in a hydraulic dynamometer. Each vane has lost about 10 cm^3 (0.6 $in.^3$) of material. See text for a discussion of the erosion mechanism.

For additional information on cavitation damage, see the article "Cavitation Erosion" in this Volume.

Solid Particle Erosion. It might easily be assumed that solid particle erosion would have many similarities to liquid impingement erosion, since both involve the impact of small discrete bodies. This is not the case, however, because the damage mechanisms, the effects of impact variables, and the response of materials are all quite different.

For example, the resistance of common engineering alloys to liquid impingement ranges over several orders of magnitude, whereas most common ductile alloys have about the same resistance to solid impingement; liquid impingement erosion rates vary with about the 5th power of impact velocity, whereas solid particle erosion varies with about the 2.5th power; liquid impingement erosion is greatest with normal (perpendicular) impacts, whereas solid particle erosion in ductile alloys peaks with impacts some 60 to 70° away from perpendicular; and finally, liquid impingement erosion exhibits a complicated time dependence, whereas the erosion rate due to solid particle impingement is essentially linear. See the article "Solid Particle Erosion" in this Volume for further details.

Impingement Attack and Erosion-Corrosion. There are many practical situations where material loss occurs in the presence of flowing fluids but cannot be fully explained by purely mechanical action such as liquid impingement, solid particle impingement, or cavitation. Only recently has a substantial amount of scientifically oriented work on these phenomena been reported in the literature.

"Impingement attack" is a term sometimes used for material loss in tube bends and heat exchanger tube entrances, where the forces of unsteady, turbulent, or bubbly flows are believed to remove protective oxide layers and thus permit continuing and accelerated corrosion. "Wire drawing" is a term used for a grooving type of erosion produced in small gaps such as valve seats and component joints with a high pressure drop across them. This type of erosion could be due to localized cavitation or to erosion-corrosion.

"Erosion-corrosion" can refer to any conjoint (synergistic) action between corrosive and erosive processes, such that the resulting material loss rates are greater than the sum of the individual processes taken by themselves. Corrosive actions in the presence of solid particles, slurries, and sliding wear are covered in detail in the articles "Solid Particle Erosion," "Slurry Erosion," and "Corrosive Wear" in this Volume.

For purely fluid systems, some recent work on "corrosive-erosion" has emphasized a mechanism in which impulsive mechanical interactions play little or no role. For example, the flow of liquid or droplets along a carbon or low-alloy steel surface prevents equilibrium in the corrosive process and results in continuing chemical dissolution of the protective oxide (magnetite) layer (Ref 28). This is more accurately called "flow-assisted corrosion."

Only a few references can be cited here. Keck and Griffith (Ref 29) propose models for both convection-assisted oxide dissolution and for oxide fatigue by liquid droplet impacts. Coulon (Ref 30) distinguishes mechanisms by the flow velocity causing them: corrosion, 0 to 10 m/s (0 to 35 ft/s); corrosion-erosion, 10 to 50 m/s (35 to 165 ft/s); erosion-corrosion, 50 to 200 m/s (165 to 655 ft/s); and erosion, >200 m/s (>655 ft/s). Henzel *et al.* (Ref 31) give an update on experience and remedies. Both Ref 30 and 31 provide empirical schemes for estimating material loss due to erosion-corrosion, including factors relating to material, flow velocity, and temperature, as well as geometry factors borrowed from another empirical model by Keller (Ref 32).

Mechanisms of Liquid Impact Erosion

Liquid/Solid Interactions--Impact Pressures. The high-velocity impact of a liquid drop against a plane solid surface produces two effects that result in damage to that surface: high contact pressure, which is generated in the area of the impact, and subsequent liquid "jetting" flow along the surface, radiating out from the impact area (Ref 33). A first approximation of the average impact pressure, before radial outflow initiates, is the one-dimensional water-hammer pressure; that is, pressure generated in the impact of an infinite flat liquid surface against an infinite flat rigid surface. In this case a plane shock wave is formed at the instant of impact and travels into the liquid, bringing to rest one "layer" after another.

This impact or shock pressure, P, can be defined as:

$$P = \rho CV$$

where ρ is the liquid density, C is the shock wave velocity in the liquid, and V is the impact velocity. For practical impact velocities, this can be approximated by:

$$P = \rho C_0 V (1 + kV/C_0)$$

where C_0 is the acoustic velocity of the liquid, and $k = 2$ for water. For example, for water impacting at 500 m/s (1640 ft/s), this pressure is about 1250 MPa (180 ksi)--considerably above the yield strength of many alloys. The stagnation pressure of a continuous jet ($\rho V^2/2$) at that speed is about one-tenth of the former.

The real situation is much more complicated, because of the roundness of the impacting droplet and the elastic and plastic deformations of the solid surface. Although much work has been done on this topic in recent years (for example, Ref 34, 35, 36, 37), a complete understanding has not yet been achieved. However, the following salient features (see Fig. 4) are now widely accepted for the impact of a round drop on a rigid surface:

- At the initial instant of impact, contact is made at a point. Because the droplet radius of curvature is initially infinite compared to the contact radius, quasi-one-dimensional conditions prevail and a shock wave of the one-dimensional impact pressure is formed at that instant and begins to travel up into the drop (Fig. 4a)
- As the contact area spreads out, its perimeter at first is moving radially outward at a speed greater than the shock velocity; consequently an obliquely attached bulbous shock front is formed enclosing the compressed liquid and no free outflow can take place (Fig. 4b). During this stage, the highest impact pressure is found at the growing contact perimeter, where its value gradually increases up to about $3\rho C_0 V$, while that at the impact center decreases
- At some point, defined by a critical contact angle, ϕ_c, the conditions for an attached shock are no longer met; the shock front then detaches from the solid surface and moves up along the surface of the droplet. The compressed liquid is now free to spread or "jet" out laterally and relieve the contact pressures (Fig. 4c). In experiments, however, actual jetting is not observed until the contact angle ϕ has reached a value significantly greater than the theoretical critical value ϕ_c; the reasons for this behavior are not yet fully understood. The maximum lateral jetting velocity is many times greater than the impact velocity, but theoretical prediction of its value is still uncertain.

Figure 5 shows high-speed photographs at various stages of the impact between a solid projectile and a gelatine droplet in a laboratory apparatus. In this case the impact velocity was 110 m/s (360 ft/s) and the maximum jetting velocity 1170 m/s (3840 ft/s).

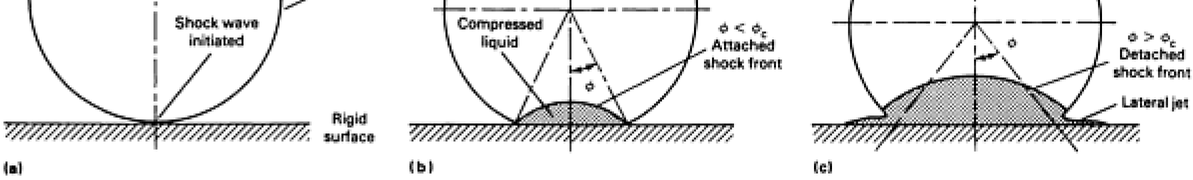

Fig. 4 Idealized diagram of the early stages of liquid drop impact. (a) Initial contact. (b) Compressible stage with attached shock front. (c) Detached shock and jetting stage. See text for detailed discussion of these three stages.

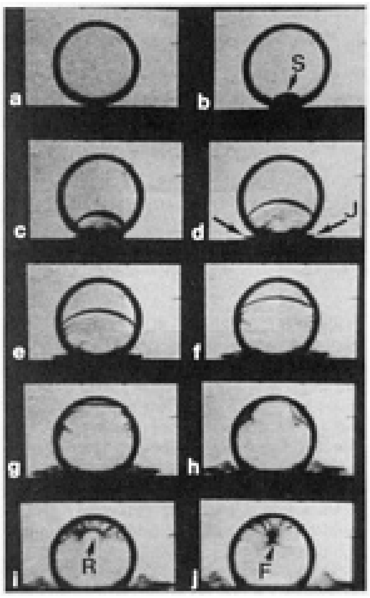

Fig. 5 High-speed photographs of the impact between a 10 mm (0.4 in.) diam two-dimensional droplet of gelatin and a metal slider moving at 110 m/s (360 ft/s) at intervals of 1 μs. S denotes the shock front, first seen in frame b. Jetting is just visible in frame c and is labeled J in frame d. Note the reflection of the shock as a rarefaction wave R in frames h through j, causing a region of cavitation indicated by F. In these photos, there has not yet been time for any gross spreading out of the droplet to occur. Courtesy of J.E. Field, Cavendish Laboratory, University of Cambridge, United Kingdom

The liquid/solid interaction is further complicated when the solid surface becomes deformed from erosion, usually exhibiting jagged peaks and craters. Then both the pressures and jetting patterns will be affected by where the initial contact takes place, and by the size of the droplet in relation to topographic features. For example, a drop falling on a peak or slope may not develop full impact pressure; one falling in a crater may produce increased pressures due to shock wave collisions or "shaped charge" effects. This may explain the characteristic pitted appearance because if even shallow pits are formed, subsequent material loss occurs preferentially in the pits and continues to deepen them.

Material Response--Development of Damage. As described above, the solid surface is subjected to a multitude of sharp pressure pulses and jetting outflows, each of very short time duration and acting on a very small area. What then happens to the solid material is hard to generalize because it will depend on whether the solid is ductile or brittle, on its microstructure, and on whether the impacts are severe enough to produce single-impact damage. Adler (Ref 3) lists the primary causes of damage as direct deformation, stress wave propagation, lateral outflow jetting, and hydraulic penetration. At impact, the formation of the shock front in the liquid is accompanied by corresponding stress waves propagating into the solid; the solid response is therefore also impulsive and governed by its dynamic rather than static mechanical properties.

In ductile materials, a single intense impact may produce a central depression, with a ring of plastic deformation around it where the jetting outflow may remove material by a tearing action (Fig. 6). With less intense but repeated impacts, there is no immediate material loss, but randomly disposed dimples gradually develop, and the surface undergoes gradual deformation (often characterized by twinning) and work hardening. Metallographic and x-ray diffraction studies have shown that during this "incubation stage," these effects eventually extend to 30 to 50 μm below the surface, thereafter remaining about the same as actual erosion (material loss) then begins and progresses. The material loss may occur through propagation of fatiguelike cracks that eventually intersect to release erosion fragments. The fractures have often been described as transgranular. This process can be assisted by tearing that is due to increased liquid forces on irregular surface steps and fissures. In materials with pronounced nonuniform structure, damage will initiate at weak spots or in the weaker components. Figures 7 and 8 illustrate the character of erosion damage in a martensitic stainless steel (AISI type 403) and Stellite 6B, respectively.

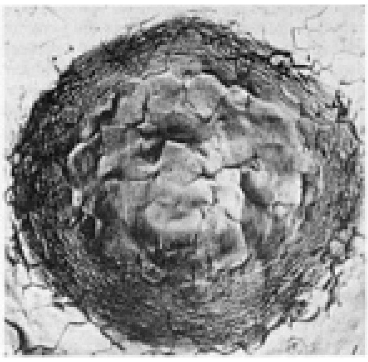

Fig. 6 Deformation due to a single impact on aluminum impacted by a short discrete jet of water at 750 m/s (2460 ft/s). Note the central depression, which is of similar diameter to the impacting jet, and the circumferential surface ripples surrounding it. Courtesy of J.E. Field, Cavendish Laboratory, University of Cambridge, United Kingdom

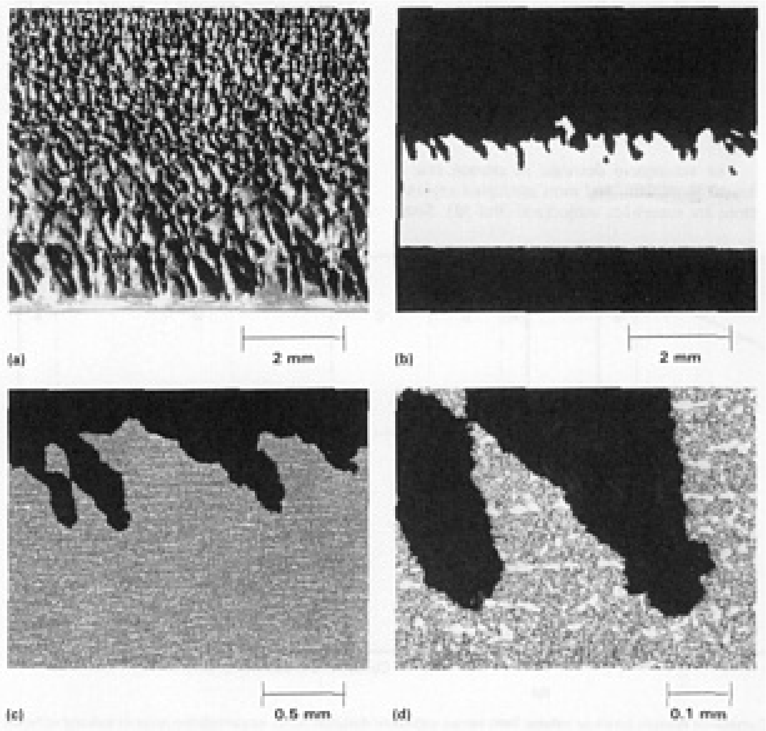

Fig. 7 Character of erosion in type 403 martensitic stainless steel. (a) Macrograph of eroded area. 10×. (b) Unetched section. 10×. (c) Section through several pits. GRARD II etch. 50×. (d) Enlarged portion of (c). 200×. Courtesy of Westinghouse Electric Corporation

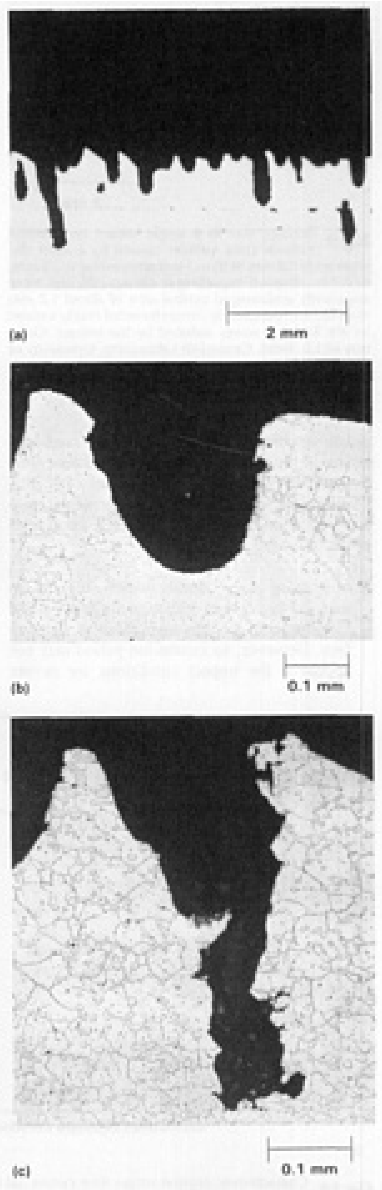

Fig. 8 Character of erosion in Stellite 6B alloy. (a) Unetched section. 10×. (b) and (c) Etched sections through specific pits. Both at 200×

In brittle materials, circumferential cracks may form around the impact site that are caused by tensile stress waves propagating outward along the surface (Fig. 9). In thin sheets subjected to impacts, material can spall off the inside surface due to the compressive stress wave from the impact reflecting there as a tensile wave.

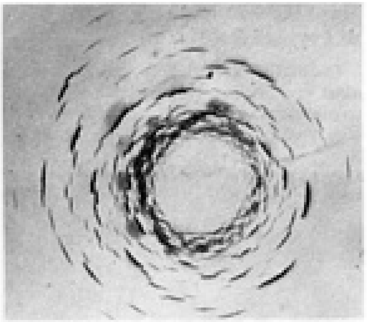

Fig. 9 Damage due to a single impact on a brittle material (zinc sulfide) caused by a short discrete jet of 0.8 mm (0.03 in.) (corresponding to a 5 mm, or 0.2 in., droplet) impacting at 300 m/s (985 ft/s). Note apparently undamaged central area of about 1.2 mm (0.05 in.) surrounded by circumferential cracks caused by the Rayleigh waves induced by the impact. Courtesy of J.E. Field, Cavendish Laboratory, University of Cambridge, United Kingdom, from Ph.D. thesis by D. Townsend

For materials and composite structures used in aerospace applications, it is difficult to generalize damage mechanisms. For example, in thermosetting polymers or chopped fiber-reinforced composites, the damage takes the form of chunking (removal of large-size lumps of material) from the surface (Ref 25). Furthermore, the initial measure of damage for radome and infrared window materials is not gross material removal, but impairment of electromagnetic transmission characteristics, which leads to loss of function. In the extreme, however, damage can be catastrophic, as shown in Fig. 2.

Corrosion Interactions. More research on corrosion interactions has been done for cavitation than for liquid impingement, but the general observations described below can apply to both.

In the early days before high impact pressures were understood, it was often supposed that liquid impingement as well as cavitation damage had to be largely or significantly corrosive in nature. It is now recognized, and has been proven experimentally, that such erosion can occur without any corrosive component. Moreover, under impingement of high intensity, material loss can occur so rapidly that corrosion--even if otherwise possible--does not have time to play a role. Nevertheless, at intermediate mechanical intensities there is opportunity for corrosion to weaken the material and facilitate its removal by the mechanical impact forces. Several investigators have shown some parallels between erosion and corrosion fatigue behavior.

Time Dependence of Erosion Rate

Qualitative Description. Liquid impingement erosion shares with cavitation erosion a unique characteristic that makes accurate long-term predictions or extrapolations of erosion nearly impossible. This is the very nonlinear nature of the progress of erosion with time, under constant impingement conditions (Ref 38). Qualitatively, the so-called "erosion-time pattern" depicted in Fig. 10 is generally composed of the following stages:

- *Incubation stage,* during which little or no material loss occurs, although roughening and metallurgical changes take place in the surface. However, an incubation period may not appear if the impact conditions are severe enough for each single impact to cause material loss
- *Acceleration stage,* during which the erosion rate increases rapidly to a maximum
- *Maximum rate stages,* during which the erosion rate remains constant or nearly so. The erosion rate for this stage is most commonly quoted as a single-number result of an erosion test. However, some tests show only a fleeting peak in the erosion rate-versus-time curve, with no prolonged steady rate
- *Deceleration (or attenuation) stage,* during which the erosion rate declines to some fraction (often from $\frac{1}{4}$ to $\frac{1}{2}$) of the maximum rate
- *Terminal (or final steady-state) stage,* during which the rate remains constant once again indefinitely. However, some tests do not show this stage, and the erosion rate either continues to decline or goes into a series of fluctuations. With some brittle materials or coatings, the rate can increase in what is called a

"catastrophic stage"

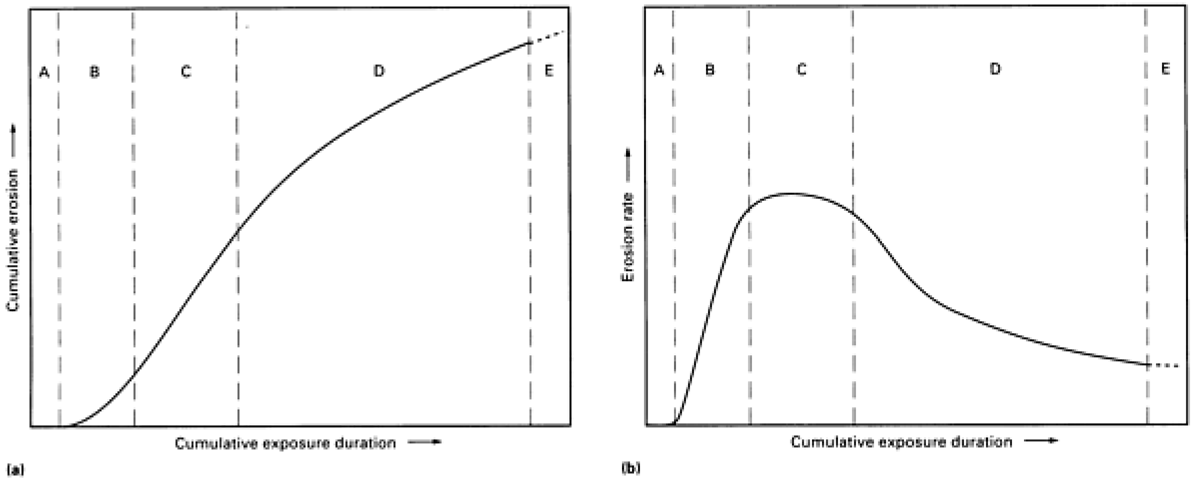

Fig. 10 Characteristic erosion versus time curves. (a) Cumulative erosion (mass or volume loss) versus exposure duration (time, or cumulative mass or volume of liquid impinged). (b) Corresponding instantaneous erosion rate versus exposure duration obtained by differentiating curve (a). The following stages have been identified thereon: A, incubation stage; B, acceleration stage; C, maximum rate stage (sometimes called first steady-state stage); D, deceleration stage; and E, terminal or final steady-state stage, if assumed to exist.

Figure 11 shows some nontypical curves that are sometimes encountered. All of the curves in Fig. 10 and 11 have been derived from actual test curves in the literature.

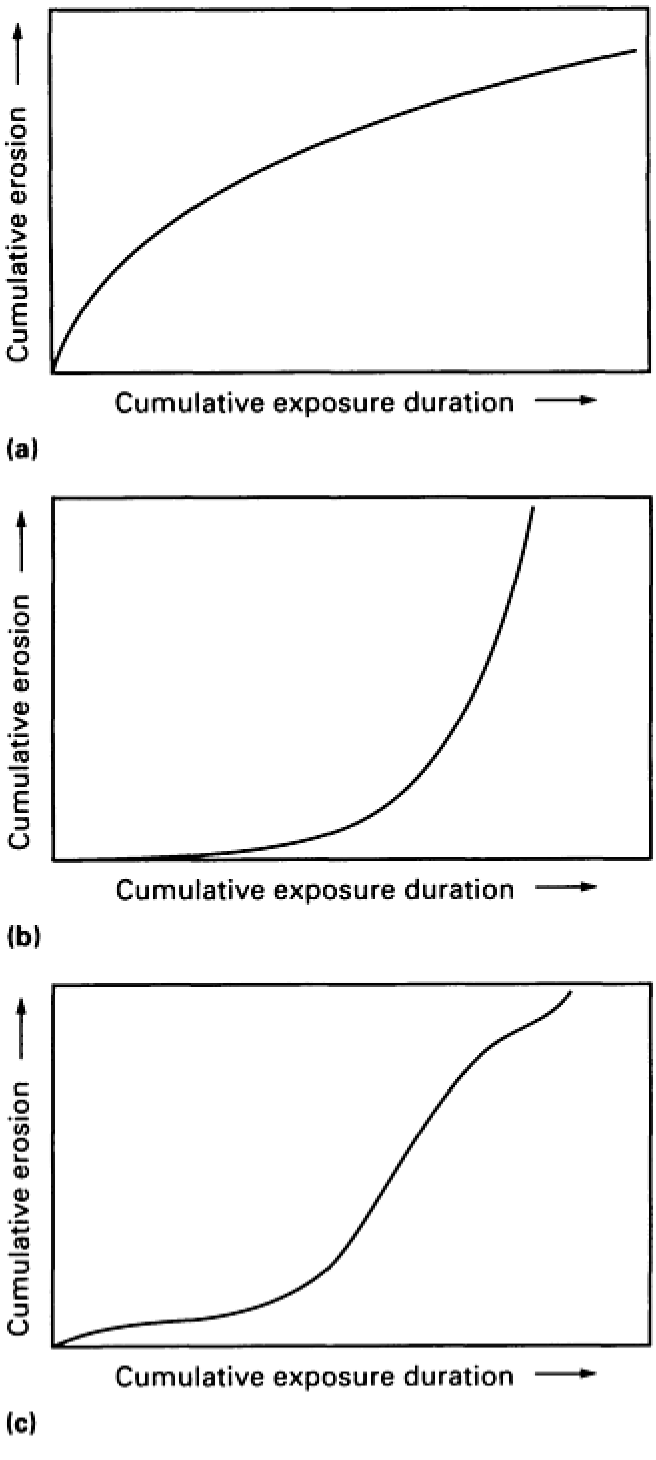

Fig. 11 Less common types of cumulative erosion versus time curves sometimes obtained. (a) Curve without incubation or acceleration stages, with continuously decreasing rate (obtained in this case with very small droplets and very high impact velocity). (b) Curve with continuously increasing erosion rate, resulting in catastrophic damage (obtained in this case on titanium carbide). (c) Curve with fluctuations in erosion rate (obtained in this case on a titanium alloy)

Reasons for Time Dependence. The incubation and acceleration stages are easy to explain in qualitative terms if one postulates that the removal of erosion fragments results from a fatiguelike failure mechanism. Then many impacts must occur in one area for a fragment to be loosened from the surface. The statistical nature of the process then results in a gradual transition--the acceleration period--from the incubation stage to the steady-state (maximum rate) stage.

The subsequent decrease in erosion rate is harder to explain, and most attempted explanations are somewhat conjectural (Ref 38). Some have also been based on the statistics of the damage mechanisms, combined with changes in the surface properties brought on by erosion itself. Some are based on the topographical changes in the surface: as the surface is roughened, the surface area is increased, and more energy is needed to continue erosion. Also, liquid drops will now tend to impact on the peaks or the slopes of the roughened surface; in both cases the impact pressures may be reduced. Finally, the liquid retained in erosion craters has been supposed to cushion and protect the surface.

Implications for Testing and Prediction. Clearly, this complicated time dependence of erosion, and the variations thereof, make it very difficult to define a single meaningful test result of an erosion test, or assign from that an erosion resistance of a material, or predict long-term erosion behavior from a short test. Many authors in the literature have proposed mathematical formulations for the erosion-time curve (or portions of it). Some of these have been essentially empirical, some have been based on proposed analytical models for the erosion process; however none so far has achieved general acceptance. See the discussion of "Comprehensive Prediction Methods and Erosion Theories" later in this article for additional information.

For the purpose of reporting test results, ASTM Standard Practice G 73 for Liquid Impingement Erosion Testing (Ref 39), as well as ASTM Standard Method G 32 for Vibratory Cavitation Erosion Testing (Ref 40) recommend that curves of cumulative mass loss versus time be shown in a test report, since any other parameters (for example, erosion rates) must be derived from that. For tabular data and comparisons (between materials or test conditions), ASTM G 73 prescribes tabulating the maximum erosion rate and a nominal incubation period, which is simply the intercept on the time axis of the maximum erosion rate line. In order to describe the longer-term behavior, some authors also use the terminal (final steady-state) erosion rate and some parameter that defines the intersection of that line with the maximum-rate line or the erosion axis (Fig. 12). Note that even this simplified model of the erosion-time pattern, consisting of three straight-line segments, requires four experimentally or analytically derived parameters to define it.

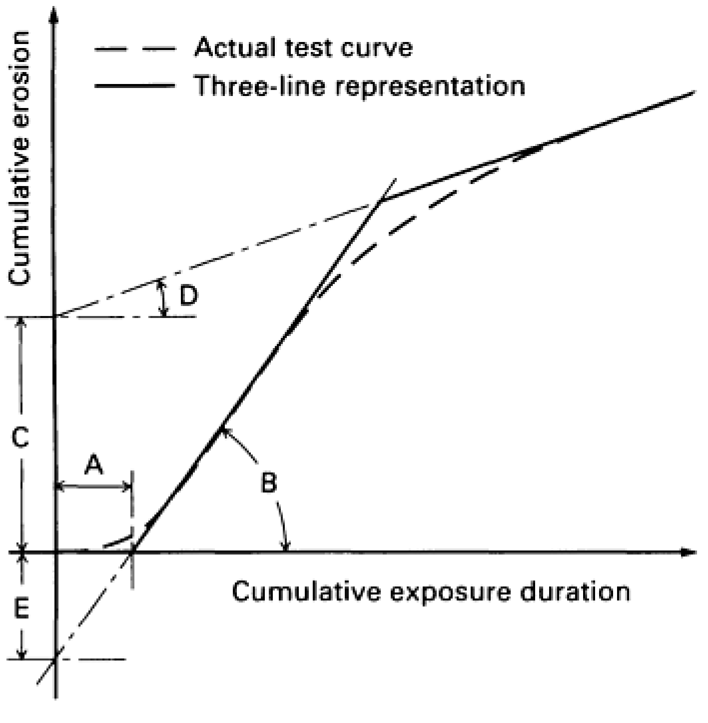

Fig. 12 The erosion versus time curve from Fig. 10, showing some numerical parameters that may be recorded to characterize the test results. A, nominal incubation period; B, slope representing maximum erosion rate; C, *y*-axis intercept of terminal erosion rate line; D, slope representing terminal erosion rate. ASTM G 73 (Ref 39) specifies that at least A and B be tabulated in any test report. Some authors have used E (*y*-axis intercept of maximum erosion rate line) in place of A; it tends to be constant when some parameters (for example, impact velocity) are varied.

The author's experience, in attempting to correlate test data from various sources, has been that the maximum erosion rate is the most predictable by empirical relationships. However, this parameter alone cannot be used to predict long-term

erosion in the absolute sense, and there are indications that it does not predict it well even in the relative sense. Thus, more work is certainly needed in reaching a generalized method for long-term erosion prediction.

Factors Affecting Erosion Severity

In order to understand the mechanics of erosion and to subsequently predict the erosion behavior of various materials, there are a number of critical parameters that must be examined. Following a brief discussion of the dimensionless parameters used for characterizing erosion, this section will review critical empirical observations regarding both impingement variables (velocity, impact angle, droplet size, and physical properties of liquids) and erosion resistance of materials, including the correlation between erosion resistance and mechanical properties and the effects of alloying elements and microstructure. Empirical erosion prediction equations developed from ASTM-sponsored test programs are also described.

Dimensionless Parameters for Describing Erosion

When a physical phenomenon is fully understood, it should be possible to describe it mathematically in terms of a functional relationship between a set of dimensionless parameters. This ensures dimensional consistency in the functional relationships, makes the equations independent of the set of units of measurement adopted, and can help ensure--by use of dimensional analysis--that the correct number of independent parameters are included for each dependent parameter of interest. Unfortunately, no such complete relationship for predicting erosion has been generally accepted to date, although some authors have made attempts toward it. Although an extended discussion of this topic is beyond the scope of this article, two dependent variables of interest in dimensionless form will be introduced. These are:

- The "rationalized erosion rate," R_e, which is defined as the volume of the target material lost divided by the volume of liquid impinged (where both pertain to the same area and the same time interval)
- The "rationalized incubation period," N_0, which is defined as the number of stress pulses experienced by a typical point on the target surface during the incubation period

In the following discussions, the "erosion rate" referred to is always the "maximum erosion rate" (see the previous section of this article on "Time Dependence of Erosion Rate"). The empirical data regarding incubation periods are much less abundant, but several studies have suggested that the nominal incubation period defined in Fig. 12 is approximately inversely proportional to the maximum erosion rate and, moreover, the product of the rationalized quantities R_eN_0 is on the order of unity (Ref 41).

Impingement Variables

Velocity Dependence/Threshold Considerations. It is conceptually very attractive to suppose that there is a "threshold velocity"--dependent on the material--below which no erosion would occur, analogous to the endurance limit in fatigue. Several investigators have presented evidence for such a threshold (Ref 22, 42), which may also depend on droplet size (Ref 43). However, the author has found that most test data, from many sources, seem to better fit a simple power law in which the rationalized maximum erosion rate varies with about the 4th to 5th power of impact velocity (Ref 44). For brittle materials, exponents as high as 6 to 9 have been reported (Ref 45). At low impact velocities, the incubation period may become so long that no actual material loss takes place in a reasonable testing or operating time, giving the appearance of a threshold. Thus, the question of a threshold phenomenon is not yet firmly settled.

Dependence on Impact Angle. It is generally considered that, to a first approximation, erosion depends on only the normal component of the impact velocity; thus, because of the strong dependence on impact velocity, erosion is reduced strongly as impacts become more glancing. Some investigators have suggested a small added contribution from the tangential component, and intuitively one might suspect that once a surface becomes roughened by erosion, the effect of the tangential component would become more pronounced.

Dependence on Droplet Size. By and large, test data show that R_e decreases with drop size (Ref 41, 43); that is, a given total amount of liquid does less damage if divided into smaller drops, even though this implies a greater number of impacts on the surface. There is no obvious explanation for this phenomenon. One suggested explanation is that it is due to the shorter time duration of each pressure pulse with smaller drops; another postulates that it is a material-related size

effect similar to those in fatigue notch sensitivity or in metal cutting, where the spatial extent of imposed stresses must exceed some characteristic dimension.

Dependence on Liquid Properties. Most liquid impact erosion tests have been conducted with water at near normal atmospheric conditions. Knowledge of how erosion varies with the physical properties of the liquid is necessary if one wants to extend empirical relationships to other liquids and conditions, and also if one wants to construct a true analytical model that is dimensionally consistent. The results of one investigation (Ref 46) suggested dependencies on approximately the 2nd to 2.5th power of liquid density and the $\frac{1}{2}$ to $\frac{3}{4}$ power of the inverse of viscosity; the dependence on acoustic velocity (which theoretically enters into impact pressure as well as acoustic impedance relationships) remained unclear. More work in this area is desirable.

Erosion Resistance

What Is Erosion Resistance? In the absence of any widely accepted, dimensionally consistent, analytical model for the erosion process, it is impossible to specify an independent definition, dimensions, or units for the property of erosion resistance. Although a concept of "erosion strength" having the units of a mechanical strength or strain energy property has been proposed (Ref 42), this has not gained wide acceptance.

All one can do is to conduct erosion tests and compare the results between different materials. Generally one material is selected as a reference material and results for the others are referred to that. ASTM G 40 (Ref 1) defines a "normalized erosion resistance" as follows: "The volume loss rate of a test material, divided into the volume loss rate of a specified reference material similarly tested and similarly analyzed . . ." In Ref 44 the reference material is austenitic stainless steel of hardness HV 170. ASTM G 73 (Ref 39) defines an "erosion resistance number" based on up to three reference materials covering a range of resistances. Some recent cavitation test programs have adopted stainless steel type 308 weld overlay as the reference.

Correlations with Mechanical Properties. Hardness has a strong effect on erosion resistance, but by itself is not a sufficient indicator. For the same or similar materials, erosion resistance generally varies with about the 2nd to 2.5th power of Vickers hardness number, but that does not necessarily apply when different types of materials are compared. For example, austenitic stainless steels have higher resistance than martensitic stainless steels of the same hardness, and cobalt-base alloys (for example, Stellites) have an even higher resistance in relation to hardness (Ref 44).

Other parameters based on mechanical properties have been proposed as indicators of erosion resistance. These include the strain energy to fracture parameter, and the so-called "ultimate resilience" ($s_u^2/2E$), where s_u is ultimate strength and E is modulus of elasticity; neither is very successful over a broad range of materials (Ref 44).

Since liquid impingement and cavitation erosion is due to repeated stress pulses and thus related to fatigue, some authors have tried unsuccessfully to correlate resistance with endurance limit or finite fatigue life. Recently, however, Richman and McNaughton (Ref 47) demonstrated good correlation with cyclic deformation properties for a number of alloys and pure metals.

Several authors (Ref 48, 49, 50) who have attempted theoretical analyses of the erosion process have come up with much more complicated parameters to define the resistance of a material, but these parameters tend to be difficult to evaluate or, in some cases, fail to predict the empirically observed dependencies.

Effects of Alloying Elements and Microstructure. The coverage in this section is based on cavitation erosion as well as liquid impingement studies. See also the article "Cavitation Erosion" in this Volume for additional information.

Improved erosion resistance has been associated with alloying elements such as chromium, manganese, and cobalt. The effect of nickel is inconsistent. For example, a steel containing 12% Cr and 4% Ni is better than straight 12% Cr steel, but some studies have found nickel deleterious. Fine microstructure is advantageous and so is the ability of the surface layer to work harden as a result of impact-induced deformation. The extremely high erosion resistance of Stellite (cobalt-chromium-tungsten alloy) has been variously explained by a microstructure consisting of small hard carbide particles in a strong but more ductile matrix, or by crystallographic transformations induced by the liquid impacts.

Very high resistance has been reported for chromium-manganese steels (about 10% Cr and 12% Mn) that undergo austenitic-martensitic phase transformation under impingement (Ref 51). Akhtar *et al.* (Ref 52) investigated stainless steel

as well as nickel and cobalt-base weld overlays and found certain optimum composition parameters for each, but not the same for all. They also found that stress-induced martensitic transformations control erosion of austenitic stainless steels.

Simoneau *et al.* (Ref 53) found that low stacking-fault energy is the key to high erosion resistance in austenitic stainless steels as well as cobalt-base alloys. They have developed a new class of cobalt-containing austenitic stainless steels with erosion resistance comparable to cobalt-base alloys such as Stellite. The low stacking-fault energy results in a "cavitation-induced hardened surface layer" featuring "planar deformation, fine twinning, high strain hardening and high fatigue resistance, smoother eroded facies, fine eroded particle size."

Comprehensive Prediction Methods and Erosion Theories

Reference 44 gives a simple empirical prediction equation for the maximum erosion rate in liquid impingement erosion, as well as a simplified time dependence factor based on the assumption that the rate continues to decline indefinitely from its maximum. Slightly more elaborate equations for maximum erosion rate and for incubation period are given in Ref 39 and 41, based on an interlaboratory test program sponsored by ASTM Technical Committee G-2 on Wear and Erosion. These are:

$$\log R_e = 4.8 \log V - \log NER - 16.65 + 0.67 \log d + 0.57\ J - 0.22\ K$$

$$\log N_0 = -4.9 \log V + \log NOR + 16.40 - 0.40\ J$$

where R_e and N_0 are the rationalized erosion rate and incubation period, respectively, V is impact velocity (m/s) normal to the target surface, d is drop diameter (mm), J is 0 for droplet impingement and 1 for repetitive impacts against cylindrical jets, K is 0 for flat targets and 1 for round or curved targets, and NER and NOR are the "erosion resistance number" and "incubation resistance number," respectively, as defined in Ref 39. The latter are normalized resistance values with respect to AISI type 316 stainless steel of hardness about HV 165.

The purely empirical formulations given above are based on a wide collection of test data from different laboratories with widely different impingement conditions. With all the variabilities that occur, no erosion prediction can be very accurate, but the above equations have been shown to predict the maximum erosion rate within a factor of less than 3 for most test results with essentially uniform drop size and impact velocity conditions. The error for incubation period is greater. In real situations with a distribution of drop sizes and impact velocities, prediction is still more unsure.

These equations still do not suffice for long-term prediction. Although Ref 44 offers a very tentative correction factor for the time dependence, it is based on the assumption of a continually decreasing erosion rate. A more conservative approach may be to assume that the "terminal erosion rate" is approximately 30 to 60% of the maximum rate and continues indefinitely. Rao and Buckley (Ref 54) have also tried to unify the time dependence from many test data.

Some other comprehensive prediction methods and theories should be mentioned. Springer (Ref 48) presents semi-analytically based relationships, but they overestimate incubation periods and underestimate erosion rates by about 4 orders of magnitude; this was subsequently attributed by the author to a numerical error in calculating one of the empirical constants from experimental data (Ref 55).

Ruml (Ref 56) has proposed an empirical equation for the whole erosion-time relationship in terms of dimensionless parameters; many empirical constants are required. Karimi and Leo (Ref 49) offer a new analytical model for erosion rates and their time dependence, but it involves statistical parameters difficult to determine. Other recent contributions toward representation of long-term erosion include those of Beckmann (Ref 50), Shubenko and Kovalsky (Ref 57), and Stanіša *et al.* (Ref 58). Perhaps these new efforts will eventually result in a practical generalized prediction scheme.

Test Methods for Erosion Studies

Erosion tests are conducted to evaluate materials as well as to study the effects of other variables on erosion. Basic studies of single impacts have been conducted with "liquid gun" devices, in which a small quantity of liquid is ejected through a carefully designed nozzle and impacts a stationary specimen (Ref 33), or by projecting a solid target against a stationary liquid or gelatine body (Ref 37).

However, for multiple-impact studies and for evaluating the resistance of materials, the usual approach is to attach the specimen(s) to the periphery of a rotating disc or arm, such that in their circular path they repeatedly pass through and impact against liquid jets, sprays, or simulated rain drops (Ref 20, 21, 39, 41, 42). The velocity of the specimen then determines the impact velocity. Such test facilities range from small laboratory apparatus with specimen velocities of up to about 200 m/s (655 ft/s) to large self-contained facilities (some with vacuum-controlled test chambers); some of the latter are capable of impact velocities up to 1000 m/s (Mach 3, or 3300 ft/s). ASTM G 73 (Ref 39) gives comprehensive guidelines for conducting this type of test and for analyzing the data.

The successful selection and development of improved materials and coatings for rain erosion have been largely based on rotating arm tests. Service experience and in-flight tests have confirmed that the laboratory tests predict the correct relative erosion resistance as well as the failure modes. For high supersonic rain erosion studies, however, specimens have been attached to rocket sleds propelled at speeds up to 1700 m/s (5580 ft/s) through an artificial rain field (Ref 45). Wind tunnels have also been adapted for rain erosion tests.

As noted earlier, cavitation erosion test methods such as the vibratory method (Ref 40), the cavitating jet method, and the submerged rotating disk method have also been used to screen materials for service under liquid impingement conditions.

Means for Combatting Erosion

Modification of Impingement Conditions. If possible, the geometry and/or fluid dynamics should be modified to reduce the amount of liquid impacting the exposed surfaces, to reduce the impact velocity of the droplets (or change the impact angle to reduce the normal component of impact velocity), to reduce the droplet size, or to reduce time of operation under the most severe conditions. Efforts in all of these directions are made in steam turbines as well as in aircraft and missiles, but details are beyond the scope of this discussion.

Material Selection and Protective Shielding. Some of the material aspects have already been covered in earlier sections of this article. Figure 13 provides an overview of relative erosion resistance of metallic alloys, based primarily on a series of results (from both impingement and cavitation tests) examined in Ref 44. Some items from recent investigations (Ref 52, 53, 59, 60) have been added; most of these were cavitation tests. Because of the inconsistencies inherent in erosion testing, this can be used only as a rough guide. Some investigators have found that the relative resistances of some materials depended on the impact velocity, implying significantly different velocity dependencies for them.

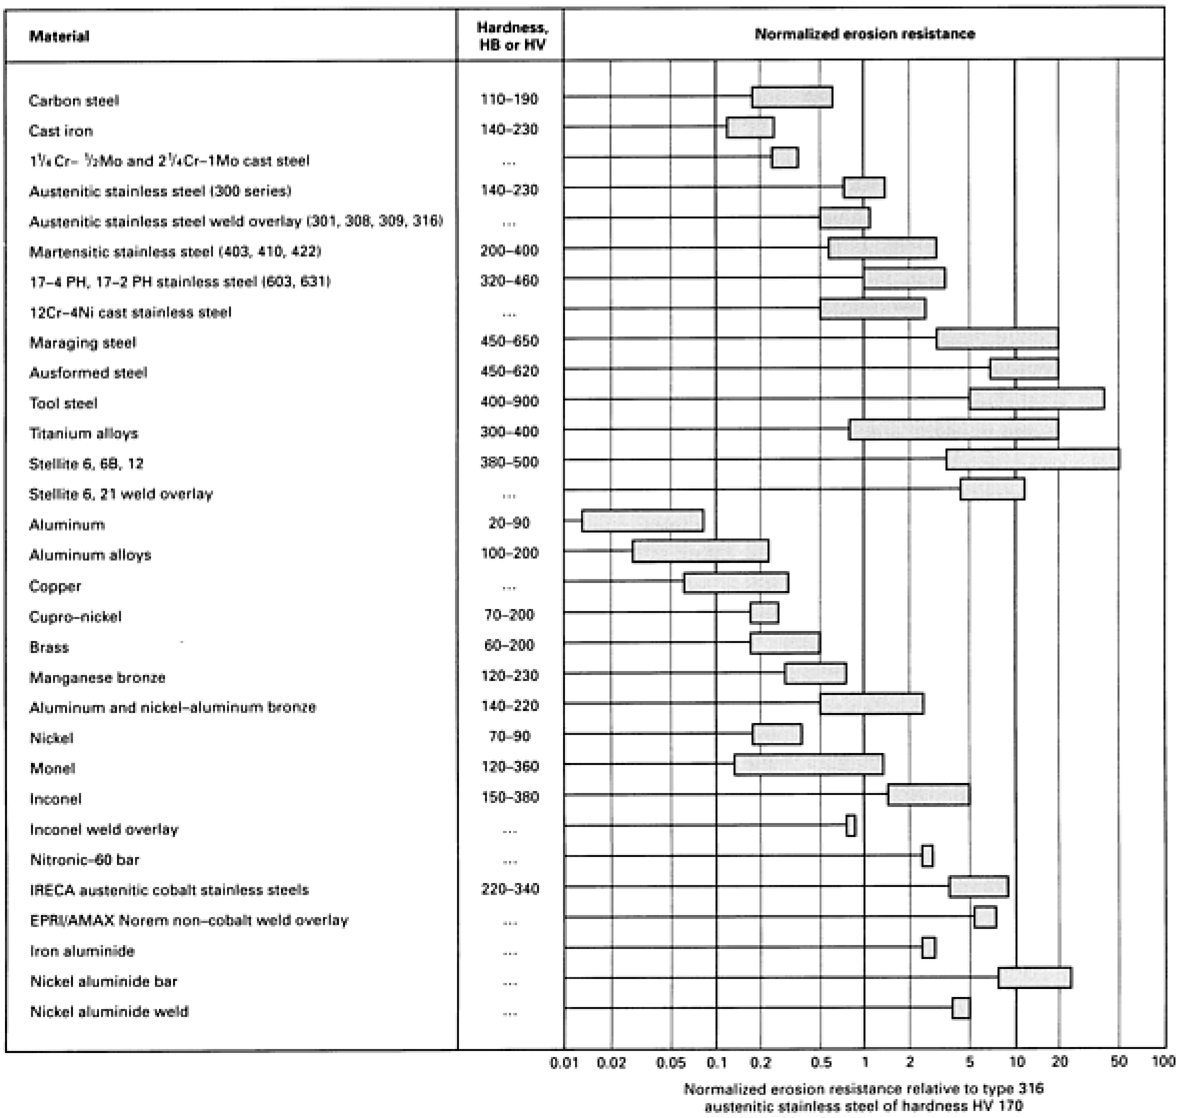

Fig. 13 Normalized erosion resistance of various metals and alloys relative to type 316 austenitic stainless steel of hardness 170 HV (the erosion resistance number according to ASTM G 73). Data deduced from many sources in the literature including both impingement and cavitation tests. It must be cautioned that erosion test data are not very consistent, and the information herein should be used only as a rough guide.

Shielding or cladding approaches for erosion protection have usually employed a harder layer than the base material, or one that by virtue of its composition or microstructure is more resistant to erosion (and corrosion). However, another approach that can be successful in low-intensity environments is the use of elastomeric coatings, which, by virtue of their elasticity, reduce the magnitude of the impact pressures; this approach is widely used against rain erosion at moderate speeds.

Table 1 lists some of the materials and coatings used for rain erosion applications, in order of preference as specified by Schmitt (Ref 25).

Table 1 Materials in use for rain erosion protection

"Recommended" as well as "not recommended" materials are listed in order of preference or resistance. "Not recommended" materials may have good erosion resistance but other undesirable properties such as poor shock resistance.

Materials for aircraft radomes	
Recommended	**Not recommended**
Elastomeric coatings:	
Polyurethane	Silicone
Fluorocarbon	Acrylic
Neoprene	Polyester
Bulk plastics:	
Modified polyphenylene oxide	Tetrafluoroethylene
Polycarbonate	Polyimide
Polyethylene	Epoxy
Polyacetal	Acrylonitrile-butadiene-styrene (ABS)
Nylon	
Modified acrylic	
Reinforced composites:	
Glass cloth reinforced epoxy	Chopped glass reinforced epoxy or polyester
Filament wound glass epoxy	Kevlar-epoxy
Quartz cloth reinforced epoxy	

Materials for missile radomes	
Recommended	**Not recommended**
Monolithic ceramics:	
Hot-pressed silicon nitride	Slipcast fused silica
Alumina	Boron nitride
Beryllia	
Cordierite	
Reaction-sintered silicon nitride	
Reinforced ceramics:	
1-D celcon polyacetal silica	. . .
Alumina cloth-silica matrix	
3-D reinforced silica-silica	

Materials for optical and infrared domes	
Recommended	**Not recommended**
Glasses and ceramics:	
Sapphire	. . .
Spinel	
Calcium aluminosilicate	
Calcium borosilicate	
Magnesium fluoride	
Clear fused silica	
Chalcogenides:	
Germanium	. . .
Zinc sulfide	
Gallium arsenide	
Zinc selenide

Slurry Erosion

John E. Miller, White Rock Engineering, Inc.

Introduction

A SLURRY can be described as a mixture of solid particles in a liquid (usually water) of such a consistency that it can be readily pumped. The term "slurry erosion" is strictly defined as that type of wear, or loss of mass, that is experienced by a material exposed to a high-velocity stream of slurry. This erosion occurs either when the material moves at a certain velocity through the slurry or when the slurry moves past the material at a certain velocity.

Typical pumpable slurries possess inherent "apparent abrasivity," which must be determined by testing to enable cost predictions for pump replacement parts or other equipment used for slurries. Apparent abrasivity, without inhibition, is the complex synergistic reaction of many factors (Fig. 1). This reaction, known as the Morrison-Miller effect (Ref 1), is such that the wear response of a given material in a certain slurry does not indicate how that material would respond to another slurry. Similarly, the effect of a certain slurry on one material does not indicate how it would affect another material.

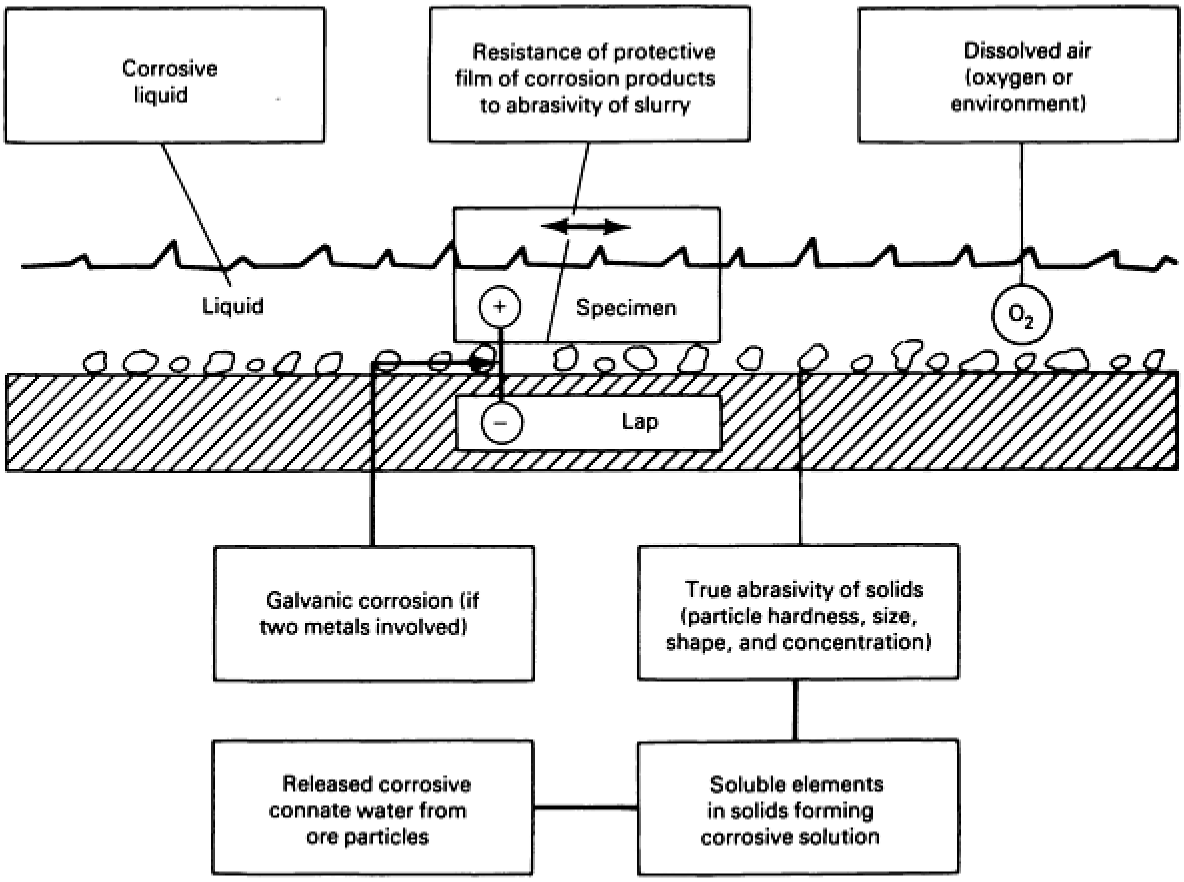

Fig. 1 Synergistic effects of seven factors in slurry abrasivity

Other modes of wear are also encountered when handling slurries, the most severe of which is the combination of abrasion and corrosion. The elusive erosion-corrosion combination was recognized as early as 1967. As shown in Fig. 2, it was found that the mass-loss rate was the reverse of what had been expected.

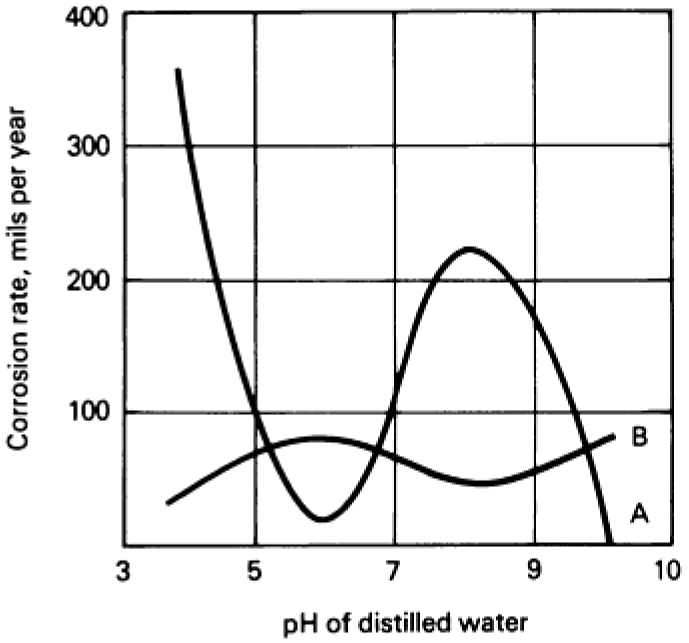

Fig. 2 Effect of pH of distilled water on erosion-corrosion of carbon steel at 50 °C (120 °F) and velocity of 12 m/s (39 ft/s). Curve A represents erosion-corrosion disk, and curve B represents specimens immersed in tank. Source: Ref 2

The slurry-handling process has been of increasing interest to industry, particularly because of the relatively new method of transporting minerals (coal) and other solids over long distances through pipelines at pressures in the order of 14 MPa (2 ksi). Therefore, this article identifies a variety of slurry wear modes, their effects, and the tests associated with them. Dry abrasivity is another wear mode that is only briefly discussed in this article because it is seldom, if ever, encountered in slurry handling.

Slurry Wear Modes

The most common wear modes are described below and illustrated in Fig. 3. Several of these modes will be characterized by:

- The types of motion to which they respond, that is, reciprocating, oscillating, circular, or continuous
- The slurry media, that is, oil or liquids other than water
- The ratio of areas of mating parts, as shown in Fig. 3

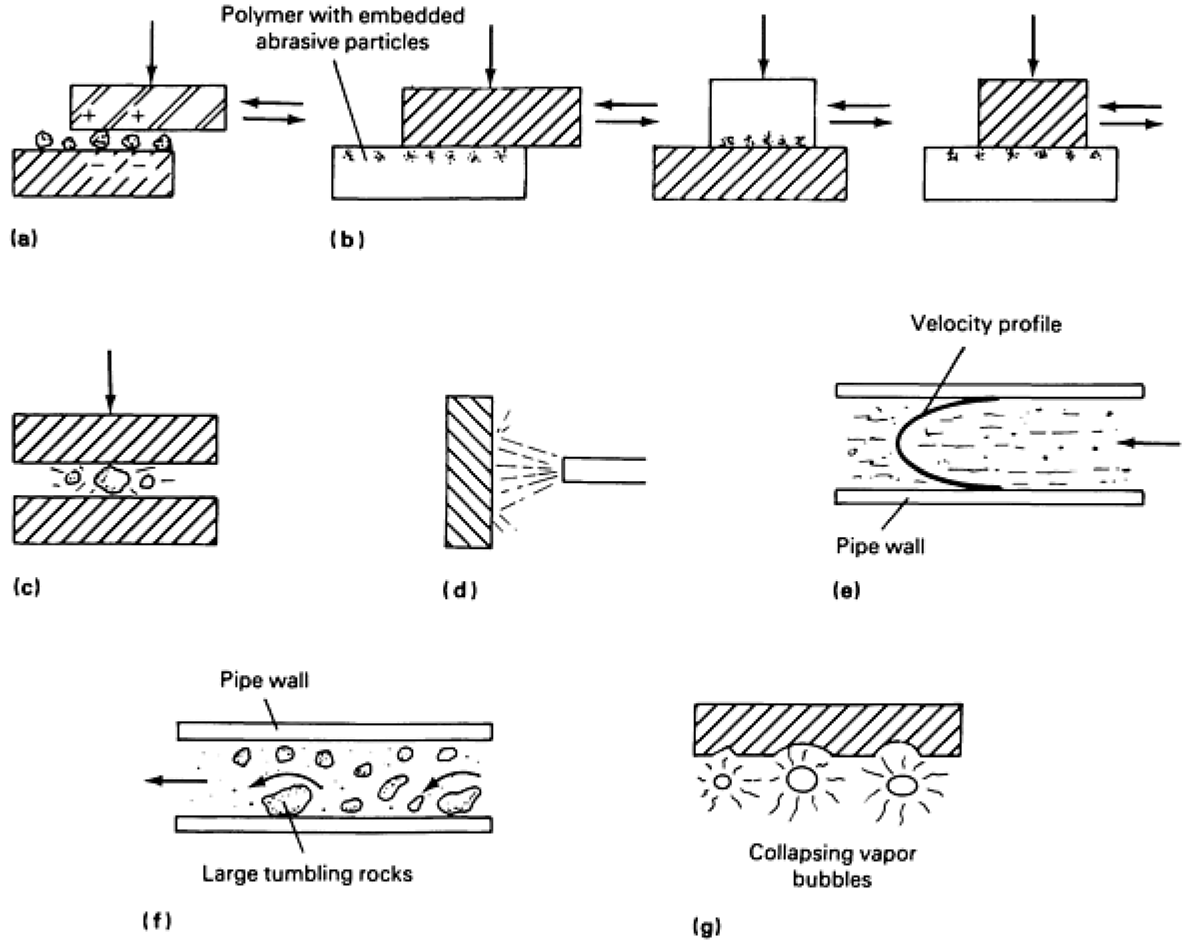

Fig. 3 Slurry erosion wear modes. (a) Abrasion-corrosion. (b) Scouring wear, with wear areas equal (left) and unequal (center and right). (c) Crushing and grinding. (d) High-velocity erosion. (e) Low-velocity erosion. (f) Saltation erosion. (g) Cavitation

Abrasion-corrosion wear is the result of any metal-to-metal rubbing in the presence of abrasive solids in a corrosive liquid. This is the most destructive and misunderstood mode encountered when handling slurry, aside from high-velocity erosion. Typical parts of reciprocating pumps that are involved are: metal-to-metal valves and seats (upon each closure), metal piston parts that rub on metal liners and plungers, or piston rods that rub against metal stuffing box parts or trim. In the case of parts of different metals exposed to slurry, electrolytic effects are included in this mode.

Scouring wear is encountered with elastomer-to-metal rubbing. Abrasive solid particles become embedded in the softer elastomer, or rubber, as in the case of pistons, packing, and valve inserts.

Crushing and grinding occur in abrasive metal-to-metal contact. An example is a valve that repeatedly closes with great force against solid particles that are trapped between the valve and seat at closure.

High-velocity erosion can become very destructive, although it is not the mode of wear that is usually found in reciprocating pumps handling slurry. High velocity is usually considered to be greater than 6 to 9 m/s (20 to 30 ft/s). When a valve seat or piston wears to the extent that a slight leak develops, the extremely high velocity of slurry leakage through that small gap can result in catastrophic and rapid failure of the parts, as well as the costly liquid end of the pump (Fig. 4 and 5). Slurry-throttling valves and parts that are downstream also experience this type of rapid wear, as do the impellers and cut-water mechanisms of centrifugal pumps.

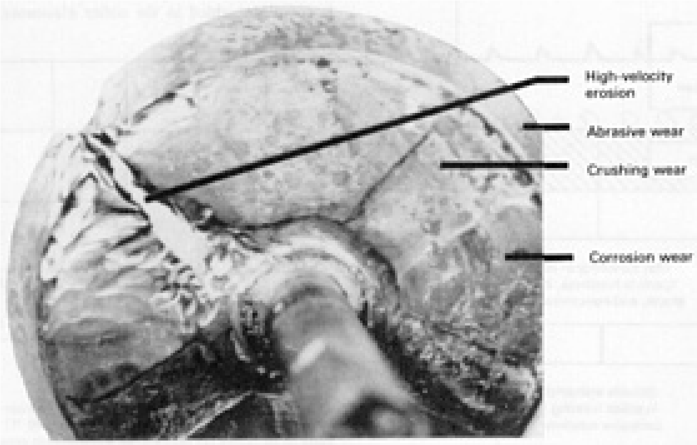

Fig. 4 Typical worn and washed-out valve

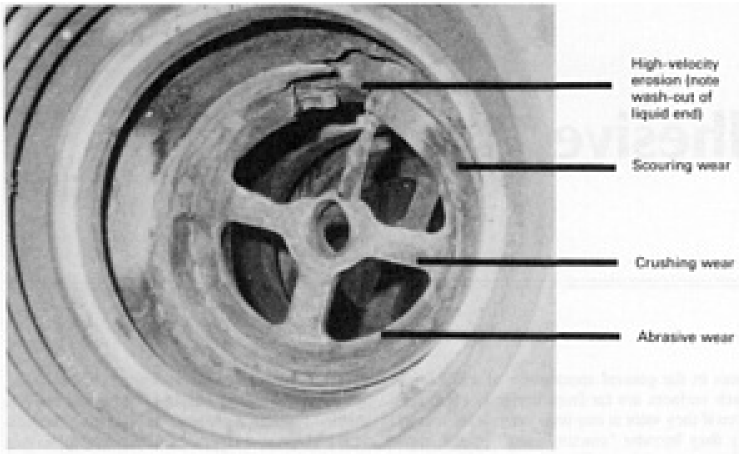

Fig. 5 Typical worn and washed-out slurry valve seat

Low-velocity erosion is usually a low-rate wear mode that occurs when there is a flow of slurry at regular low velocities. In a pipeline with laminar flow, the velocity profile (in the shape of a parabola) is such that the velocity near the wall of the pipe is nearly zero, and minimum wear takes place. The impellers and cut-water mechanism of centrifugal pumps are sometimes subjected to this mode.

Saltation wear results from the transport of a sediment, where the particles are moved forward in a series of short intermittent bounces from a bottom surface. Rapid wear of this type occurs, for example, in pipelines that transport phosphate rock from slurry pit to the processing plant. The pipe requires frequent turning to distribute the wear.

Cavitation can result in damage to the metal in the liquid end of the pump. The parts of a reciprocating pump can also sustain damage from the microscopic, but intense, liquid pressure blasts against the metal near the cavitation area, following the repeated collapse of the vapor bubbles.

Effects of Wear

The effect of solids concentration on abrasivity should be recognized. Figure 5 shows how abrasivity increases very rapidly from a concentration of 0 to about 10%, and then begins to flatten. It is interesting to note that the slurry that is well-known in the oil well drilling industry as "drilling mud" in itself is not abrasive. Rather, its abrasivity comes from the solid particles of crushed and broken rock, or cuttings, that are generated in the drilling process. Contaminated mud is usually "cleaned" by settling, screening, or being subjected to centrifuge. The curve in Fig. 6 is supported by the fact that

the sand content of drilling mud must be reduced to less than 2% before effective improvement in the life of pump parts can be realized.

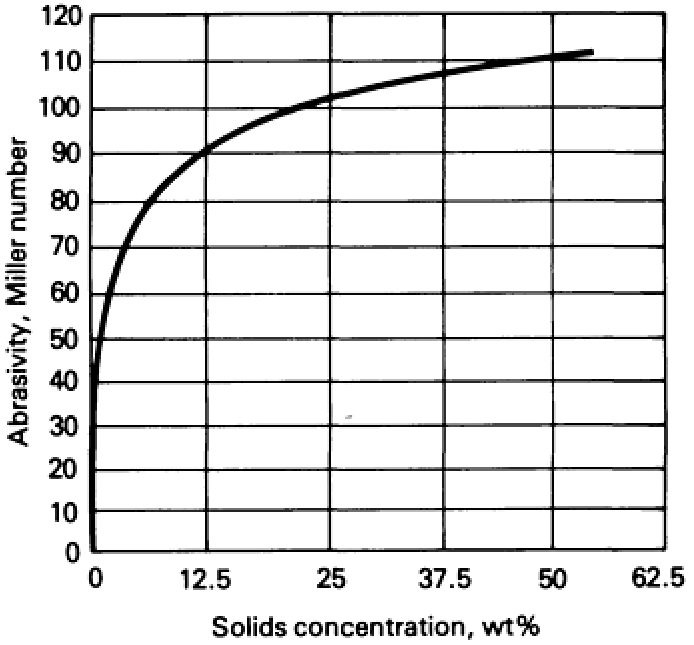

Fig. 6 Solids concentration versus abrasivity for 70 mesh urn sand, showing abrupt change in relationship of solids concentration to abrasivity in region below about 10 to 12% solids

ASTM G 75 Tests

Miller numbers are used to determine the abrasivity of slurries, based on the rate of metal loss from a standard 27% chrome-iron wear block that reciprocates through any slurry, on a rubber lap, with an imposed load of 22.2 N (5 lbf) placed on the wearing block. The higher the number, the greater the aggressive effect of the slurry on part life. The additional effect of corrosion (usually present in liquid slurries, even those mixed with distilled water) was slow to be recognized. This was because such chrome-iron is rather corrosion resistant and the original test actually fulfilled its objective to reveal the "true abrasivity" of the dry particles. The effects of both abrasion and corrosion must be recognized in the operation of any slurry-handling system.

Table 1 lists typical Miller numbers for selected slurry materials. The wide variation in Miller numbers for some materials is due to the inclusion of varying amounts of "tramp" materials that usually occur with the basic mineral. Information about the factors that contribute to Miller number abrasivity can be found in the ASTM G 75 standard.

Table 1 Typical Miller numbers for selected slurry materials

Material	Miller number(s)
Alundum (400 mesh)	241
Alundum (200 mesh)	1058
Aragonite	7
Ash	127
Ash, fly	83, 14
Bauxite	9, 33, 50, 76, 134
Calcium carbonate	14
Carbon	14, 16
Carborundum (220 mesh)	1284
Clay	34, 36
Coal	6, 10, 21, 28, 47, 57
Copper concentrate	19, 37, 58, 68, 111, 128

Detergent	6, 8
Dust, blast furnace	57
Gilsonite	10
Gypsum	41
Iron ore (or concentrate)	28, 37, 64, 79, 122, 157, 234
Kaolin	7, 30
Lignite	14
Limestone	22, 30, 39, 43, 46
Limonite	113
Magnesium hydrate	4
Magnetite	64, 71, 134
Microsphorite	76
Mud, drilling	10
Nickel	31
Phosphate	68, 74, 84, 134
Potash	1, 2
Pyrite	194
Quartzite	99
Rutile	10
Salt brine	11
Sand and sand fill	51, 68, 85, 116, 138, 149, 246
Sea bottom	11
Shale	53, 59
Serpentine	134
Sewage, digested	15
Sewage, raw	25
Sodium sulfate	4
Soda ash tailings	27
Sulfur	1
Tailings (all types)	24, 61, 91, 159, 217, 480, 644
Tar sand	70
Waste, nickel	53
Waste, coal	22, 28

Slurry Abrasion Response (SAR). It soon became evident that the response of various metals differed widely in different slurries. Therefore, a new test, the Miller number "in reverse," was developed. The slurry abrasion response (designated by an SAR number) of any selected material in any given slurry is based on the same Miller number procedure. It was demonstrated that the aspects of corrosion varied widely with different materials and interfered or sometimes obscured the effects of true abrasive erosion, or wear.

Dry Abrasivity

As a result of further work, it was decided that all Miller or SAR number tests would be run in duplication. One would have the "as-received" material, and the other would have an inhibited slurry obtained by adding a dose of strong NaOH solution to raise the pH to the order of about 13. Thus, a "number" approaching the dry abrasivity could be obtained by the reduction of corrosion effects. An increase in the pH of the slurry by the addition of NaOH (as is sometimes done in actual systems) reduces the Miller or SAR number, in most cases.

Sliding and Adhesive Wear

K.C. Ludema, University of Michigan

Introduction

SLIDING AND ADHESIVE WEAR refer to a type of wear generated by the sliding of one solid surface along another surface. Erosion, cavitation, rolling contact, abrasion, oxidative wear, fretting, and corrosion are traditionally excluded from the class of "sliding" wear problems even though some sliding (slip) may occur in some of these types of wear. Apparently, sliding wear is a category of wear that is "left over" when all other types of wear are identified under separate headings.

Adhesive wear is as ambiguously defined as is sliding wear, though the two are not strictly synonymous. Adhesive wear denotes a wearing action in which no specific agency can be identified as the cause of the wear. Adhesion has been confirmed in the 1930s to be a major contributor to sliding resistance (friction) and was inferred in mechanics at least to be operative in wear as well. Thus, if no abrasive substances are found, if the amplitude of sliding is greater than that in fretting, and if the rate of material loss is not governed by the principles of oxidation, and so on, adhesive wear is said to occur.

Adhesion is most clearly demonstrated in sliding systems when, for example, a shaft seizes in a bearing. Again, adhesion is implicated in galling and scuffing (which some researchers classify as surface damage rather than wear) even when no material is lost from the system. From these examples, it can be seen that adhesion is not the cause of wear, but only the consequence of contact. Wearing occurs when interfaces in contact are made to slide and the locally adhered regions must separate. This separation may occur by one or two of the failure modes of solids, resulting in a very wide range of wear rate.

The purpose in defining and studying specific wear modes is to find ways to prolong the wear life of sliding systems. Each mode of wear can best be resisted by the proper choice of material, lubricant, and method of operation. Unfortunately, the making of slow-wearing products requires considerable experience, because there are very few fundamental principles in friction and wear to use in the design process.

Sliding Surface

The focus of this section is the case of long-distance sliding of nominally clean and dry surfaces in the general atmosphere of technology. Such surfaces are far from perfectly clean, and even if they were at one time very clean, inevitably they become "contaminated" by the atmosphere around them. We may thus define "standard conditions" for sliding, for the three classes of materials (metals, polymers, and ceramics) as follows:

- Metals will usually be covered with a film of oxide, which is covered by a second film of adsorbed gases and hydrocarbons (oils)
- Polymer surfaces may contain absorbed water and "bloomed" plasticizers, and will likely be covered with mold release agents, adsorbed gases, and oils
- Ceramic materials will also be covered with adsorbed gases and oils; in addition, the nonoxide ceramics may oxidize

The thickness of the adsorbed layers and coatings is of the order of 10 nm (100 Å). Such thin films are not discernible by optical means or by scanning electron microscopy (SEM) techniques. The presence of thin films must therefore be verified by sophisticated chemical analytical instruments, or taken on faith. These films are very important because they intervene in the bonding or adhesion between the substrate materials. Variations in the thickness and properties of these films is one major reason for the very wide range of friction data reported for all materials.

These films control the variations in wear as well. The reason that these films control wear becomes evident in the example that follows. When a piece of brass "contacts" a piece of silicon carbide, the weight of the upper body is carried through a chain of bonds, from the silicon carbide to a layer of silicon dioxide, to two layers of adsorbed gas, to a layer of ($CuO + ZnO_2$), and finally to the brass. The contact bridge between the brass and silicon carbide is shown in Fig. 1.

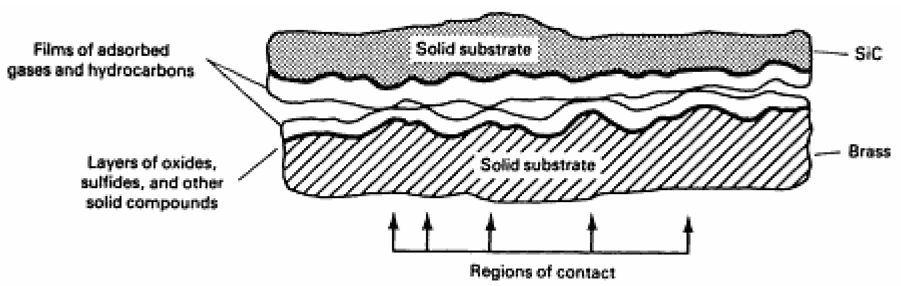

Fig. 1 Schematic of a bond bridge produced when two solid surfaces are in contact with each other. It should be noted that when two rough surfaces are brought together, actual contact occurs only in a few isolated regions.

When two such surfaces slide against each other, there will be some squeezing out of the adsorbed films, producing some contact between solid (oxide, sulfide, and so on) layers. If the contact pressure is high, a solid layer may fracture and expose substrate material, particularly if the substrate beneath the solid layer deforms plastically. Small regions of both substrate materials may finally come into contact and bond together.

Material-Dependent Bond Strength. At the small points of substrate-to-substrate contact, the bond strength will depend on the materials. Identical metals (for example, iron against iron) bond together most completely when the bond strength is very near the strength of the metals themselves. Dissimilar metals will usually bond with less strength in the first instant, but these "bonds" increase in strength with time, particularly between metal pairs that will mix or alloy via diffusion. Two pieces of identical ionic or covalent atomic structures, such as ceramic materials, will bond very well if the atomic lattices are well aligned. Bond strength will usually be less where the lattice dimension of one is different from that of the other. Recall that oxides, sulfides, and other compounds are also ionic and covalent structures. Finally, the atoms in polymer chains are usually bonded covalently. The polymer chains bond to each other and to other material by the weaker van der Waals bonds.

Conformity of Contacting Surfaces. A second consideration in bonding is the conformity of the contacting surfaces. Ductile materials will conform somewhat via plastic flow, but the brittle materials will not conform.

Sliding adds shear stress to any normal stresses already imposed, increasing the probability of plastic flow and fracture of materials in the contact region. After some sliding, there will be a layer of turbulently mixed substances, some of which will fall out as wear debris, but most of which will remain as a "transfer film." The wear rate will depend on the properties of all of the substances, the properties of the mixed composite material, and the tendency for bits of that turbulently mixed material to leave the system. The latter tendency will depend on the shape and vibration modes of the contacting bodies, the temperature, possible chemical reactivity with the surrounding environment, and many other parameters. It is clear that adhesion is prominent, although not well-defined in these events.

Wear Equations, Design Criteria, and Material Selection

The above brief description of the wearing process showed it involves very many variables, few of which have been researched sufficiently to formulate wear equations that can be used by designers. Some wear equations can be found in the literature, but none can be generally applied. The most widely publicized equation is due to Archard, in which the rate of wear, Υ (volume per unit of time), is:

$$\Upsilon = k \cdot \frac{WV}{H} \quad \text{(Eq 1)}$$

where W is the applied load, V is the sliding speed, H is the hardness of the softest of a pair of the materials, and k is a constant sometimes referred to as a wear coefficient.

Clearly, neither this equation nor any other published equation can adequately describe what occurs in Fig. 1. However, Eq 1 is widely known, and values of k for various materials are increasingly found in the literature. These numbers range from 10^{-3} for unacceptable wear rates to $\leq 10^{-7}$ for practical systems. These numbers serve as very broad guidelines for anticipated wear rates of materials, just as do published values of coefficients of friction. However, designers need coefficient values of high reliability within a range of ±20% or better in order to design acceptable systems.

Most engineers are certain that one or more wear equations exist that are more applicable to their problem than is suggested above. This belief likely arises from the existence of good equations in most other topics in engineering; there are equations for the bending of beams, the electrical resistance of materials, the rate of heat transfer, and the natural frequency of vibration of machinery. These are relatively simple phenomena, however, governed by very few variables. Adhesive wear, on the other hand, appears to involve over 25 variables, some of which can be measured easily and others of which are difficult or impossible to measure.

The point should be emphasized that there is no equation which can be generally applied. In fact, there are many practical situations in which the published equations lead to erroneous conclusions. For example, cam shafts in auto engines are not fully hardened because in that state they wear far too fast; some brake materials wear faster at low speeds than at high speeds; and some hardenable steels wear faster at low sliding speed than at high sliding speed. It is therefore important not to rely on any specific equation without considerable simulative testing. In testing, it is very important to characterize the sliding system thoroughly, including factors such as stiffness of the system, vibration modes, and atmospheres surrounding the test. Finally, even the characterization of the system as done by humans is inadequate. The most accurate method of determining whether a laboratory test truly simulates a mechanical component under study is to verify that the progression of surface change (wear rate, friction, appearance, and so on) and the wear debris in both are identical or nearly identical.

The sections that follow in this article are descriptions of the wearing of metals, polymers, and ceramic materials. These are presented to provide a perspective on the complexity of dry sliding wear, also frequently referred to as adhesive wear, conditions.

Primary Parameters in the Wear of Metals, Polymers, and Ceramics

Material selection for wear resistance requires careful consideration of the operating environment of the workpiece in addition to the total functional performance required of the workpiece itself. Wear properties of the steels vary widely with processing and heat treatment. Polymers are selected for sliding contact applications because of inherent properties such as inertness to many chemicals, relatively low galling tendency, and self-lubricating properties. Ceramics are used where extreme resistance to high-temperature oxidation or resistance to highly corrosive materials or gases is required.

Dry Sliding Wear of Clean Metals

The term dry means no deliberate lubrication, and the term clean indicates no obvious oxide scale or greasy residue.

60-40 Brass versus Tool Steel. A.W.J. DeGee and J.H. Zaat (Ref 1) found that adhesive wear occurs via two different mechanisms. These two mechanisms produce two effects, which are shown in Fig. 2 for 60-40 brass rubbing against tool steel. Brass was found to have transferred to steel where it remains attached, but some brass is also removed (worn) from the system. The extent of each event depends on the zinc content in the brass:

- *Local adherence of brass to steel:* No iron is observed to be present in the wear fragments. Brass particles come loose from the steel, but new material fills the impression again. Most of the steel surface remains undisturbed as seen by the unaltered surface features. The oxide film present on the brass is composed of CuO. The combination of CuO plus iron oxide apparently lubricates well except at some isolated points where brass transfers to steel
- *Continuous film:* The oxide present on the brass surface is zinc oxide. This oxide possibly does not lubricate and there is a considerable adhesion area. A thin film of brass is found on the steel in which the wear particles are large but few. This film covers (that is, fills) the surface roughness so that the

mechanism is independent of surface finish

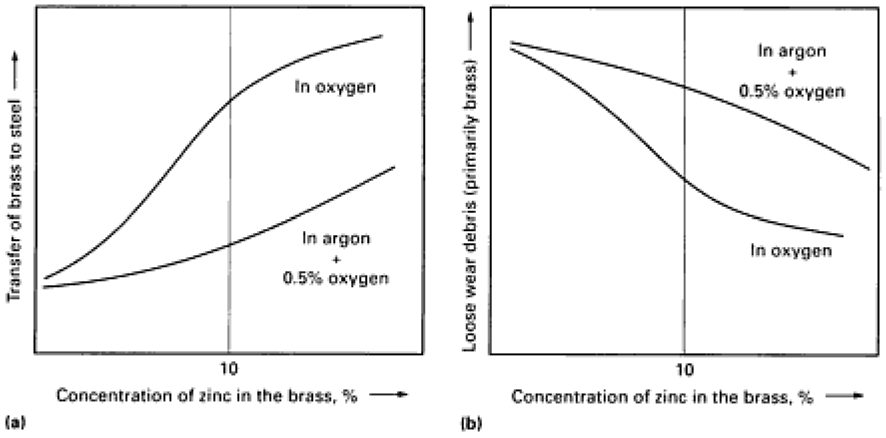

Fig. 2 Two different mechanisms that generate adhesive wear when 60-40 brass is rubbed against tool steel. (a) Transfer of brass to steel. In an oxygen atmosphere, the transfer film is mostly CuO, locally adhering, and dependent on surface roughness. In an argon/0.5% oxygen atmosphere, the continuous transfer film consists primarily of ZnO. (b) Removal of brass from system due to loose wear debris. Source: Ref 1

Lancaster (Ref 2) also studied the effect of 60-40 brass on high-speed steel and concluded:

- Transition between severe wear and mild wear is affected by sliding speed, applied load, and ambient temperature (Fig. 3 and 4; note the effect of atmosphere)
- Thickness of the oxide is the critical factor. The actual thickness is determined by the time available to reoxidize a denuded region and by the rate of formation of the oxide (Fig. 5). Reoxidation time is determined by sliding speed only. Oxide formation rate is influenced by temperature
- Hard metals do not necessarily wear soft metals away (Fig. 6)
- The ratio of various elements in the wear products is not predictable (Fig. 7)
- Wear rate, Υ, coefficient of friction, μ; and electrical contact resistance can vary independently (Fig. 8)

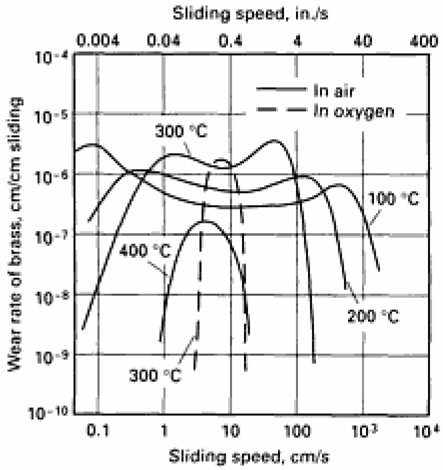

Fig. 3 Plot of wear rate versus sliding speed for a 60-40 brass on high-speed tool steel system using a 3 kgf (7 lbf) load both in air and in an oxygen atmosphere

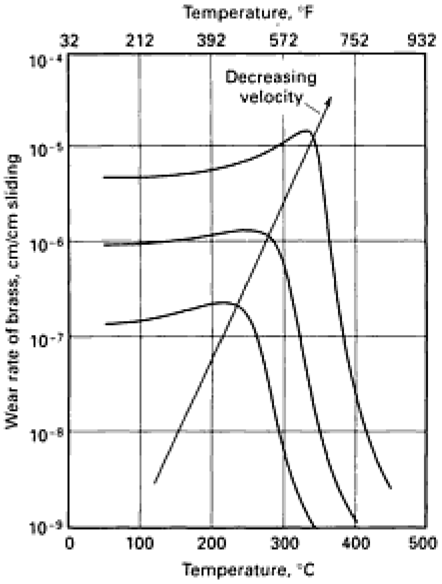

Fig. 4 Plot of wear rate versus ambient temperature as a function of sliding speed for 60-40 brass being rubbed on high-speed tool steel

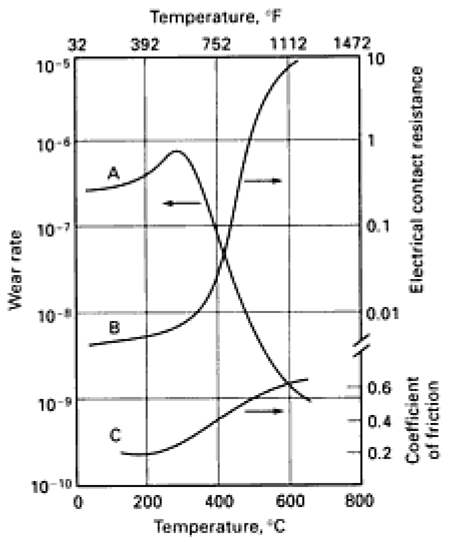

Fig. 8 Friction, wear, and contact resistance as a function of temperature for a 60-40 brass/high-speed tool steel system. A, wear rate, Υ; B, electrical contact resistance; C, coefficient of friction, μ

0.12% Carbon Steels. Low-carbon steel is a readily available low-cost material capable of being processed in numerous ways to resist wear. N.C. Welsh (Ref 3) tested 0.12% C steels and came to the following conclusions:

- Increasing applied load may decrease wear rate (Fig. 9), presumably by increasing the temperature at the points of contact. The rubbing temperature becomes high enough to form austenite. Partial proof of this transformation can be seen in Fig. 10
- Wear debris from rubbing of steel parts is a mixture of oxides (Fig. 11)

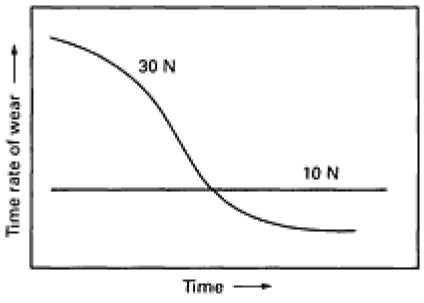

Fig. 9 Plot of wear rate versus time for a low-carbon (0.12% C) steel tested with a 10 and 30 N (1 and 3 kgf) load

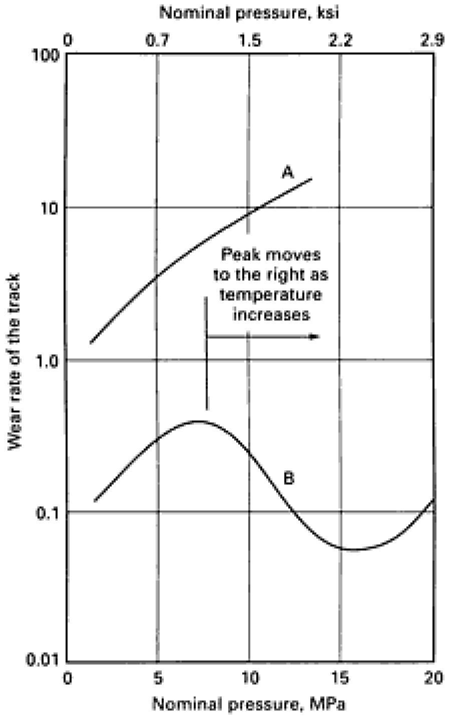

Fig. 10 Plot of wear rate versus nominal pressure as a function of unhardenable and hardenable 0.12% C steels. A, wear with galling (soft steel rubbing on soft steel); B, soft steel rubbing on hardenable steel

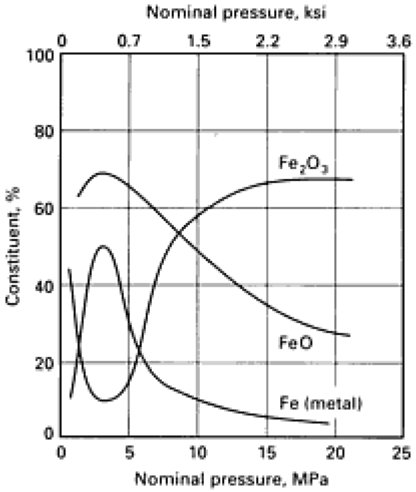

Fig. 11 Plot of wear debris constituent concentration versus nominal pressure for the conditions (debris from soft 0.12% C steel sliding on hardenable 0.12% C steel) in Fig. 9

N.C. Welsh (Ref 4) later measured wear rate versus load for steel on steel and again found transitions between severe wear and mild wear. His data were published in the form shown in Fig. 12. The data indicated that:

- Effect of hardness is to diminish the likelihood of transition to severe wear. It can be speculated that the critical oxide thickness is less for hard substrates than for the soft substrate
- Transition does not occur immediately with a change in sliding conditions
- Low sliding speed shifts the transition to the right and high speed shifts the transition to the left
- Inert gas broadens the transition region, whereas oxygen narrows the transition region
- In the mild wear regime, initial wear rate is high where the oxide is chemically removed and rubbing

resumes (Fig. 13)

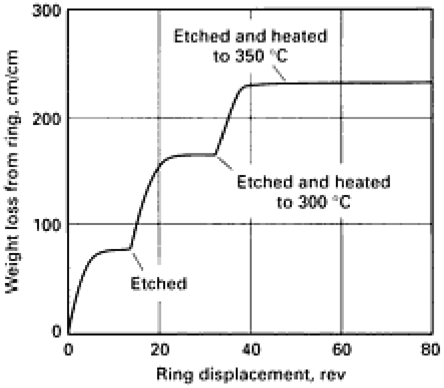

Fig. 13 Plot of weight loss from ring versus ring displacement to show effect of heating steel on wear rate. Velocity, 1 m/s (3.3 ft/s)

Dry Sliding Wear of Polymers

In the rubbing of polymers (and also of dry bearing materials that include polymers) on metals, a very thin film of polymer, invisible to the naked eye, is first established upon the metal surface; the presence, and indeed the nature, of this thin transferred film can play a crucial role in the subsequent wear behavior.

Wear of Metals Generated by Plastic. The friction of polymers is about the same as that of metals (with the exception of PTFE), but the seizure resistance of plastics is superior to that of soft metals. General uncertainty exists about the effect of surface roughness on wear rate, and the astounding finding has been made that some polymers wear metals away without the presence of abrasives.

The general state of understanding of polymer wear is that rubbing surfaces experience a break-in period, followed by a steady-state behavior, which is often referred to as linear wear (Fig. 14).

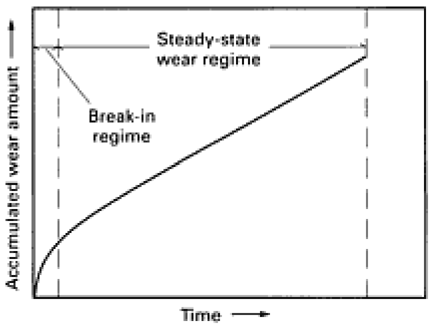

Fig. 14 Typical wear behavior of a polymer, showing the break-in period and the steady-state period of the curve generated when wear is plotted versus time

It is in the linear region that people have been searching for a useful wear coefficient. A second number often used in connection with polymers (and bearing bushings) is a descriptor of the rubbing severity, above which severe or catastrophic wear may occur. The most widely known descriptor is the *PV* limit, where *P* is the average contact pressure (in psi) and *V* is the sliding speed (in ft/min). Each polymer has a unique *PV* limit as measured by some test, most often a washer test. The *PV* limit for polymers is often thought to be based on thermal behavior of the materials, but this is not a valid assumption.

Transfer films of polymer control the wear process. If a film of polymer is transformed on the metal counterface and remains firmly attached, the loss of the polymer from the system is minimal. If, during sliding, a particle of polymer is removed from the polymer bulk but does not remain attached to the metal, it is lost from the system. An intermediate state of wear is the case where a transfer film is formed, but fragments of the film are later lost, probably due to fatigue or some other mechanisms. Because the behavior of the system is very different in each of the three regimes, the discussion will now be focused in turn upon the break-in period, the steady-state wear regime, and the severe wear regime.

Surface Finish Orientation Relative to Sliding Direction. In the early stages of sliding, the rate or buildup of the transfer film is dependent on the orientation of surface finish relative to the sliding direction, and the rate varies depending on the type of contaminant or dirt on the sliding surface. Surface finish appears to have almostno effect on the steady-state wear rate, probably because the products of wear fill the grooves in the surface.

To check the effect of surface roughness on wear in the early stages of sliding, several polymers were slid on carbon steel with surface roughnesses from 0.1 to 3 μm (40 to 125 μin.) root-mean-square roughness (R_q), some parallel with the sliding direction and some perpendicular. For nylon 6/6 pins of 12 mm ($\frac{15}{32}$ in.) diameter with 100 N (10 kgf) load on each pin and a speed of 0.4 m/s (1.3 ft/s), the data in Fig. 15 were obtained. It appears that the nonlinear period, or beak-in period, may persist twice as long with parallel sliding than with perpendicular sliding and that the weight loss at the end of break-in may vary by a factor of four or more.

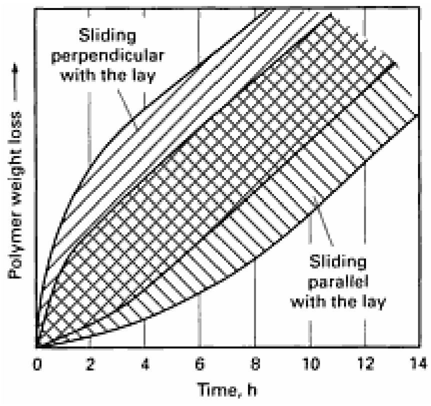

Fig. 15 Wear rate of nylon 6/6 polymer pin that was slid on rough (0.1 to 3 μm, or 40 to 125 μin., R_q roughness) carbon steel both parallel and perpendicular to the sliding direction. Test parameters: pin diameter, 12 mm ($\frac{15}{32}$ in.); load on pin, 100 N (10 kgf); velocity, 0.4 m/s (1.3 ft/s)

The break-in period designates the time when a film of polymer is transferred to the metal. The equilibrium film thickness for all tests run on various surfaces at one speed and one load were about the same.

Surface Cleanliness. The second factor in controlling the establishment of the transfer film is surface cleanliness. The tests were conducted with metal surfaces subjected to three conditions:

- Laboratory clean (covered with an adsorbed water film)
- Covered with a thin film of inert hydrocarbon (vacuum pump oil)
- Covered with a machine oil

In all cases, a transfer film begins to form and it may become continuous, each in a different time. The higher the temperature of the counter surface, the more quickly the transfer film formed.

As the transfer film forms, the loss rate from the polymer is high, but after the film forms, the wear rate is much lower (sometimes <1% of the initial rate). Thus, predicting the total wear rate of a bearing over some specified time should not be done on the basis of the steady-state wear rate. For short-time use of a polymer bearing, the break-in stage could produce much more wear than an amount based on predictions from data for steady-state wear. Furthermore, wear rate predictions are complicated by variations in temperature, by variations in the amount of contamination, by variations in speed, by start-stop or forward-reverse cycles, and by other factors.

The transition to severe wear occurs by the following sequence of events. During low wear rate sliding conditions, the transfer film remains as a transfer film behind the slider and provides (or becomes) a lubricant film upon which the slider rides in during later passes. If the temperature of the transfer film is high (such that the film of plastic has low viscosity) and if the low viscosity plastic does not wet the metal surface, the plastic agglomerates into spheres that are removed by the next slider that passes by (Fig. 16). Thus, the sliders are deprived of a lubricant film and instead give up some material to establish a new film that again is quickly detached. The difference between a tenacious and fleeting transfer film is a wear rate that varies by more than 2000 times. Relevant variables in this entire process must include the temperature and thermal properties (mass, diffusivity, and so on) of the counter surface and the contact area between the sliding parts.

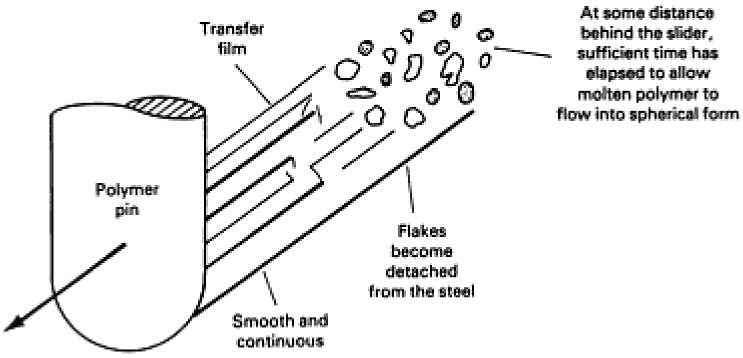

Fig. 16 Schematic showing mechanism that determines wear in a polymer moving at a high sliding speed

The overall effect of these mechanisms of material transfer and loss is the wear rate shown in Fig. 17. The wear rate increases with sliding severity, which is some combination of *P, V,* and other variables. The wear rate shown in Fig. 17 is most likely due to some combination of inadequate attachment of transfer film to the substrate and the removal of transfer film by fatiguing and other failure modes. If the surfaces are clean and attachment strength is high, at high severity of

sliding the transfer film does not readily fragment by fatigue ad wear is low. At high severity, the transfer film, however firmly or weakly attached, agglomerates and is lost as wear.

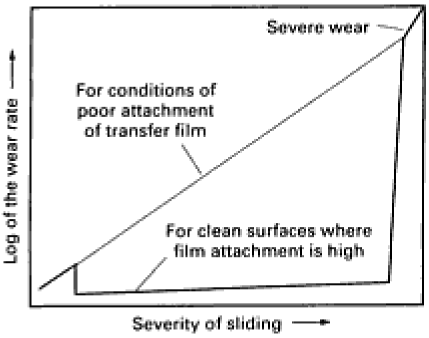

Fig. 17 Wear rate of polymers in both clean environments and contaminated environments

Metal Wear Generated by Plastics. When sliding some of the harder plastics on type 440C stainless steel that is hardened to 50 HRC, at all speeds and loads, iron and chromium are found attached to the polymer at the end of the test in the mild wear regime. These results indicate:

- A transfer film is not laid down by successive and simple shear from the polymeric sliding. Rather, there is a considerable turbulence or rolling of polymer within the transfer film, at least in the early life of the transfer film
- Transfer of iron and chromium to the polymer indicates that the metal is wearing away. Soft plastics did not wear away the type 440C stainless steel

Table 1 is a list of plastics used in one set of experiments with a sliding speed of 1.47 m/s (4.83 ft/s) and a load of 222 N (22.6 kgf) per pin of 13 mm ($\frac{1}{2}$ in.) diameter.

Table 1 Wear properties of selected polymers

Polymer type	Material	Shear strength		Coefficient of friction, μ	Effect of polymer on wear of type 440C stainless steel surface
		MPa	**ksi**		
Polyamide (PA)	Nylon 6/6	70.5	10.2	0.66	[(a)]
Polyoxymethylene (POM)	Delrin	65.5	9.5	0.65	[(a)]
High-density polyethylene (HDPE)		63.4	9.2	. . .	[(b)]
Polyoxymethylene + polytetrafluoroethylene (POM + PTFE) composite	Delrin AF	55.2	8.0	0.20	[(b)]
Polyamide (PA)	Nylon 11	41.4	6.0	0.50	[(b)]

(a) Hard plastic wears away steel surface.

(b) Soft plastic does not produce wear on steel.

Rubber is a polymer, but it differs from plastics in that its molecules are cross-linked. Thus, the migration or flow of the molecules is severely limited. Rubber wears by two mechanisms, tearing and fatigue. Ultimately, these are not very distinct mechanisms because tearing, or fracture, is failure in $\frac{1}{4}$ cycle of fatigue. However, the tearing mechanism is immediately visible. It occurs on rough, hard surfaces, particularly on a surface of sharp stones or abrasive paper. This

conclusion is supported by the observation that the ranking of several rubbers in a test on abrasive surfaces was the same as in tensile tests of the rubber. Even the temperature and rate dependency were the same.

The fatigue mechanism occurs when rubber slides on smoother surfaces. This mechanism was proposed on the strength of a correlation between the distance of sliding (number of deformation cycles due to passing asperities) until surface failure and the number of strain cycles to tensile failure; it is supported by a parabolic relationship between the applied stress and the fatigue life in both tests. The wear rates of various rubbers cover a very wide range. Generally, rubbers can be ranked within the range of wear rate by comparing the imposed stress state with the strengths (tearing and fatigue). The local coefficient of friction must be taken as one of the important causes of imposed stress.

Wear of Ceramic Materials

In general, ceramic materials are more brittle than metals and are often presumed to be incapable of plastic deformation. In addition, there are strong statements in the technical literature to the effect that ceramic materials are chemically inert and therefore a chemical component is not to be expected in the wearing of ceramics. The result has been that the technical community expects that the wear of ceramic materials will not be similar to the wear of metals. There are indeed differences, which are useful to list:

- Chemical reaction of a ceramic material with the environment does occur, often forming new chemical compounds, such as oxides (except on the ceramics that are oxides such as Al_2O_3, ZrO_2, and others), sulfides, phosphides, and others; these compounds influence the coefficient of friction just as they do in metals. These new surface compounds are often readily removed as wear products.
- Some ceramic materials (for example, Si_3N_4), are more ductile than some untempered martensite. In fact, white cast iron, although it is regarded as a metal, may contain well over 50% carbides of iron and chromium; these carbides are ceramic materials. However, such ceramic materials as silicon carbide and alumina are clearly more brittle than metals
- Brittle materials are much more prone to early failure due to cyclic stressing. In mechanical engineering, a response to cyclic stress is described as a fatigue property, but this term has a more technical meaning in material science. Clearly, though, the very brittle ceramics disintegrate quickly in cyclic stressing. One manifestation of this behavior may be seen in the pin-on-disk wear test. With pairs of ductile metals, the pin wears faster than does the disk; with pairs of brittle ceramic material, the disk wears faster than does the pin. The reason is that a position on the disk has the pin sliding over it repeatedly, imposing a cyclic stress on that position.
- The type and extent of failure of a surface (wear) depends strongly on the process used to form and prepare the surface. Severe processing induces fractures between grains and in the grains, so that when a surface is placed in sliding service, the fragmented surface wears away quickly. Wear particles of ceramics then carve out other grains and the wear is perpetuated.
- In repeat-pass sliding, some wear debris appears to be crushed and reattaches very firmly as a transfer film, which affects (often reduces) the wear rate by as much as a factor of 100. This reattachment appears to be interrupted by the presence of water and other fluids, which increases the wear rate by as much as tenfold

Prevention of Adhesive Wear

The following guidelines are recommendations to prevent adhesive wear in metals, polymers, and ceramics:

- Avoid sliding similar materials together, particularly metals
- If fatigue due to repeated high-contact pressure is not likely to be a problem, then high hardness is a desired property. However, avoid sliding hard metals against hard metals in lubricated systems to avoid scuffing and to accommodate debris
- Consider the effect of relative hardness of phases in materials. For example, a high-chromium cast iron may have a hardness of 400 HB, which is moderate. However, that cast iron may contain Cr_7C_3, which has a hardness of about four times that of 400 HB and will damage the counter surface considerably. The same applies to polymers, which seem rather soft relative to metals. However, wear-resisting

polymers often contain glass or some other hard filler that wears metal counterfaces rather severely. Hard phases in one body may fragment and become embedded in the counterface, which causes abrasion if the fragments extend above the surface.

- Even if done inadequately, lubrication will reduce wear. Some lubrication can be applied by providing an atmosphere that is corrosive in order to form surface films, many of which produce lower friction than if that film were not present

Fretting Wear

R.B. Waterhouse, University of Nottingham (United Kingdom)

Introduction

FRETTING is the small-amplitude oscillatory movement that may occur between contacting surfaces, which are usually nominally at rest. One of the immediate consequences of the process in normal atmospheric conditions is the production of oxide debris, hence the term "fretting wear" or "fretting corrosion" is applied to the phenomenon. The movement is usually the result of external vibration, but in many cases it is the consequence of one of the members of the contact being subjected to a cyclic stress (that is, fatigue), which gives rise to another and usually more damaging aspect of fretting, namely the early initiation of fatigue cracks. This is termed "fretting fatigue" or "contact fatigue." Fatigue cracks may also be initiated where the contacting surfaces are under a very heavy normal load or where there is a static tensile stress in one of the surfaces. There are cases where the movement is not simply tangential, but is complicated by the normal force also oscillating to the extent that the surfaces lose contact in each cycle. This leads to a hammering effect, which is termed "impact fatigue." In this case, the phase relationship between the two motions can be an important factor.

Other terms that have been used to designate fretting-type damage are "false brinelling," which is particularly applied to bearings where the craters caused by the vibration of the ball against the race are circular and resemble Brinell impressions, and "fitting rust," where gages or shims are clamped together and experience vibration.

The terms "fretting" and "fretting corrosion" are now widely accepted in most languages, but the term "reiboxydation" is still used in Germany, and "corrosion de trepidation" is occasionally used in France.

Fretting was first reported by Eden, Rose, and Cunningham in 1911 (Ref 1), who found that brown oxide debris was formed in the steel grips of their fatigue machine in contact with a steel specimen. It was not until 1927 that Tomlinson (Ref 2) conducted the first investigation of the process and designed two machines to produce small-amplitude rotational movement between two annuli in the first case, and an annulus and a flat in the second case. The movement was controlled by a long lever system. Because the resultant debris on his steel specimens was the red iron oxide α-Fe_2O_3, which had arisen from chemical reaction with oxygen in the air, he coined the phrase "fretting corrosion." He also established that the damage could be caused by movements with amplitudes as small as a few millionths of an inch ($\sim$ 125 nm, or 1250 Å), and the important fact that relative movement had to occur, which he termed "slip."

The next important stage in the development of fretting studies was made by Warlow-Davies (Ref 3) in 1941, who produced fretting damage on the gage length of steel fatigue specimens and found a subsequent reduction in fatigue strength due to the pitting of the surface of between 13 and 17%. This was to be expected, but later investigations,

particularly by McDowell, Tierney, and McClellan (Ref 4) showed that the con-joint action of fretting and fatigue, which is the usual case in practice, was much more dangerous, producing strength reduction factors (SRFs) of 2 to 5 and even greater. Fenner and Field (Ref 5) in 1958 demonstrated that fretting greatly accelerated the crack initiation process. In normal fatigue, crack initiation may account for 90% of fatigue life, whereas in fretting fatigue, initiation could occur in $\leq$5% of the fatigue life.

Fretting Wear in Mechanical Components

Because vibration is one of the main causes of the fretting movement, it follows that the most likely area for it to occur is in machinery. The contacts between hubs, shrink- and press-fits, and bearing housings on loaded rotating shafts or axles are particularly prone to fretting damage, but because the movement arises from alternating stresses in the shaft surface, the problem is more one of fatigue than wear (Ref 6). However, wear rather than fatigue can be a problem in bearing housings. Thin-shell bearings are universally used in diesel engines, and such bearings involve an interference fit between the bearing and the housing. If the contact pressure is not high enough, movement can occur, giving rise to the fretting damage shown in Fig. 1 (Ref 7).

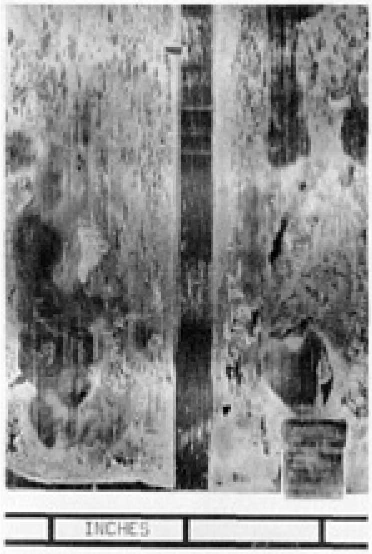

Fig. 1 Fretting damage incurred in a bearing shell component because of insufficient contact pressure between the shell and housing of a bearing. Source: Ref 7

Flexible couplings and splines, particularly where they form a connection between two shafts and are designed to accommodate some slight misalignment, can suffer severe fretting wear. Recent examples of such cases are described in the paper by Heinz (Ref 8).

Jointed structures are another source of fretting problems. According to Mitchell (Ref 9), there is no such thing as a static joint on an aircraft. An aircraft structure is largely an assemblage of aluminum and steel components riveted together or joined by fasteners. Even in a simple riveted joint, there are at least three possible sites where fretting can occur (Fig. 2):

- Between the riveted panels
- Between the underside of the rivet head and the panel
- Between the shank of the rivet and the rivet holes

Typical fretting damage is shown in Fig. 3.

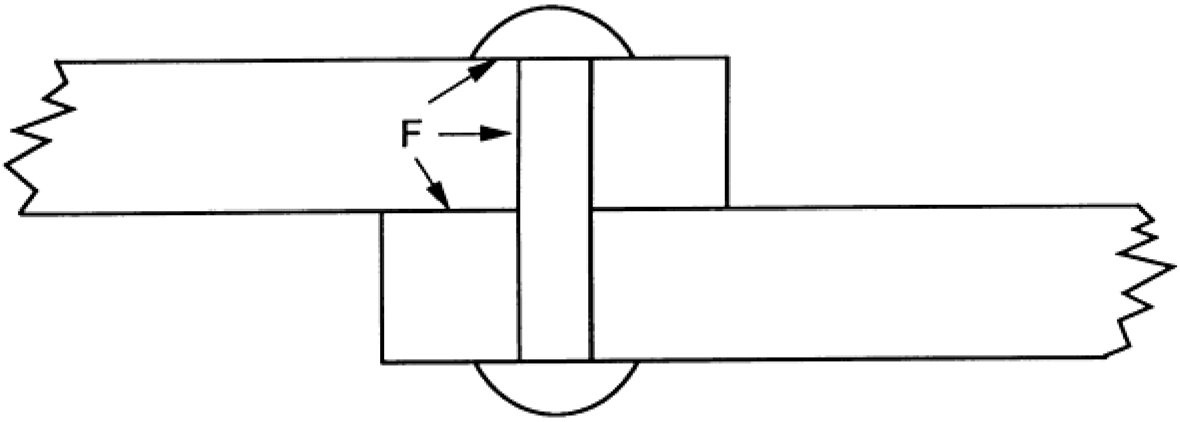

Fig. 2 Locations (indicated by F) prone to fretting in an aluminum-steel riveted joint

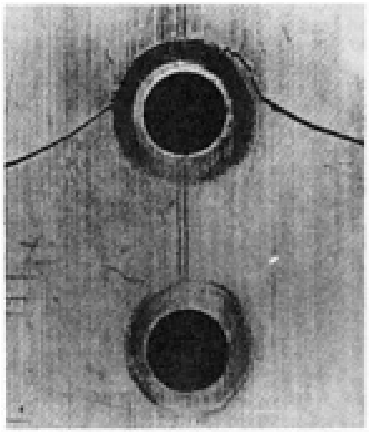

Fig. 3 Fatigue crack generated by fretting damage at a rivet hole

Turbines, both steam and gas, operate under conditions that subject these components to fretting damage. There are three main sites:

- Where the turbine disk is either shrink-fitted onto the driving shaft or attached to the shaft by means of a bolted flange
- Where the blades are fixed into the disk by either a dovetail or fir-tree type fixture
- Where snubbers at the outer ends of the blades contact those on adjacent blades

The first two sites are more likely to be areas for fatigue crack initiation, but loss of material by wear of the snubbers will give rise to increased vibration of the blades and the onset of impact fretting. In some turbines, a wire is threaded through holes in the outer ends of the blades to dampen down vibration. In this case, the frictional energy dissipated in the fretting process is the effective agent and may be said to be one of the few cases where fretting is beneficial.

The rotors of electrical generators have slots along their lengths in which the windings are located. These are held in place by wedges. Fretting can occur between the wedges and the undercut portion of the winding channel with the development of fatigue cracks in the rotor. These problems in turbines and generators are the subject of a recent review (Ref 10).

Steel ropes are used widely as mooring ropes, haulage ropes, mining ropes, and on cable cars. Overhead power lines are in effect ropes made up to aluminum wires wound on a steel support rope; more recently, they have been made up entirely of aluminum (the all-aluminum conductor). Any bending movement or alternating tension can result in local movement in

the numerous interwire contacts. Most ropes include some form of internal lubrication to lessen the effects of such movement. Again, one of the main dangers is fatigue failure of a wire, which increases the load on the remaining wires. However, in the locked coil rope that is designed with shaped wires to give an almost solid outer structure (Fig. 4), fretting debris with a greater volume than that of the metal from which it was formed can lead to the forcing apart of the wires, with the escape of lubricant and the ingress of a corrosive atmosphere. The accumulation of debris also leads to a reduction in flexibility at this point and, in the case of a mining rope, can cause jolting when this part of the cable passes on to the winding drum.

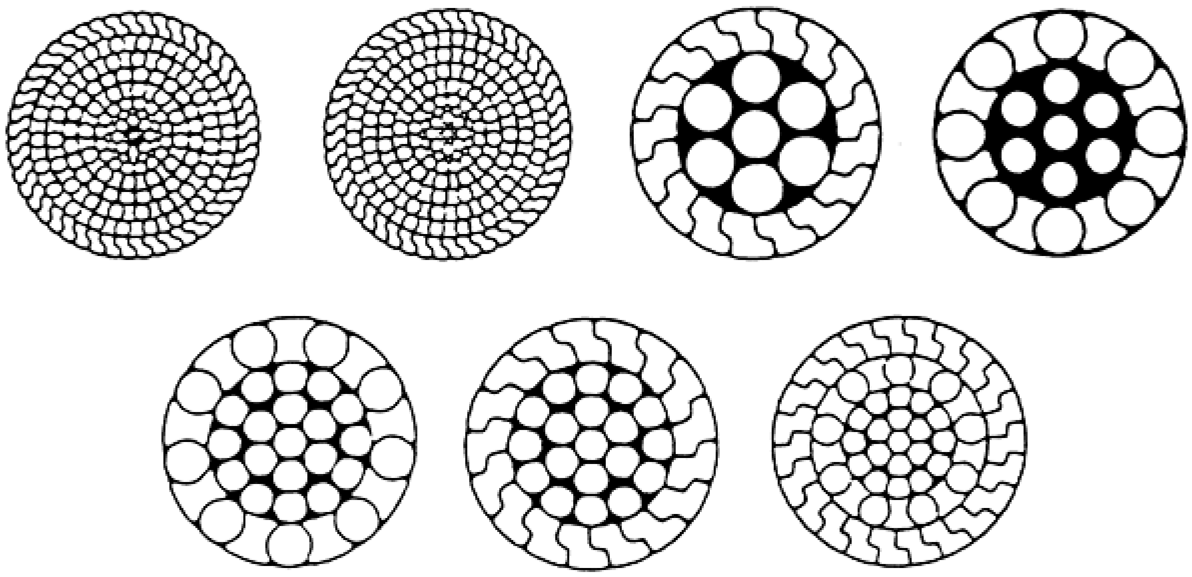

Fig. 4 Cross-sections of typical locked-coil track strand wire rope construction

In steam generators and heat exchangers, flow-induced vibration results in fretting between the tubes and the supports or baffles through which they pass. In the past, this appears to have been a particular problem in the nuclear power industry (Ref 11, 12) and chemical processing plants (Ref 13). A large contribution to the fretting in these industries is from impact fretting, which is discussed in the section "Impact Fretting" of this article.

Another example where movement is an integral part of the *modus operandi* of the device is the leaf spring used at one time in automobiles and railway rolling stock. It consists of an assemblage of steel plates, whose purpose is to dampen down vibration transmitted from the wheels to the carriage. Accumulation of debris could result in the plates not moving easily over one another and a stiffening of the spring.

The accumulation of debris is also the main problem in the fretting of electrical contacts (Ref 14). Because the oxide debris is nonconducting, interference or distortion of electrical signals can be generated in telephone equipment and also in computer connections. In some countries, aluminum conductors are used in domestic electrical circuits. Here the movement is due to temperature variations and is, therefore, of extremely low-cycle frequency. However, the buildup of aluminum oxide in connections can cause the formation of electrical arcs, which in extreme instances has led to houses being burned down.

The transportation of goods by road or rail obviously means that these are subjected to vibration. This gave rise to the classic case of fretting in the bearings of automobiles being transported by rail from Detroit to the West Coast of the United States. As the bearings were stationary, fretting occurred between the loaded balls and the race, giving rise to the false brinelling mentioned above. This has also been a problem with the transport of stacks of aluminum sheets with highly polished finishes. It also led to the abandonment of using stacked aluminum trays to transport food stuffs. Another example involved the transport of live ammunition in aluminum boxes, because the fretting debris was found to be pyrophoric. In a case investigated by the author, high-purity (HP) aluminum "logs" (cylinders 250 mm, or 10 in., in diameter), were transported by rail to the plant where they were to be extruded as buss bars. Black marks (that is, fretting debris) were noticed on the cylinders (Fig. 5) that gave rise to serious surface tears on extrusion (Fig. 6).

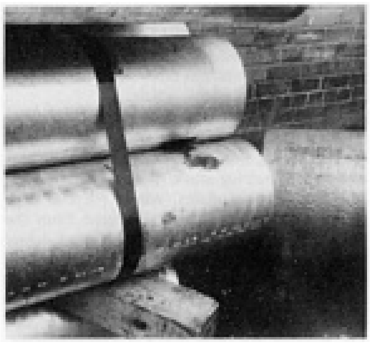

Fig. 5 Typical fretting marks on a high-purity aluminum cylinder

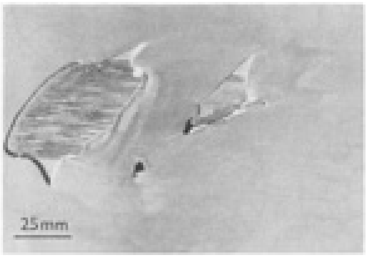

Fig. 6 Surface tears caused by fretting damage when aluminum cylinders in Fig. 5 are extruded

Fretting can also occur in certain orthopedic devices, particularly fracture fixation devices such as bone plates. These are used to hold together the parts of fractured bone. They consist of plates of corrosion-resistant materials that are attached to the bone by means of screws of the same material. Fretting can occur between the underside of the screw head and the countersink of the hole in the plate. Fretting in this case results in disruption of otherwise protective films and the continual release of heavy metal ions into the body fluids, with possible toxic reactions. This aspect of fretting in aqueous electrolytes is dealt with in detail below. Fatigue failure is also possible (Fig. 7).

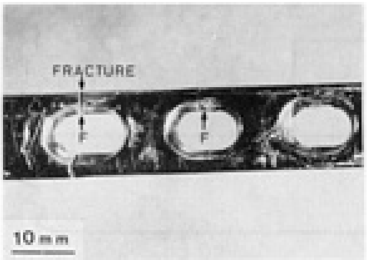

Fig. 7 Fracture in an orthopedic bone plate. A failure was caused by fretting damage (loss of protective oxide layer) in the countersunk portion of the plate.

The possible situations in which fretting can occur are legion, and it is only possible in this review to give some typical examples. In most of the cases described, suitable methods of overcoming the problem have been forthcoming as the result of detailed investigation; these are described in detail in the section "Prevention of Fretting Damage" in this article.

A few years ago, the author was approached by a professor of dentistry from Paris, who was convinced that the spots of damage (caries) that develop between contacting teeth, particularly the molars, were a form of fretting corrosion due to the relative movement occurring during chewing and swallowing, and certainly the examples he produced looked very much like it. This extends the possibility of fretting damage to materials other than metals. With increased use of

polymers, both simple and reinforced, in addition to ceramics, this is an area where further examples of a somewhat different kind are likely to be encountered. Some research already is being devoted to the topic and is described in the section "Parameters Affecting Fretting" in this article.

Parameters Affecting Fretting

Experimental investigations have concentrated on the effect of specific physical variables (such as amplitude of slip, normal load, frequency of vibration, and the circumstances of the fretting situation, such as type of contact, mode of vibration, and the condition of the surfaces) to indicate how the problem can be overcome in the future design of contacting components. These results are discussed in detail below.

Amplitude of Slip. Tomlinson (Ref 2) established that relative movement was essential for fretting to occur and showed that extremely small movements of the order of a few nanometers were capable of causing damage. This aspect of fretting--the lower limit of slip--has more recently been the subject of investigation (Ref 15, 16). One of the problems in experimental work has been the control and measurement of small amplitudes of movement. The most satisfactory method which avoids possible losses due to elastic deformation in the supports or actuators, is to concentrate on the situation of partial slip. This is best studied with a contact consisting of a ball (typically a bearing ball) on a flat, a situation that was analyzed by Mindlin. Figure 8 shows the form of contact of a ball on a flat developed by Mindlin from the Hertzian solution for a stationary contact. On the application of a tangential force or a torsional force, slip occurs over an outer annular region of the circle of contact. If the applied force is oscillating, then fretting occurs in the slip region. Johnson used this method to verify the Mindlin analysis (Ref 17). More recently, Nowell and Hills (Ref 18) have shown that the stress distributions are somewhat distorted but the basic idea remains the same. The center of the contact region remains locked (that is, the nonslip region). The amplitude of movement in the slip region for torsional excitation presumably rises from zero at the inner boundary to some greater value at the outer edge. The dimensions of the damage area closely approach these limits.

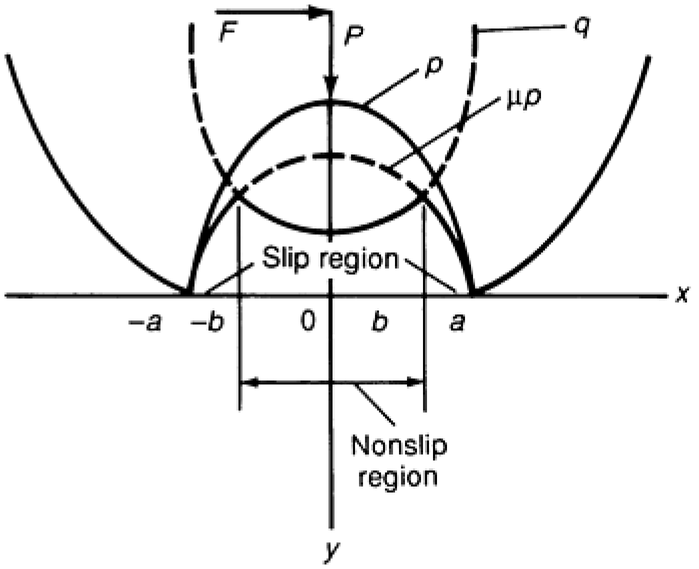

Fig. 8 Mindlin analysis of partial slip for a ball in contact with a flat and subjected to a tangential force

In the investigations by Kennedy and his colleagues, the amplitude of slip at which damage was detected on steel specimens under a load of 88 N (8.8 kgf) was 0.06 μm (2.4 μin.). A narrow annulus of damage was detected at an amplitude of 0.1 μm (4 μin.). As the amplitude was increased, the damage area, characterized by the appearance of the typical reddish-brown oxide, increased in width, with the outer radius remaining constant. This situation has been investigated by Kuno (Ref 19) using a linear vibratory motion, where it was found that the annulus of damage for a fixed amplitude increased in width with the number of fretting cycles, but the outer radius remained constant (Fig. 9).

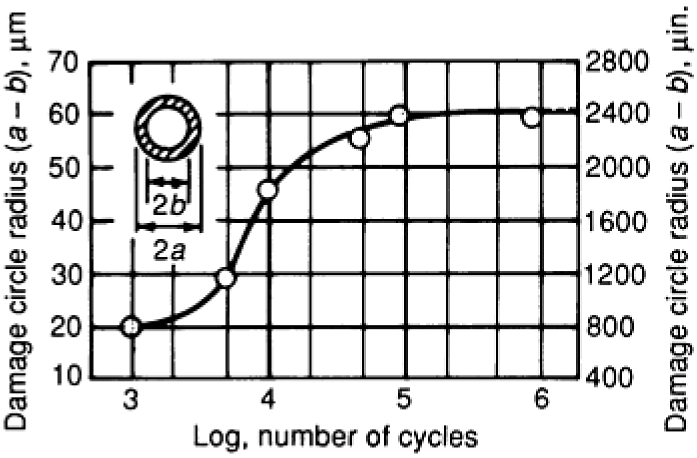

Fig. 9 Relation between diameter of fretting scar and the number of cycles for a ball on a flat under conditions of total slip. *P,* 437 N (43.7 kgf); P_{max}, 1.2 GPa (175 ksi); amplitude of movement, 8 μm (320 μin.); frequency, 50 Hz

In the Kennedy experiments, the damage was detectable by profilometry of the flat surface at an amplitude of 0.53 μm (21 μin.) and was said to be severe at 2.8 μm (110 μin.). The level of slip amplitude at which slip occurs over all of the contact area depends on such factors are the normal load and the mechanical properties of the materials. In the heavy loads used by Goto (Ref 20), which were sufficient to produce a Brinell impression, the slip annulus was extremely narrow and it is doubtful whether total slip could ever be achieved under these conditions (Fig. 10). Under more normal conditions (amplitude 8 to 25 μm, or 320 to 1000 μin.; normal load 135 N, or 13.8 kfg) Kuno found that total slip occured at an amplitude of 25 μm (1000 μin.). At this amplitude and above, the radius of the damage circle increased linearly with the number of cycles.

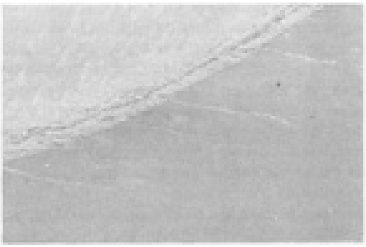

Fig. 10 Annulus of fretting damage produced by contact of a ball on a flat under heavy normal load

The amplitude of slip where the slip becomes total has been termed the critical amplitude, Δ. Vingsbo and Söderberg (Ref 21), using a crossed-cylinder arrangement with steel specimens, have mapped the relation between the critical amplitude and normal load (Fig. 11). These results are somewhat different from those of Kennedy, whose experimental values agree well with calculations based on elastic theory (Fig. 12). The discrepancy is attributed to plastic deformation occurring in the crossed-cylinder experiments (Ref 22).

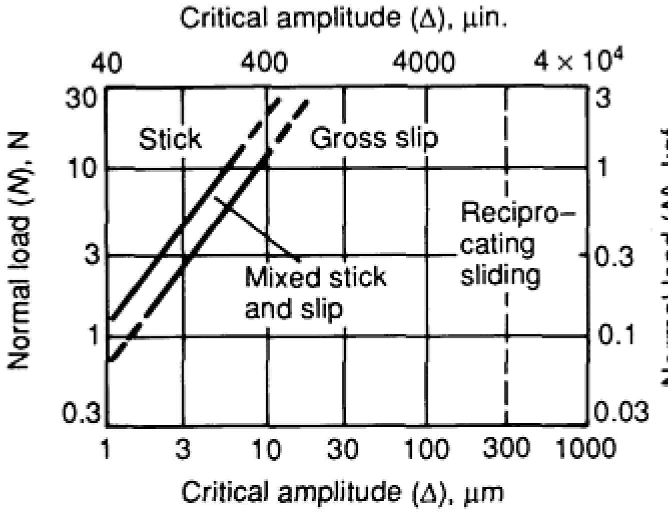

Fig. 11 Plot of normal load versus critical amplitude as a function of normal slip for a crossed steel cylinder arrangement. Source: Ref 21

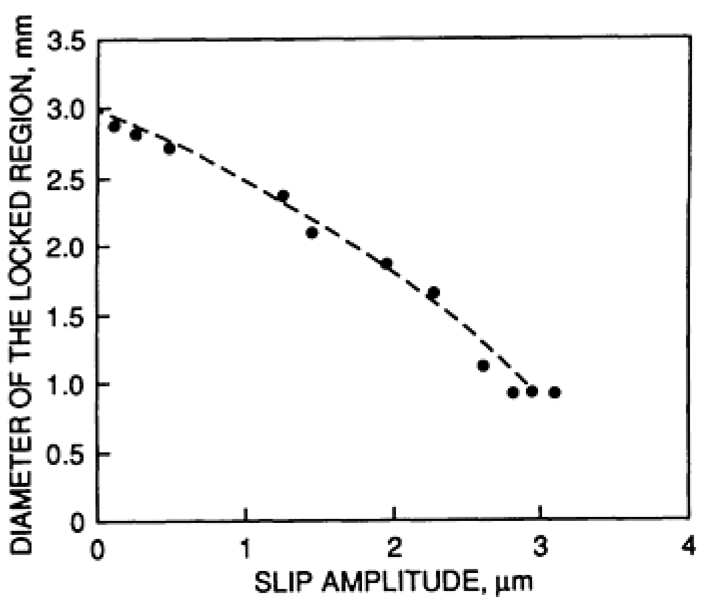

Fig. 12 Comparison of the theoretically predicted diameter of the nonslip region versus slip amplitude based on experimental data

In other investigations, using a variety of different contact geometries and different methods of assessing the wear rate and plotting the results as the specific wear rate (that is, the loss of material per unit of sliding distance per unit of applied normal load), the curves are of the form shown in Fig. 13. The curves are sigmoidal, with the specific wear rate becoming constant at amplitudes >100 μm (>0.004 in.) (that is, identical with unidirectional sliding or reciprocating sliding wear rates). This then gives a possible upper limit for the slip amplitude for the case of true fretting.

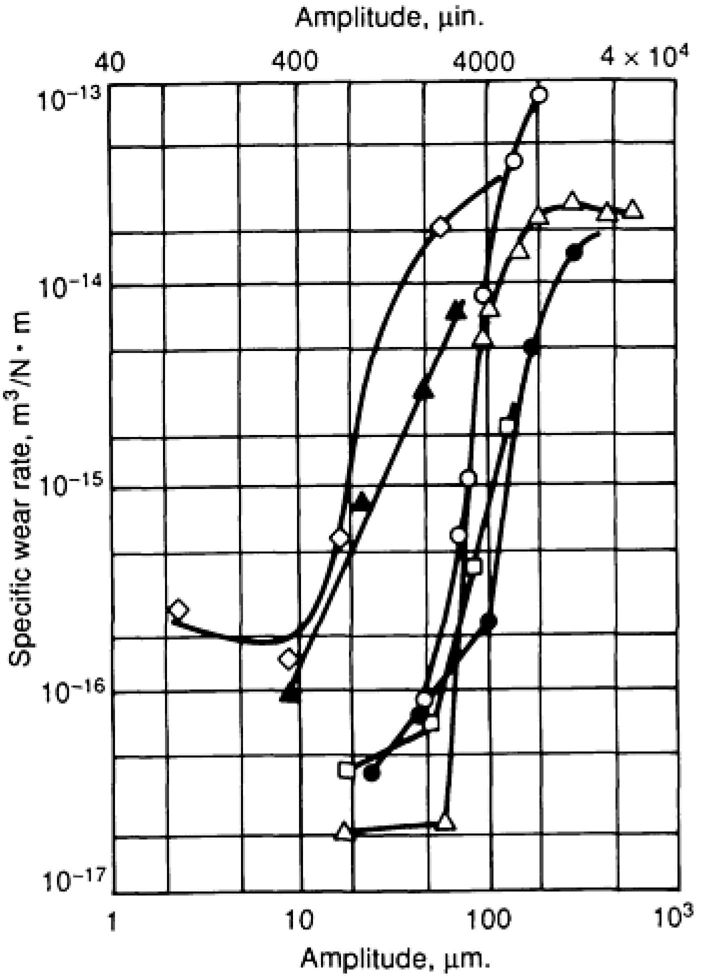

Fig. 13 Plot of specific wear rate versus amplitude of slip. Each core is the result of a separate investigation.

The small-amplitude characteristic of fretting is the basis of many of the important features of the process. It means that the relative velocities of the two surfaces are much lower, even at high frequencies, compared with conditions in unidirectional sliding. At a frequency of 25 Hz and an amplitude of 25 μm (1000 μin.), the average velocity is 1.25 mm/s (0.0492 in./s), whereas sliding speeds in bearings are of the order of 1 m · s. Debris tends to stay where it is generated, so that high spots (for example, machining marks) become imprinted on the other surface if it has a higher degree of finish (Fig. 14). The debris may never become exposed to the atmosphere and can become compacted under the compressive load, often changing its appearance, as discussed in the section "Effect of Debris on Wear" in this article.

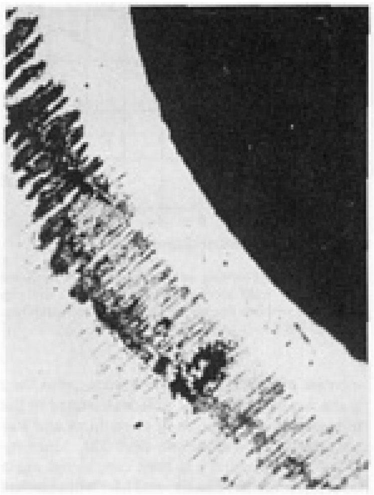

Fig. 14 Marks produced by a machined surface fretting against a polished flat

Normal Load. When two surfaces are placed in contact and loaded, plastic deformation of contacting high spots (asperities) occurs, as established by Bowden and Tabor (Ref 23). However, certain contacts (for example, sphere on flat and cylinder on flat), where the contact area tends to be extremely small, still conform to the elastic theory of Hertz because the overall contact is determined by the elastic stress field developed in the hinterland or bulk of the material. In most practical cases of contact between conforming surfaces, plastic deformation is to be expected at containing high points. The real area of contact, *A,* is therefore directly proportional to the applied load, *P:*

$$A = \frac{P}{p_0} \quad \text{(Eq 1)}$$

where p_0 is the yield pressure and roughly equal to 3*Y,* and where *Y* is the yield stress in tension. Because fretting only occurs at contacting areas, it follows that the amount of wear should be directly proportional to the applied load. This is generally found to be the case if the amplitude of slip is kept constant. In the early stages there is a running-in period in which metal-to-metal contact predominates (Fig. 15). This can be detected by measurement of contact resistance which remains low and depends for a given number of cycles on the magnitude of the load (Fig. 16). These observations are discussed in greater detail in the section "Mechanism of Fretting Wear" in this article.

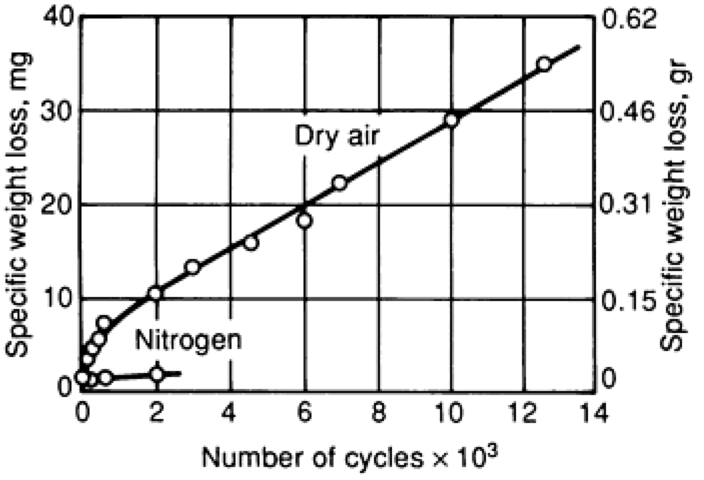

Fig. 15 Plot of fretting wear versus number of cycles for mild steel with 90 μm (0.0036 in.) slip amplitude in

both dry air and nitrogen atmospheres. Source: Ref 24

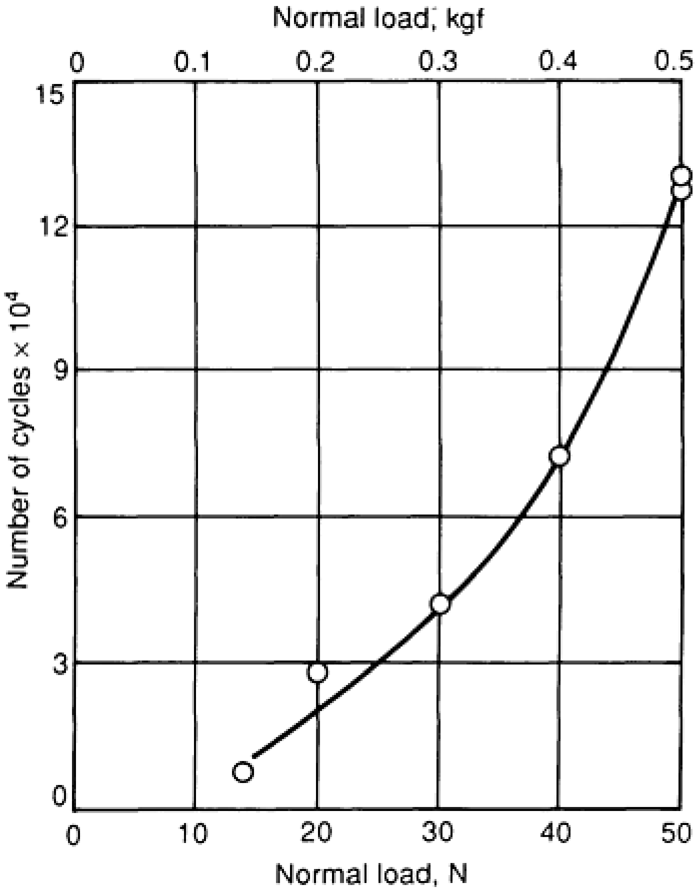

Fig. 16 Relation between initial period of metal-to-metal contact and normal load

Frequency. The effect of frequency was originally studied by Uhlig (Ref 24), who found an increase in wear volume at low frequencies for a given number of cycles. This was related to the formation and disruption of oxide films and was considered by Waterhouse (Ref 25). More recently, the question has been considered again by Söderberg, Bryggman, and McCullough (Ref 26), who were looking at a means of speeding up fretting wear tests, assuming that high frequencies had no significant effect. The range of frequencies investigated was from 10 to 10^4 Hz, using steel specimens in a crossed-cylinder contact. Their conclusion was that, in the partial-slip situation, although there was little effect on measurable wear, the increase in the interfacial strain rate at high frequencies led to increased fatigue damage and increased corrosion due to the rise in temperature. However, in the total-slip situation, there was little effect over the frequency range 100 to 20×10^4, and these high frequencies could be used in accelerated tests.

Not all movements that can lead to fretting damage take place at anything like the frequencies mentioned above. Relative movement can be due to differential thermal expansion, which, if arising from diurnal changes in temperature, can have a frequency of only a few cycles a day. The pressurizing of airplane cabins is in a similar frequency range. The movement of mooring cables due to water flow is of considerably higher frequency but is assumed to be ~0.1 Hz. In such circumstances, the environmental and corrosion effects have much greater importance, as can be seen by the extrapolation of Uhlig's results to lower frequencies (Fig. 17).

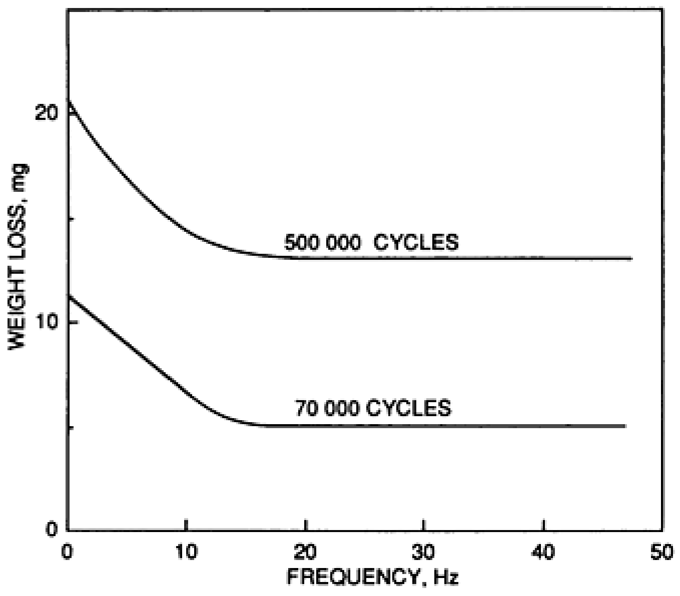

Fig. 17 Plot of wear versus frequency of fretting vibration

The area of low frequency has been mainly investigated in relation to electrical contacts. In many of these investigations, the low-frequency movement (0.003 to 0.03 Hz) has been produced by cyclic heating and cooling of a copper rod. This allows also very low amplitudes to be investigated (Ref 27). The extensive work of Antler (Ref 28) in the United States and of Braunovic (Ref 29) in Canada has explored the effect of different contacting surfaces on the contact resistance under fretting conditions. In these studies the aim has been to maintain metal-to-metal contact throughout the working life of the contact. A complication in these experiments is the formation of a friction polymer from carbonaceous impurities in the atmosphere, which can have a profound effect on the contact resistance. For separable connectors, gold plating appears to be the most satisfactory surface, although cheaper coatings are actively being sought (Ref 30) and are discussed further in the section "Prevention of Fretting Damage" in this article.

Type of Contact. As will be seen later when the role of fretting debris in the process is discussed (see the section "Effect of Debris on Wear" in this article), the ease with which debris can escape from the contact region is an important factor in the fretting process itself. It also gives rise to further problems by contamination of other surfaces (in a machine, for example).

Tomlinson's original design of an apparatus with torsional vibration of annulus on flat has much to commend it because no part of the contacting surfaces becomes exposed, and, for debris to escape, it must move at right angles to the direction of motion. A further slight advantage is that the amplitude of slip has a small variation from the inner to the outer edge and can therefore be used to investigate the effect of amplitude in one test. With flat contact surfaces, however, the initiation and development of areas of wear damage are sporadic no matter how carefully the surfaces are prepared and the alignment controlled. Contact pressure is usually expressed as the nominal value calculated from the apparent area of contact and the applied load. Measurement of the real area of contact would require contact resistance measurements at the outset of the test, or it could be calculated with a knowledge of the yield pressure (Eq 1). Contacts consisting of geometrical surfaces such as sphere on flat, cylinder on flat, and crossed cylinders allow some initial calculations based on elastic theory of the area of contact and stress distribution therein. However, these quantities are rapidly changed as the wear process proceeds. Also, such contacts increase the possibility for debris to escape. It has recently been shown that the escape of debris in the crossed-cylinder arrangement is greatly influenced by the direction of motion (Ref 31). The arrangement shown in Fig. 18 (b) allows the debris to escape by being pushed out by the axial movement of the upper cylinder, leading to more frequent metal-to-metal contact and a higher wear rate than the arrangement shown in Fig. 18 (a). However, in experimental investigations, the ease and cost of preparing specimens are significant factors, and the crossed-cylinder arrangement is one of the most convenient. It also mirrors the situation of contact between wires in steel ropes.

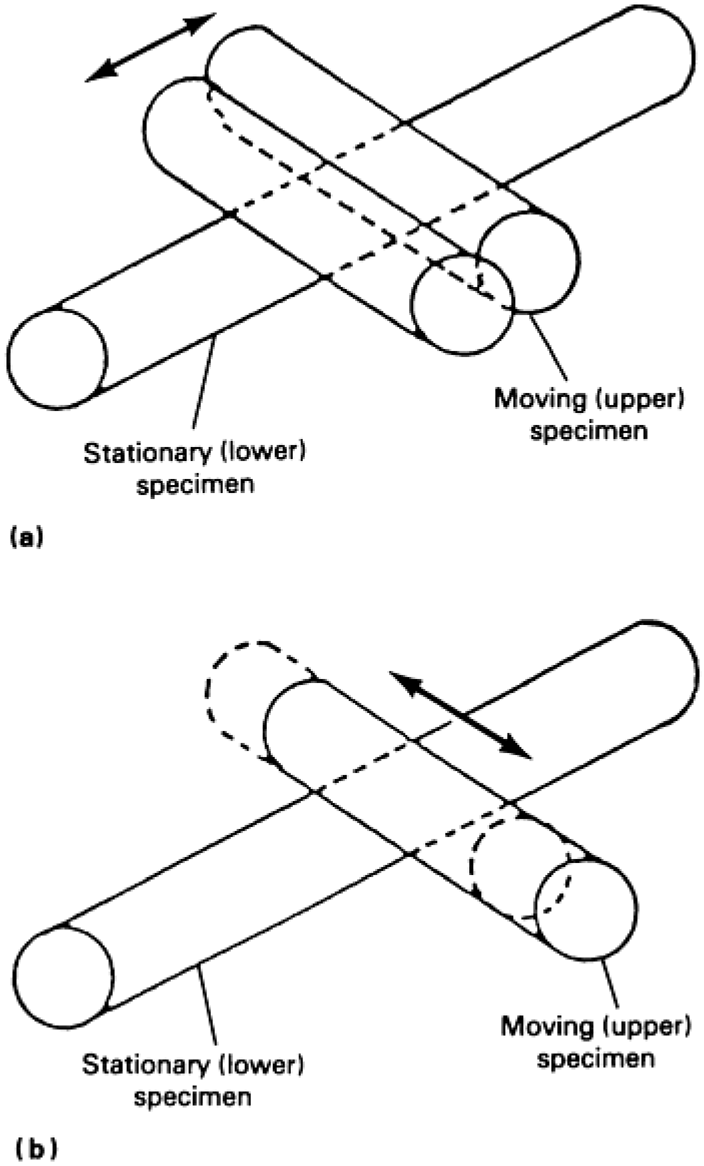

Fig. 18 Two test directions for determining fretting in a crossed-cylinder arrangement. (a) Parallel to axis of lower specimen. (b) At right angles to axis of lower specimen

Type of Vibration. In most experimental investigations, the vibration is simple harmonic motion of constant amplitude. This may be the case in practical cases of rotating shafts, but is very far from situations in which frequencies may vary and pass through areas of resonance. In addition, aircraft structures will be entirely under the influence of random loading with no fixed frequency or amplitude. The same can be said of ropes and cables in moorings, overhead ropeways, and elevator ropes.

There have been few investigations into this aspect of fretting wear. Elliott, Mabie, Furey, and Mitchell (Ref 32) conducted a detailed analysis of the vibrations in one of the bearings supporting the shaft of an ac/dc generator operating onboard a ship. Spectra of the relative displacements in the axial, tangential, and radial directions were determined in the frequency ranges 0 to 500 Hz and 0.5 to 10 kHz, with no load and under full load. Although it was not possible to distinguish between elastic movement and rigid body movement, it was assumed that amplitudes >1 μm (>40 μin.) were due to the latter. The amplitude range was from 4.30 to 10^{-4} μm (173 to 0.004 μin.) in the frequency range <250 Hz, with several of the peaks being >0.05 μm (>2 μin.). The tangential component under full load had an upper limit of 8 μm (320 μin.) and combining this with the movements in the axial and radial directions gave a vector sum of 120 μm (480 μin.), at which considerable fretting damage was experienced. Their analysis indicated that there was significant relative motion normal to the fretting surface.

This latter observation has been investigated by Golego and his co-workers (Ref 33). The construction of their tribometer allowed frequency variations, phase differences between tangential and normal vibration, and the control of resonance. They identified three areas:

- Subresonant loading conditions in which the damage was said to resemble typical fretting damage
- Resonant conditions in which the surface damage was significantly less due to the lower dissipation of energy due to friction
- Superresonant operation, which showed tearing of the surface that was associated with a phase shift of 90° between the tangential and normal vibrations

Impact Fretting. In the section "Type of Vibration," the effect of a cyclically varying normal force superimposed on the tangential movement was considered for situations in which the two surfaces remained in constant contact. The circumstances where the two surfaces can become separated during some part of each cycle are somewhat different, because of the contribution of impact. As mentioned earlier in the section "Fretting Wear in Mechanical Components," this is a problem frequently encountered in heat exchangers, where pipes or fuel rod containers are restrained by supports or baffles but experience vibration as a result of fluid flow.

Two types of wear can be distinguished in the practical case encountered in nuclear reactors. The first involves whirling of the tube resulting in intermittent unidirectional sliding and is obviously not fretting. The small-amplitude movement that results in fretting-type damage is the result of flow-induced vibrations. The important parameters are impact force, clearance between tube and support, support plate thickness, and frequency. The wear rate for stainless steel increases by an order of magnitude for a tenfold increase in impact force, and a similar increase for a fourfold increase in the clearance. Increasing the support plate thickness from 10 to 20 mm (0.4 to 0.8 in.) reduces the wear rate from 0.7 to 0.2 μm (30 to 8 μin.) per 10^6 cycles. At frequencies below 40 Hz, there is no effect of frequency, but at higher frequencies the wear rate is reduced due to the reduction in contact time per cycle (Ref 34). These results were obtained at room temperature, whereas in operation these devices would be at a higher temperature and thus the wear rates could be profoundly influenced both by temperature and environment; such effects are discussed in the section "Environmental Effects."

Many years of work by de Gee (Ref 35) indicated that the combination of impact and fretting was more severe than fretting alone, whereas much of the work on tube and tube support vibration suggests that the impact contributes little to the wear rate and that continuous contact is more damaging (Ref 36, 37). An important variable in considering this type of motion is the phase relation between the normal and tangential vibrations. Differences are to be expected between impact at maximum tangential velocity and zero velocity. Also, the time period per cycle that contact is made will be of great significance. In Ref 34, the following contact times per cycle are quoted as a function of frequency:

Frequency, Hz	Contact time per cycle, s	Difference between impact at maximum tangential velocity and zero velocity, %
26	0.022	57
40	0.010	40
60	0.005	30

Rigs have been constructed to study the effects of these phase relationships, particularly under severe environmental conditions, and those results that have been published are referred to in Ref 34.

Surface Finish. Early observations of practical examples of fretting damage suggested that the more highly polished the contacting surfaces, especially if flat, the worse the damage. On polished aluminum where the debris is largely Al_2O_3 (corundum) with a high hardness, it could spread the damage, whereas on a rough surface the debris can escape into the hollows between the real contact areas. There is also the possibility that on a rough surface, if the exciting force is of small amplitude, some of the relative movement will be taken up by elastic deformation of the asperities. Some work by Calhoun shows that a rougher surface suffers less damage (Ref 38).

Shot peening is a widely applied surface treatment that produces roughening, work hardening, and a residual compressive stress in the surface. The author showed that shot peening a steel surface reduced the coefficient of friction in fretting (Ref 39), but this could also be due to work hardening and possibly also to the compressive stress. To investigate this phenomenon further, and to try and separate the three effects of shot peening, a series of tests was carried out on treated cylindrical steel specimens. The residual stress and work hardening could be removed by annealing, the residual stress could be reduced by controlled tensile straining, and the surface roughness could be removed by careful surface polishing (Ref 40). The shot-peened surface of 0.4% C steel had a very low value for fretting wear; however, polishing raised the level of wear to that of the unpeened steel.

Residual Stresses. Because one of the possible mechanisms of fretting damage is surface fatigue, it is to be expected that a residual stress field will have some effect on the wear process. Experiments were performed with a bearing ball on a bearing steel (1.0C-1.5Cr) specimen that was statically bent to give residual stresses over a range -900 to 900 MPa (-130 to 130 ksi). When the specimen was vibrated with a contact load of 216 N (22 kgf) and an alternating tangential load of ±20 N (±2 kgf) so that partial slip was occasioned, the depth of the wear scar increased with tensile stress but decreased with compressive stress (Fig. 19).

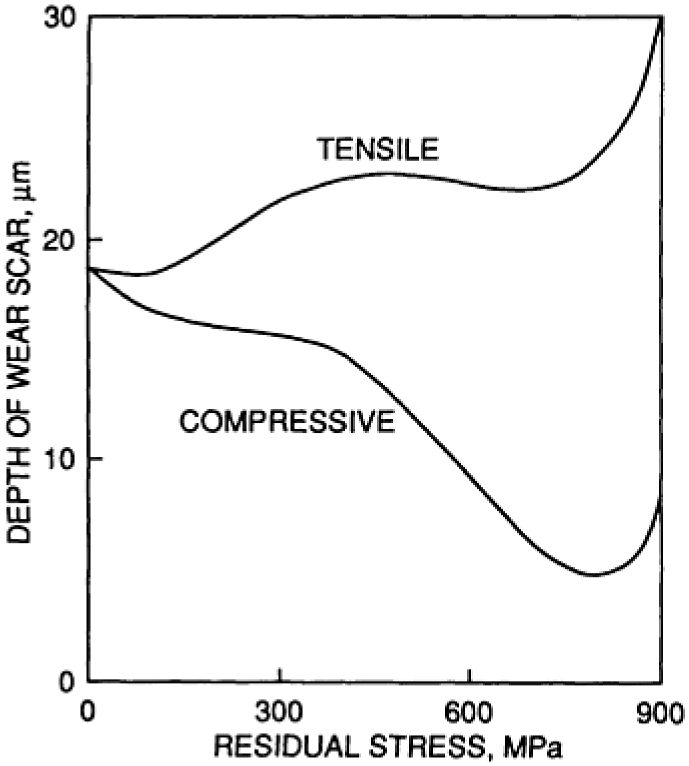

Fig. 19 Plot of depth of wear scar versus compressive and tensile residual stresses in the fretted surface. Source: Ref 41

Endo had shown earlier that residual stresses can be generated by the fretting action (Ref 42) and this has been confirmed in further work by Yournadj, Maeder, and Moisan (Ref 43). In fretting, flat steel surfaces with residual compressive stresses up to 735 MPa (107 ksi) were generated; these were most important in a direction at right angles to the direction of motion. The converse of this effect, namely the modification of existing compressive stresses by fretting, has been observed by Fair, Noble, and Waterhouse (Ref 44) in fretting-fatigue experiments. The stresses fade under normal fatigue but disappear much more rapidly under fretting fatigue (Fig. 20).

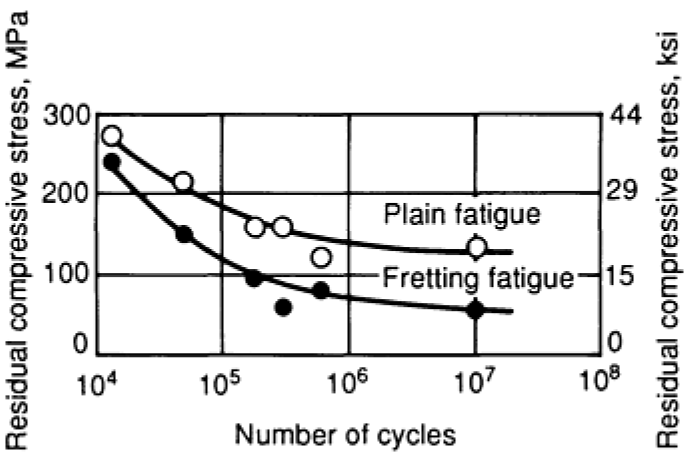

Fig. 20 Fading of surface compressive stress induced with a number of fretting cycles by shot peening

Finally, the presence of a static tensile stress can lead to the propagation of cracks initiated by the fretting (Ref 45).

Materials

If fretting wear is a possible occurrence in the design of a machine or structure, it may be possible to reduce the effect by choosing materials that are more resistant to such damage. This section deals with bulk materials not coated or surface treated; coated and surface-treated materials are dealt with in the section "Prevention of Fretting Damage" in this article. In addition, information on the behavior of new materials such as composites and ceramics must also be considered because of their increasing use in engineering applications.

Steels have been most extensively studied, largely because of their ability to change mechanical properties over a wide range by heat treatment without changing their chemical composition. In experiments with a steel ball on a steel flat, in which the hardness was varied from 220 to 850 HV, there was little difference in the wear loss (Ref 46). In crossed-cylinder experiments with three alloys of the same crystal structure, increasing hardness is shown to lead to a decrease in the critical amplitude between partial and total slip (Ref 47). The materials were copper, copper-silicon, and austenitic stainless steel, all materials of low stacking fault energy; as a consequence, work hardening occurred at low frequencies but softening set in at high frequencies because of the temperature rise.

In some investigations, notably those by Dobromirski (Ref 48) and Beard (Ref 49), the formation of a white etch-resistant layer has been detected in fretting of carbon steels (Fig. 21). This material is extremely hard and tends to develop cracks. It is often referred to as martensite, and some authors have regarded this as evidence that high local temperatures can be developed in fretting. The question of temperature rise is controversial and is discussed more fully below. However, if there is a temperature rise, materials that rely on low-temperature heat treatment for their optimum mechanical properties (for example, most aluminum alloys) are likely to suffer a further type of damage in fretting.

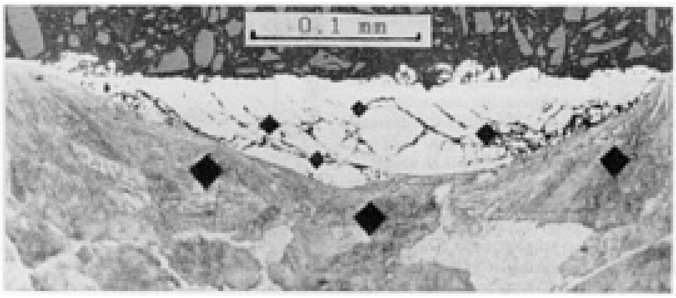

Fig. 21 Cross-sectional view of a white layer of martensite produced by fretting of a carbon steel connecting rod. Axial stress, 0 to 380 MPa (0 to 55 ksi); contact stress, 40 MPa (6 ksi); fretting cycles, 10^5. Sample was

nital etched and viewed with scanning electron microscopy (SEM).

A recent development has been the rapid quenching of liquid metals to produce amorphous metals. Fretting of two of these materials, Co-4Fe-2Mo-16Si-12B and Fe-4Si-15B, indicates that they are not wear resistant and become embrittled by the fretting action (Ref 50).

Metals and alloys that rely on a protective oxide film for corrosion resistance can suffer considerable fretting damage in environments (for example, ambient air), that would not be considered particularly corrosive. These include the more reactive metals such as aluminum, titanium, zirconium, and chromium when used as elements to alloy stainless steels. This aspect of fretting is considered in the section "Environmental Effects" in this article.

When dissimilar metals pairs are fretted against each other, their mutual solubility is a factor in the severity of the damage. Nickel, chromium, and iron are severely damaged when fretted against iron or chromium because of high mutual solubility; however, the damage is mild when these metals are fretted against copper or silver because there is no solubility (Ref 51).

In the fretting of polymers against steel, the possibility exists that one material will be transferred to the opposite surface. Damage arises in this case from platelike iron oxide particles adhering to the polymer; thus, the process becomes the fretting of two oxide-coated surfaces. Damage can occur to the polymer by the formation of cylindrical wear particles formed by rolling up of thin detached surface layers, which are extruded in a direction at right angles to the motion (Ref 52, 53).

In an investigation of fretting wear of fiber-reinforced polymers (composites) in contact with an aluminum alloy, weight loss was used to measure the damage (Ref 54). At amplitudes <900 μm (<0.036 in.), the wear was low and showed a slight increase with increasing amplitude. Above 900 μm (0.036 in.), the wear accelerated. Wear rate showed a stepwise increase with frequency, the critical frequency being 35 Hz at room temperature but reduced to 20 Hz at 80 to 100 °C (175 to 212 °F) due to a local rise in temperature. Unlike metals, which show a linear increase in wear with increasing normal load, these materials show little effect of load up to a critical value at a pressure of 20 MPa (3 ksi), above which a rapid increase occurs. Fiber orientation with respect to the sliding direction is another variable with these materials. Here the specific wear rate was negligible at angles of 0 and 90° between fiber axis and sliding direction, but showed a pronounced peak at 45°, as did the coefficient of friction (Fig. 22).

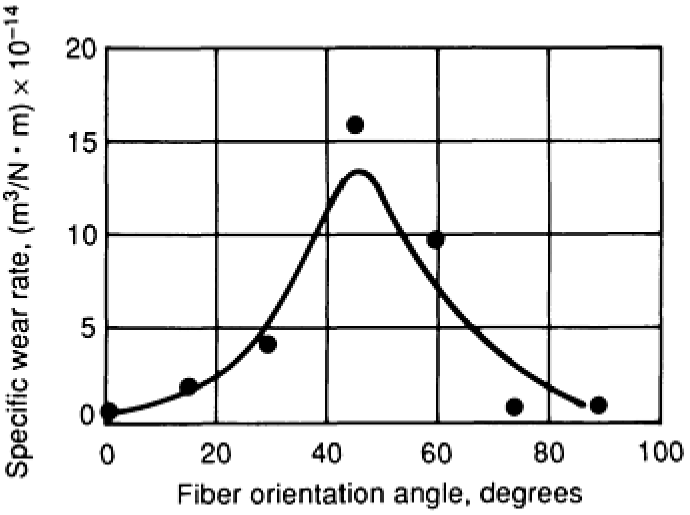

Fig. 22 Plot of fretting wear versus fiber orientation angle in a composite

In experiments involving the fretting of sintered alumina against a wide variety of metallic materials in a crossed-cylinder configuration, no detectable wear was found on the alumina, although metal transfer to its surface occurred (Ref 55). A similar result was found by Klaffke in fretting a steel ball against alumina, silicon nitride, and zirconia in dry air; however, silicon carbide produced equal wear on the ceramic and steel (Ref 56). An increase in relative humidity

generally resulted in a decrease in wear rate, except in the case of silicon nitride, which exhibited behavior similar to that silicon carbide.

It appears that when oxides such as alumina and zirconia are fretted, there is little damage. Fretting alumina against alumina produced no measurable wear, although some polishing of the surface was apparent (Ref 31, 57) (Fig. 23).

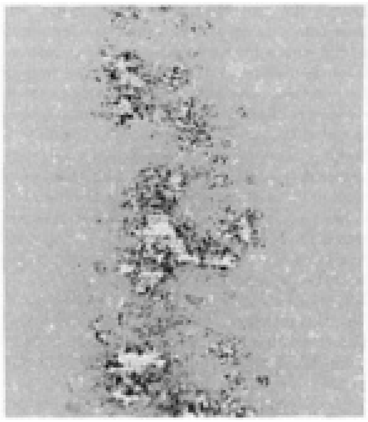

Fig. 23 Fretting mark generated by fretting an alumina cylinder against an alumina flat

In one of the earliest observations of fretting wear, Godfrey fretted a steel ball against the underside of a glass microscope slide and observed the process in the microscope (Ref 58). This type of experiment has been repeated in Japan, but no quantitative measurements of wear have been made. However, valuable information has been gained on the initiation of cracks in the glass, a typical brittle material, and on the onset of damage to the steel, and is therefore relevant to discussions on fretting mechanisms (Ref 59).

Effect of Debris on Wear

Debris oozing from a joint or connection in machinery is often the first indication that fretting damage is occurring. In recent years, the role of the debris in wear processes has been given considerable attention because it can build up between the sliding surfaces and increase the number of interfaces from one to two (Ref 60). This is particularly the case in fretting where escape of the debris is greatly restricted compared with unidirectional sliding. This section will focus on the form, composition, and role of the debris.

It is well established that the debris on mild steel and other steels in air is essentially α-Fe_2O_3, which when finely divided, is reddish brown in color and nonmagnetic. Its hexagonal crystal structure is identical with that of α-Al_2O_3. Under high compressive loads, it can become compacted, and its color is then black and iridescent. In this respect, it is identical to the mineral hematite, which in massive form is blackish but is red when powdered. On aluminum, the debris is black and consists of aluminum particles surrounded by Al_2O_3. The aluminum content is 23% and the powder is pyrophoric (Ref 61). In other metals, such as copper and titanium, the debris is the expected oxide. In some cases, depending on the method of its production, the debris can contain some unoxidized metal.

The debris is usually in the form of thin platelets a few microns thick and 50 to 100 μm (0.002 to 0.004 in.) in diameter, but it can be much smaller, as in Fig. 24, where the debris resulted from fretting steel against a polymer. The particle size was shown in this case to be related to the surface energy of the polymer. Fretting sometimes occurs between the walls of fatigue cracks, when spherical and cylindrical shapes of debris may result due to the very small movements and the high compressive stresses during the compression part of the fatigue cycle.

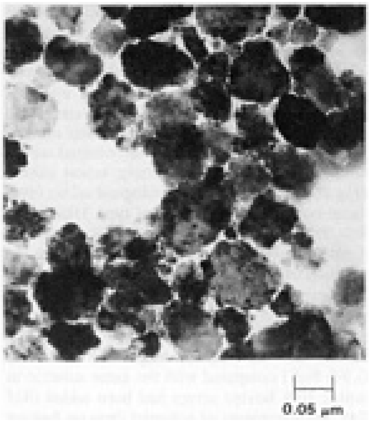

Fig. 24 Oxide debris produced when fretting steel against a polymer

The role of the debris on steel specimens has been demonstrated by carrying out tests where the fretting surfaces were periodically separated and the debris removed (Ref 62), resulting in an increase in the wear rate. Conversely, the introduction of α-Fe_2O_3 powder between the surfaces reduced the wear rate; the resultant surfaces were hardly damaged and showed signs of slight polishing. In long-term experiments, the terminal stage of fretting was identified as the formation of extensive beds of compacted oxide with a much reduced wear rate (Ref 63). With very small slip amplitudes of less than 10 μm (400 μin.), the wear ceases because the oxide beds support the load and separate the surfaces (Ref 64). At higher amplitudes of $\geq$20 μm ($\geq$800 μin.), the wear rate is much reduced; however, wear continues, and occasional metal-to-metal wear can still be detected by contact resistance measurements, even after millions of cycles (Ref 65). These observations have considerable bearing on the ideas that have been put forward for explaining the mechanism of fretting, which are discussed below. The conclusion is, however, that the accumulation of debris between the surfaces in compacted layers is more likely to reduce further wear and that abrasion by the oxide debris is not a significant contribution to the problem.

It is interesting to note that in one of the more recent investigations (Ref 64), it was stated that the debris had some of the characteristics of a thixotropic liquid, an observation that had been made by Godfrey in 1951 (Ref 58).

Environmental Effects

Obviously, most investigations and reported cases of fretting wear occur in a normal atmosphere where oxygen and water vapor are the main corrosive agents, although there is evidence that nitrogen may be involved in alloys containing nitride-forming elements.

Vacuum. An investigation on the effect of reduced air pressure on the fretting of a carbon steel cylinder on a flat showed that in a vacuum of 1 mPa (1.5×10^{-7} psi), the coefficient of friction was high at 3.0, and, although little measurable wear took place, considerable surface damage occurred due to adhesive transfer of metal, which ceased at pressures above 0.1 Pa (1.5×10^{-5} psi) (Ref 66). As the pressure was further increased, the coefficient of friction fell to a value of ~1.0 at 10 Pa (1.5×10^{-3} psi), whereas the wear remained low up to this pressure. Above 10 Pa (1.5×10^{-3} psi), the coefficient of friction remained constant but the wear rate increased rapidly (Fig. 25). Below this critical pressure, any debris formed was black and identified as Fe_3O_4, but above the critical pressure the debris was red and identified as α-Fe_2O_3. Similar results were obtained with an austenitic stainless steel, except in this case the plastic deformation at the low pressures resulted in martensite formation and the growth of surface fatigue cracks (Ref 67). The effects of slip amplitude and normal load were investigated on the initiation and growth of such cracks at a pressure of 4 MPa (6×10^{-7} psi); the tests showed that the number of cracks decreased rapidly at an amplitude $\geq$50 μm ($\geq$0.002 in.) but that the length of the longest crack increased markedly above this amplitude (Ref 68). The number of cracks increased steadily over the load range 8 to 30 N (0.8 to 3 kgf), whereas the length of the longest cracks was greatest at 8 N (0.8 kgf) but decreased rapidly at loads above 13 N (1.3 kgf). These results have considerable significance in relation to the fatigue aspects of fretting, particularly in connection with space research. Further work on an Fe-Cr-Ni-W amorphous alloy (hardness, 1300 HV) fretting against stainless steel gave similar results, although the coefficient of friction remained low over the whole pressure range, which was attributed to cylindrically shaped debris acting as rollers (Ref 69).

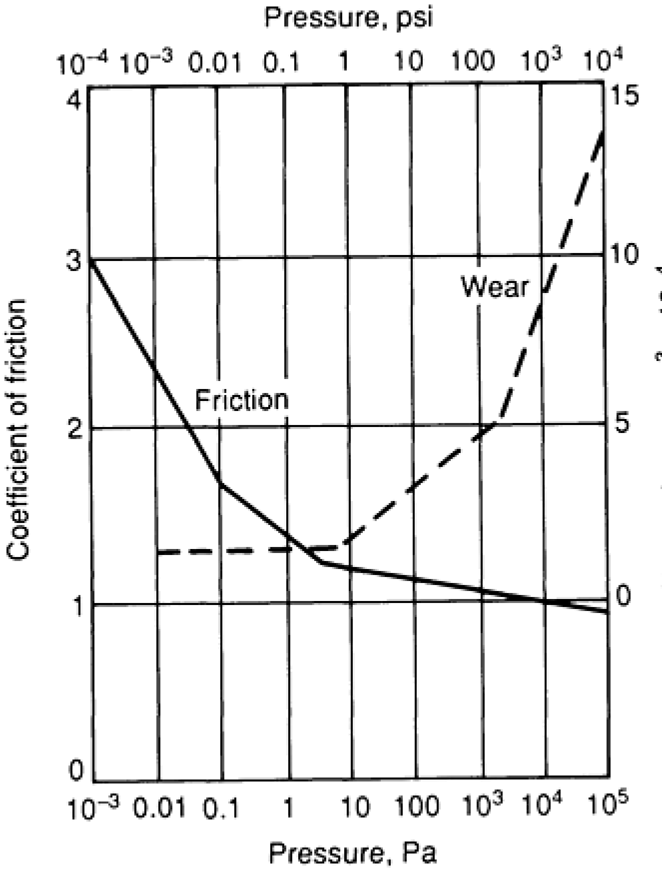

Fig. 25 Effect of atmospheric pressure on the friction and wear of a carbon steel cylinder

The effect of high pressure has not been extensively investigated. The studies that have been conducted on the effects of high pressure have been associated with the nuclear power industry, specifically relating to problems in the advanced gas-cooled reactor (AGR). In this case, the reactor is cooled by carbon dioxide at a pressure of 4 MPa (40 atm), with temperatures in the region of 600 °C (1110 °F) (see the section "Low and High Temperature" in this article).

Humidity. After oxygen, water vapor is the most significant environmental factor in fretting wear. In a study of a wide variety of pure metals tested in a hemisphere on flat configuration and at a slip amplitude of 80 μm (0.0030 in.), most metals such as silver, copper, titanium, and iron showed a peak coefficient of friction value between 10 and 15% relative humidity (RH), with a corresponding peak in wear volume (Ref 70). With chromium, the peaks appeared at 5% relative humidity, but with aluminum and nickel the peaks occurred at very low humidity. At normal atmospheric humidity (~ 50% relative humidity), all the metals except nickel showed a gradual decrease in fretting wear. This corresponds well with earlier observations on steel specimens (Ref 24). Because aluminum alloys are particularly sensitive to the effects of water vapor in fatigue situations due to the reactivity of an exposed aluminum surface and the liberation of hydrogen, further work has been devoted to the aluminum-zinc-magnesium alloy (Ref 71). Fretting wear was found to be the same in dry air as in dry argon, thus discounting oxygen as an active agent; however, in air of 60% relative humidity, the wear rate was much higher because the wear debris was nonadherent and thus metal-to-metal contact was increased. In addition, it was found that softening due to overaging of the surface material in the contact region developed in humid air.

As mentioned above, water vapor has a considerable effect on the fretting wear of certain ceramics, particularly silicon carbide and silicon nitride (Ref 56). With silicon carbide, alumina, and zirconia, the high rate of wear at 5% relative humidity is greatly reduced at humidities >50% with a steady decrease in the coefficient of friction. Silicon nitride shows a similar wear rate to silicon carbide at 5% relative humidity, but the rate increases linearly with time at ≥50% relative humidity. This is related to the propensity for silicon nitride to be transformed into silica.

Aqueous Electrolytes. Fretting of corrosion-resistant metals in aqueous environments was originally investigated because of problems associated with orthopedic implants in the human body. In some of these devices, metal-to-metal contacts (for example, screws and bone plates) could suffer fretting due to the activity of the patient. In potentiostatic

experiments on an austenitic stainless steel, it was found that the corrosion current increased linearly with the amplitude of slip at a fixed frequency and was also linearly related to frequency at a fixed amplitude (Ref 72). Where potential control was not applied, there were large drops in potential with a slow recovery when the fretting action ceased (Fig. 26). In studies in physiological saline (artificial body fluid) of fretting of type 316L stainless steel and Co-Cr-Mo alloy, the latter was found to have the lower wear rate, although the addition of albumin reduced the wear rate of the stainless steel (Ref 73). In tests with a fretting simulator using screws and a bone plate of type 316L stainless steel, the weight loss of the screws was an order of magnitude greater in 0.9% NaCl compared with the same solution to which 10% bovine serum had been added (Ref 74). Measurements of potential drop on fretting obtained in laboratory experiments were compared with *in vivo* measurements on bone plates fitted in sheep walking on a treadmill. The potential drop was found to be related to the load at low levels of torque to which the screws had been tightened (Ref 75). Further experiments on the simulator revealed that the wear weight loss of plates and screws was highest for stainless steel (2.8 mg, or 0.043 gr), less for wrought Co-Ni-Cr-Mo (0.65 mg, or 0.010 gr) and lowest for Ti-6Al-4V ELI (0.13 mg, or 0.0020 gr) (Ref 76), where ELI is extra-low interstitial. It has since been established that the effect of proteins on fretting corrosion depends on the relation of the pH of the solution to the isoelectric point of the protein. At pH values below the isoelectric point, no effect is seen, but at pH values above the isoelectric point there is a reduction in the wear rate (Ref 77).

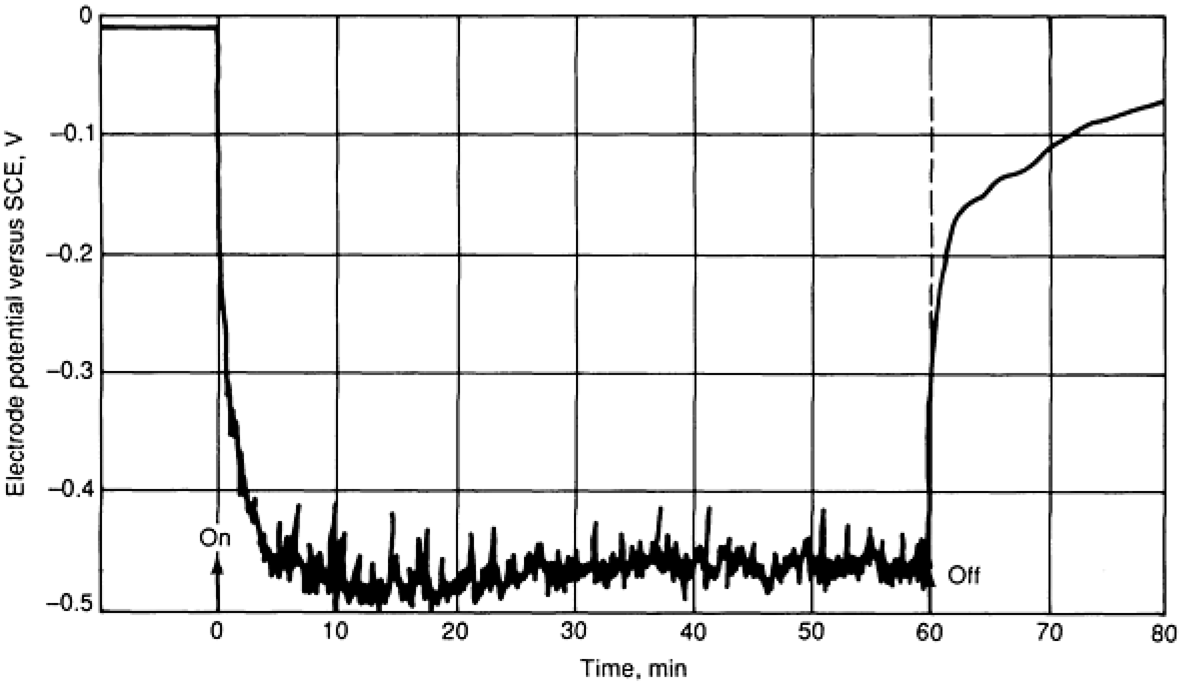

Fig. 26 Potential drop obtained when fretting Ti-6Al-4V (IMI 318) titanium alloy in a saline solution

The investigation of corrosion-resistant materials under fretting conditions in aqueous electrolytes was obviously of considerable interest because they rely on a protective oxide film for their corrosion properties. Continual disruption of this film is known to produce high corrosion rates, as confirmed by measurements of weight loss or volume of pits, which equates to rapid wear rates. The development of offshore oil rigs in the 1980s provided many more examples of fretting corrosion occurring on less corrosion-resistant materials, such as the weldable steels used in the construction of the rigs and the steel ropes used to moor them in the marine environment. The specific wear rate for a 1.5% Mn steel in air was 1.07 $m^3/N \cdot m \times 10^{-16}$ but in seawater it increased to 10.0 $m^3/N \cdot m \times 10^{-16}$ at 50 Hz and 235.5 $m^3/N \cdot m \times 10^{-16}$ at 1 Hz (Ref 78). Fortunately, application of cathodic protection of -950 mV versus standard calomel electrode (SCE) reduced the wear rate almost to that in air.

Steel ropes are extensively used in marine conditions. The development of the offshore oil industry has increased the use of these ropes as moorings for the oil rigs. The single-strand ropes are made up of layers of 5 mm (0.2 in.) diameter steel wires; successive layers are spiralled in the opposite sense to the adjacent layers. Numerous interwire contacts are referred to as trellis contacts. The fretting behavior of these wires in artificial seawater has been extensively investigated (Ref 79). In crossed-cylinder tests with an amplitude of slip of 50 μm (0.002 in.), a normal load of 3 N (0.3 kgf), and a frequency of 30 Hz, it was found that the wear volume after 5×10^6 cycles for the 0.64% C steel was 55×10^{-4} mm^3 (34×10^{-8} $in.^3$)

in air, 167 × 10^{-4} mm^3 (102 × 10^{-8} $in.^3$) in seawater, but reduced to 4 × 10^{-4} mm^3 (2 × 10^{-8} $in.^3$) when a potential of -950 mV versus SCE was applied (Ref 80). In 3.5% NaCl solution the wear was even higher at 214 × 10^{-4} mm^3 (130 × 10^{-8} $in.^3$), indicating that the magnesium salts in the seawater were having some inhibiting effect. The effect of coating the wire by hot dip galvanizing was similar to the effect of cathodic protection, reducing the wear to ~10 × 10^{-4} mm^3 (~6 × 10^{-8} $in.^3$) in seawater.

More aggressive solutions have not been widely investigated, apart from two examples by the author. Fretting of an austenitic stainless steel in 0.1 H_2SO_4 produced severe pitting in the contact region (Fig. 27). In some work related to the cooling of suspensions of radioactive solids in concentrated nitric acid, it was found that austenitic stainless steel tubes in a crossed-cylinder configuration when fretted in this mixture developed very strong adhesion as though the scouring action of the solid matter had produced clean metal surfaces that were able to form cold welds. It is interesting to note that strong adhesion was found when austenitic stainless steel was fretted against itself in liquid sodium at 500 °C (930 °F). The force to part the surfaces was calculated to require a tensile stress of 500 MPa (73 ksi), greater than the ultimate tensile strength (UTS) of the material (Ref 81).

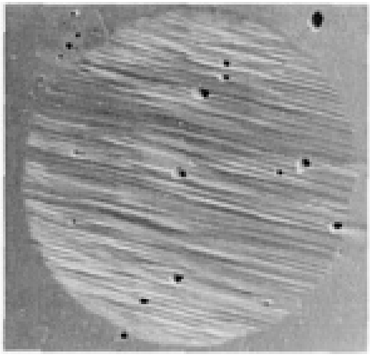

Fig. 27 Local pitting produced when an austenitic stainless steel ball is fretted against an austenitic stainless steel flat in 0.1 N H_2SO_4

Low and High Temperature. The increasing development of space engineering has meant that dynamic systems have to operate not only in vacuum but also at very low temperatures. Fretting of a spherical surface on a flat, both composed of austenitic stainless steel, at 4 K (-452 °F) in liquid helium resulted in high friction but little wear, very similar to the situation in high vacuum (see the section "Vacuum" in this article). The explanation was similar, that is, that oxide films did not grow at this temperature. At 77 K (-320 °F), the friction and wear were the same as at 293 K (-68 °F).

Much more attention has been given to high-temperature fretting in oxidizing atmospheres because this is a situation that is very common in practice (for example, in gas turbine aeroengines and in the AGR device). The pioneer work of Hurricks and Ashford (Ref 82) and later of Hurricks (Ref 83, 84) showed that there was a great reduction in the coefficient of friction and wear when mild steel was fretted in air at temperatures up to 500 °C (930 °F). In argon, however, surface damage was severe. At about this time, G.C. Wood was investigating the reciprocal sliding of certain alloys at high temperature in an oxidizing atmosphere and found that many alloys containing combinations of iron, nickel, and chromium developed a very smooth oxide, which he termed "glaze" oxide, that had low friction and low wear (Ref 85). A similar type of oxide was found in fretting a nickel-base alloy at 540 °C (1005 °F) (Ref 86). Fretting wear tests at amplitudes of 10 and 40 μm (0.0004 and 0.0016 in.) showed low coefficients of friction at 280 and 540 °C (535 and 1005 °F) compared with room temperature, and corresponding reductions in wear damage (Ref 87). However, if the air pressure is reduced to 1 mPa (1.5 × 10^{-7} psi) severe surface cracking is produced (Ref 88). The alloys that are capable of forming the "glaze" oxide are those on which an oxide with a spinel structure can develop (for example, mild steel [$FeO \cdot Fe_2O_3$], stainless steels [$FeO \cdot Cr_2O_3$, $NiO \cdot Cr_2O_3$, $NiO \cdot Fe_2O_3$], and nickel-chromium alloys [$NiO \cdot Cr_2O_3$]). If the oxide film is damaged, it is self-repairing at the high temperature but does not survive at room temperature (Ref 89). Titanium alloys do not behave in quite the same way; however, as shown in Fig. 28, implantation with bismuth or barium ions results in very low friction and wear results at temperatures between 400 and 600 °C (750 to 1110 °F) (Ref 90). For such films to survive, the substrate must have sufficient creep resistance to withstand the high stresses in the contact regions; otherwise, cracking can occur (Ref 91); see Fig. 29.

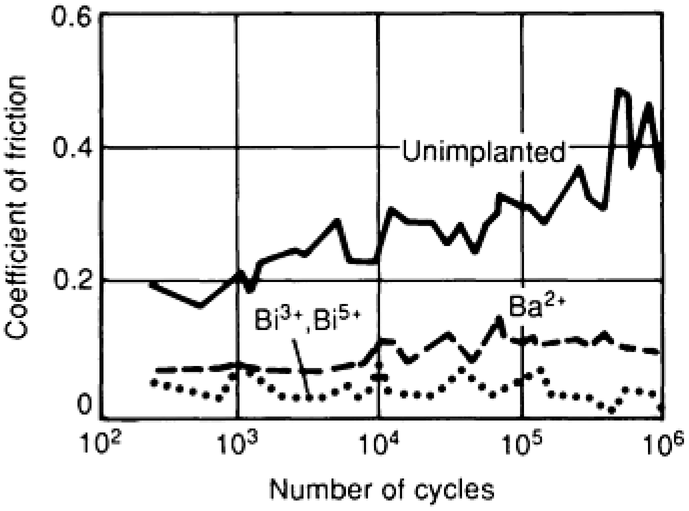

Fig. 28 Effect of ion implantation on the coefficient of friction in fretting of IMI 550 titanium alloy at 500 °C (930 °F)

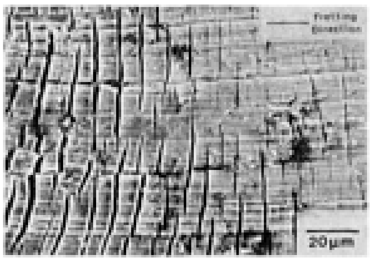

Fig. 29 Cracking of "glaze" oxide layer because of substrate creep in the fretting contact regions

Measurement of Fretting Wear

Profilometry. The very small amount of material that is removed in most fretting experiments renders the traditional method of measuring wear by weight loss impracticable. The recently developed method of surveying the surface by profilometry, where the instrument can plot out an isometric projection of the surface and the computer can produce a figure for the volume of the scar below the original surface and also the volume above the original surface, gives one of the best quantitative and descriptive assessments of the damage (Ref 92). When this method was checked with weight loss measurements, good agreement was found. Figure 30 shows the scar in a crossed-cylinder arrangement.

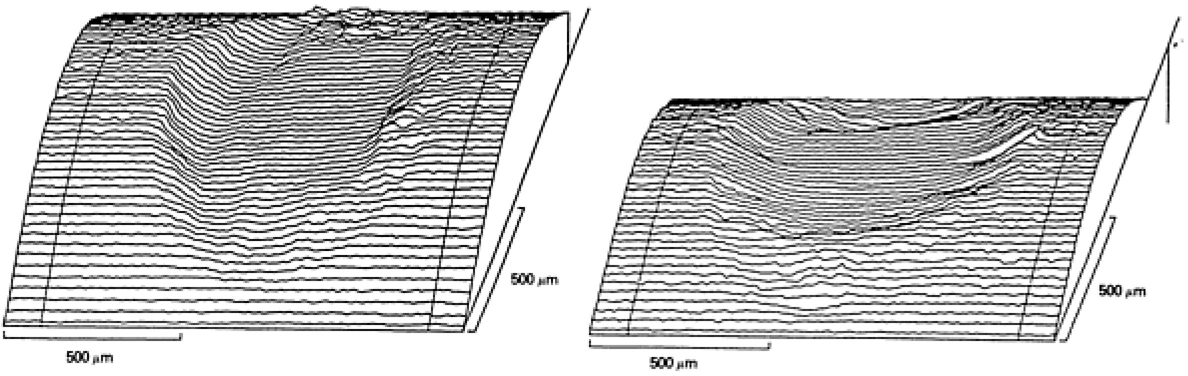

Fig. 30 Two views of an isometric projection of a scar in the crossed-cylinder arrangement

Holographic Interferometry. Another method that gives a visual impression of the damage is holographic interferometry. This enables a contour map of the surface to be generated prior to the wear process in order to compare it with a similar map generated after the wear has occurred. By using holographic image subtraction, very small changes in surface topography can be detected (Ref 93).

Thin-Layer Activation. A quantitative method applied to measuring fretting wear is "thin-layer activation" (TLA). A thin layer of radioactive atoms is produced on the surface by bombardment with a high-energy ion beam from an accelerator. After wear has taken place, debris is removed and the residual radioactivity is measured. A sensitivity of at least 0.2 μm (8 μin.) is claimed (Ref 94).

Measurement of Axial Distance. A less-sophisticated method for the case of crossed cylinders is the determination of wear from the decrease in distance between their axes (Ref 95). The advantage of this method is that it allows measurements to be made without dismantling or disturbing the contact.

Mechanism of Fretting Wear

It is generally agreed that when fretting wear is taking place between two flat surfaces or two conforming cylindrical surfaces (that is, conditions in which escape of debris is not as easy), the progress with time (or number of cycles) can be recognized as occurring in three stages (Ref 96, 97):

- Initial stage of a few thousand cycles when metal-to-metal contact is prevalent, resulting in local welding, roughening of the surface, high friction, and low contact resistance. Fatigue cracks are initiated in this stage if the movement is a result of cyclic stressing (Ref 98)
- Formation of beds of compacted oxide with a fall in coefficient of friction and erratic behavior of contact resistance as it oscillates between high and low values
- Onset of a steady state in which the friction is more or less constant and the contact resistance is generally high with occasional momentary falls to a low value

These changes are illustrated in Fig. 31, 32, and 33 and can be recognized in the wear curve (Fig. 15). The length of the initial stage depends on the amplitude of slip and the normal load (Fig. 16).

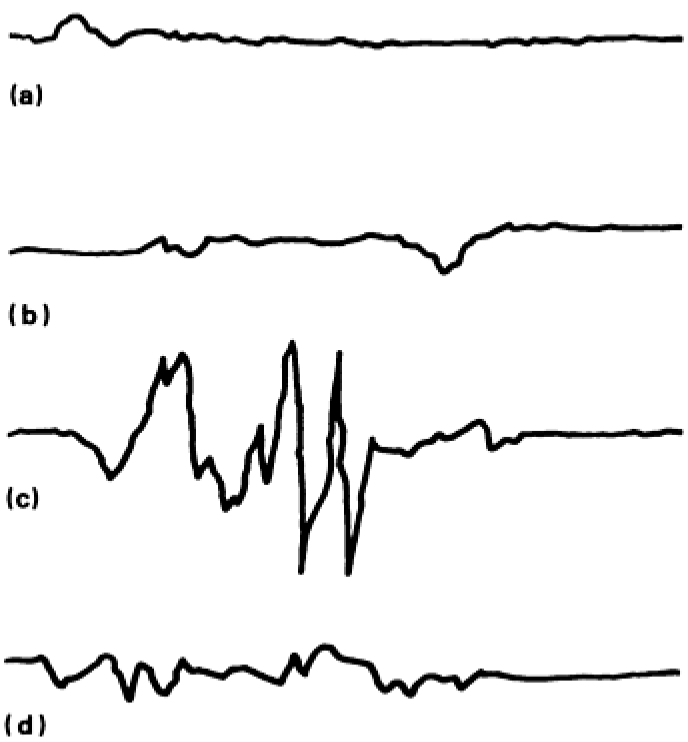

Fig. 31 Changes in surface roughness as a function of the number of fretting cycles for metal-to-metal contact. (a) As received. (b) 10^3 cycles. (c) 5×10^4 cycles. (d) 3×10^5 cycles

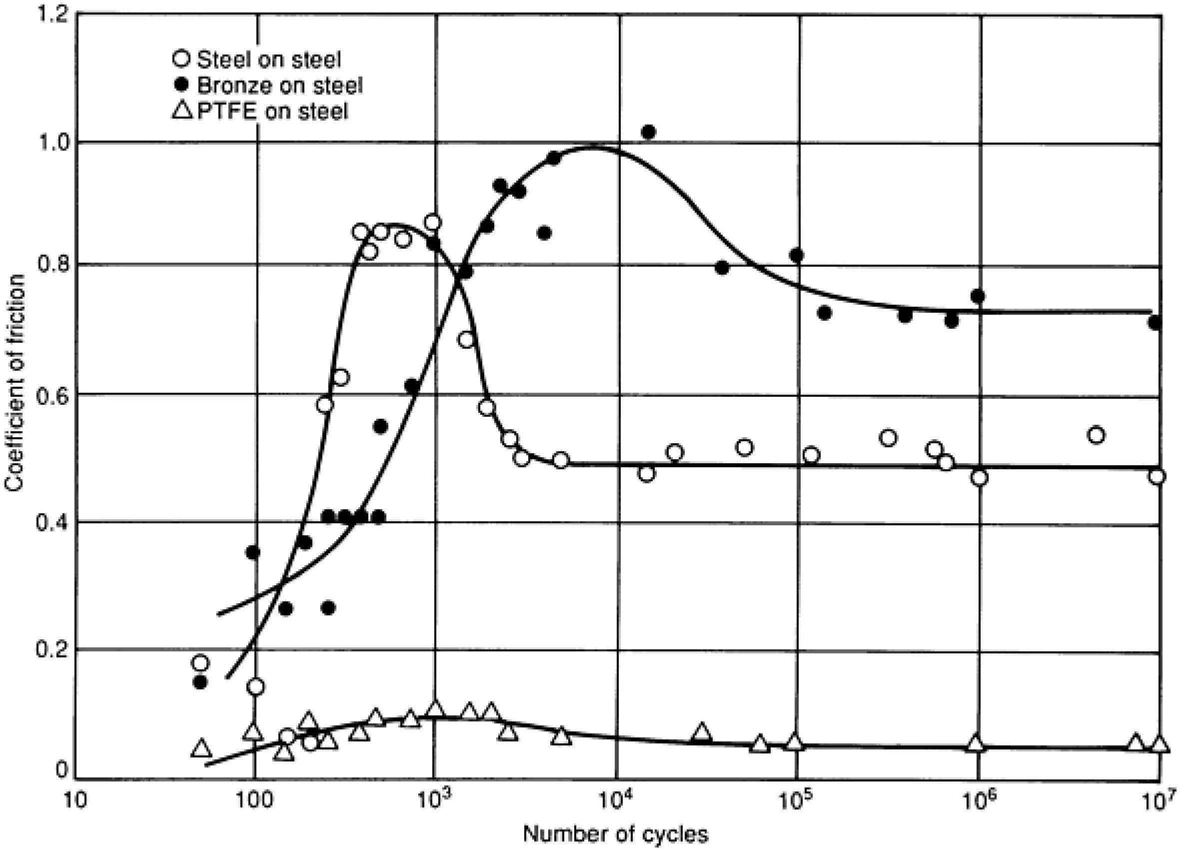

Fig. 32 Plot of the coefficient of friction versus the number of fretting cycles for three selected materials tested

on steel

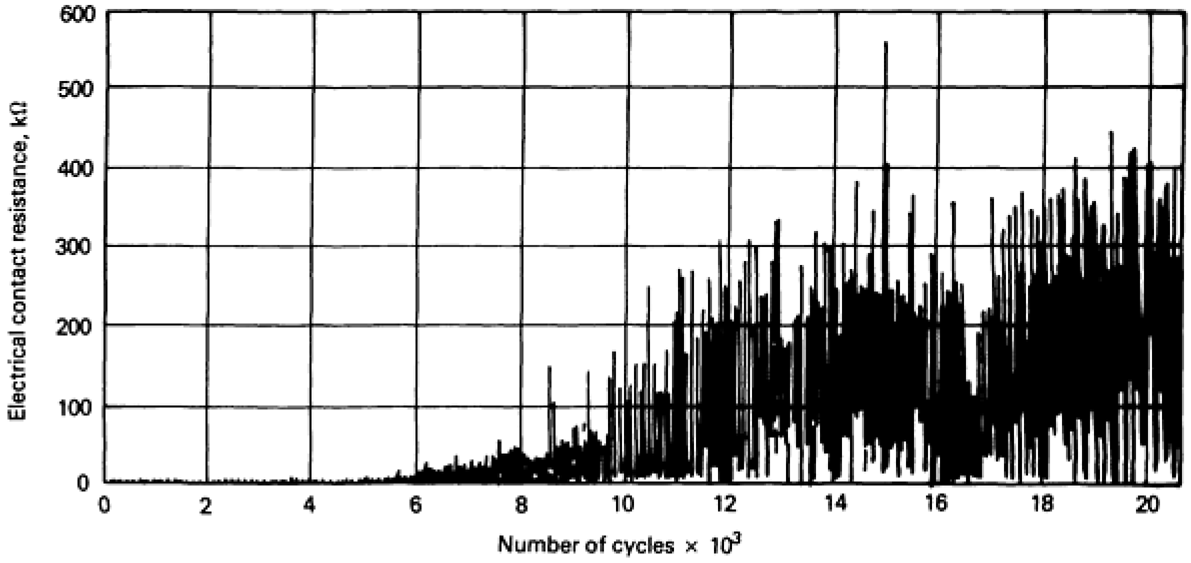

Fig. 33 Plot of contact resistance versus the number of fretting cycles

Observation of the debris on steel shows that it is platelike (Fig. 5). One of the early theories of fretting wear maintained that the debris arose by continual scraping and regrowth of oxide film (Ref 99). A modification of this idea suggests, from evidence of sections through a fretted surface on a carbon steel, that there are three well-defined zones (Ref 100):

- *Zone 1:* outer layer of compacted oxide
- *Zone 2:* severe deformation in which grains are comminuted and oriented in the fretting direction
- *Zone 3:* plastic deformation (from which it is concluded that in the steady-wear state, flake-like debris is formed by stripping oxide layers from the metal surface) (Ref 100)

The opposite point of view is that metal particles, which become progressively ground up and oxidized between the fretting surfaces, are removed. The evidence for this is that with reactive metals, such as aluminum and titanium, the debris is flakelike but contains metal (Ref 101). Furthermore, even after many millions of cycles, metal-to-metal contacts still occur in the fretting of steel flats (Ref 102). In experiments in which steel filings were introduced between two hard inert surfaces and subjected to fretting, the metal was soon converted to oxide (Ref 103). How the metal particles are generated is still a subject of controversy. However, in certain instances there is evidence that the particles are generated in the later stages of a delamination process (Fig. 34).

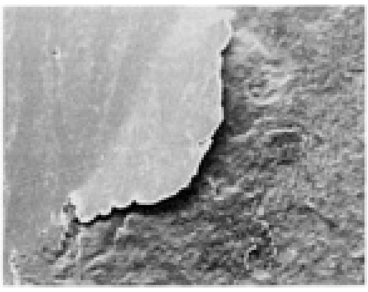

Fig. 34 Typical delamination in the fretted region produced by metal-to-metal contact

It is possible that both processes, the removal of oxide and the removal of metal, could be occurring simultaneously in different regions of the surface. In the initial stage, peaks and valleys are formed due to local welding, and these appear to persist (Ref 104). The in-between areas become filled with compacted debris that has a layerlike structure, from which oxide flakes can become detached. These areas of compacted debris are maintained by metal particles produced by the continuing metal-to-metal contacts.

Although the oxide debris is usually harder than the metal from which it arises, abrasion by the oxide is not a contributory factor on steels to the wear. In fact, the debris, by limiting metal-to-metal contact and possibly taking up some of the movement between the surfaces, has more of a protective effect (Ref 60).

Prevention of Fretting Damage

The steps that can be taken to reduce or to eliminate the damage due to fretting are extremely diverse, and each case or prospective case needs to be analyzed individually in order to select the most promising method to be applied. In this article, it is only possible to give some general indications of how the problem can be tackled. Beard (Ref 105) has pointed out that it is useful to know whether the movement is "force controlled" or whether it is "displacement controlled." Force-controlled fretting is experienced in the case of partial slip; therefore, increasing the coefficient of friction or increasing the normal load will reduce the slip. In displacement-controlled fretting, where slip is occurring over the whole interface, the amplitude is constant and wear will be reduced by reducing the normal load and also the coefficient of friction.

Improved Design. Because fretting only arises where there is relative movement between two surfaces, the elimination of this movement is a prime objective. Fretting often arises as a result of a stress concentration. In any case, reducing the stress via improved design (for example, raised wheel seats or stress-relieving grooves in hub/axle assemblies) is demanded by fatigue considerations. Increasing the normal pressure by reducing the area of contact (when the normal load is to be kept constant) or increasing the normal load will reduce the area of slip, but such action may introduce fatigue problems. The ultimate goal is to make the component in one piece and to get rid of the junction, but this is not always possible.

Surface Finish. Rough surfaces are less prone to fretting damage than highly polished surfaces. Rough surfaces can be obtained by shot peening with glass beads or steel shot. Shot peening has the advantage of work hardening the surface, although the residual compressive stress appears to have little effect on the wear process; however, it has a considerable effect if fatigue crack initiation and propagation is involved. Shot peening is often applied as a surface preparation for the application of coatings.

Coatings. Surface treatments that radically change the chemical composition of the surface can be divided into three categories:

- Methods where foreign atoms or ions are introduced into the existing surface by diffusion (for example, carburizing, nitriding, chromizing, sheradizing, and aluminizing) or by bombardment (for example, ion implantation)
- Methods where the surface reacts with a chosen environment to form a compound (for example, oxidation, anodizing, and phosphating)
- Methods where an entirely foreign material is applied to the surface (for example, electrodeposition, plasma spray, ion plating, physical vapor deposition [PVD], and chemical vapor deposition [CVD])

Most of these coatings are harder and consequently more brittle than the substrate, which, if it is not strong enough, will plastically deform in the fretting contact, where local stresses can be high. This plastic deformation will crack and break up the coating. If the coating is particularly hard (for example, titanium nitride, with a hardness of 300 HV), further damage can occur by abrasion (Ref 106).

Carburizing and nitriding of steels is a well-established treatment for reducing wear in gears and is also effective against fretting (Ref 107). Electrodeposited coatings are extensively used in electrical contacts; gold alloys are the preferred coating because they are not subject to oxide formation, which is disastrous in its effect on conductivity (Ref 108).

The growth of oxide films at high temperatures has been specified above to provide wear-resistant self-repairing coatings. These have been improved by ion implantation, particularly in titanium alloys, to give coatings that have low friction and low wear (Ref 90).

Anodizing is applied to aluminum alloys and the hard coating provides protection against fretting, but it may cause wear of the opposing surface (Ref 109).

Inserts. Separation of the two surfaces by an insert, either a shim of a soft metal or a shim of a polymer with a low elastic modulus, will sometimes be effective. The intention is to take up the movement by either plastic deformation or elastic deformation of the material. A combination of metal and polymer can be more effective because it combines the advantages of both materials--the low elasticity of the polymer and the good conductivity of the metal. Bronze-filled polytetrafluorethylene (PTFE) when fretted against steel has a very low friction coefficient and undetectable wear (Ref 110).

Lubricants. Lubricants are usually difficult to apply in fretting contacts because of the difficulty of maintaining the lubricant in the contact, but lubricants are included in the construction of steel ropes (for example, locked coil ropes) (Ref 111). In a survey of the effect of additives to a base mineral on the fretting wear of steel surfaces, zinc di-*n*-octyldithiophosphate was found to be most effective (Ref 112). Solid lubricants applied to the surfaces (for example, MoS_2) reduce the coefficient of friction initially, but eventually tend to wear away (Ref 113).

Rolling Contact Wear

Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory

Introduction

ROLLING CONTACT WEAR (RCW) results from the repeated mechanical stressing of the surface of a body rolling on another body. Only a brief overview of the subject is presented here. To obtain more comprehensive and detailed information, especially about failure analysis and materials selection for rolling contact wear, the reader is referred to the references cited in the relevant subsections. The wear can occur either on the roller surface or on the rolled surface. Rolling contact wear is a major cause of failure in rolling-element bearings, gear teeth, wheel-rail contacts, roller guides in production machinery, cam roller followers in internal combustion engines, and rolling mill rolls. It is a particularly insidious form of wear, because it is sometimes difficult to detect in its early stages. The precursor flaws may be hidden from view as they grow below the contact surface. By the time cracks grow large enough to emerge at the surface and produce wear particles or delaminations, these particles may become large spalls or flakes, resulting in immediate component loss of function or efficiency.

The first signs of RCW may include any of the following:

- Progressive noise in a bearing (rattling or grinding)
- Progressive heating in a bearing
- Onset of vibration in a precision bearing
- Rapid rise in wear debris content in oil samples (later stages of deterioration)
- Appearance of periodic surface irregularities in rolled sheet products

After a warning signal occurs, disassembly of suspect bearings, gears, and rolling contact components will then reveal the nature and extent of damage. Because RCW is generally produced by repetitive mechanical stressing of the affected surface(s), it is often associated with, or even referred to, as rolling contact fatigue (RCF). For the purposes of this

discussion, the difference between RCW and RCF is that, in RCF, surface fatigue is the damage accumulation process that eventually results in wear particle formation. Rolling contact fatigue may continue for hundreds, thousands, or even millions of cycles before the first wear particles are removed. Furthermore, the corners of pits or other RCW damage features may act as nucleation sites for additional fatigue cracks and spread the damage across the surface. Because RCF and RCW are so closely related, the causes and effects of both processes will be discussed.

The magnitude of the effects of RCW varies from one tribosystem to another. Sometimes, a component can sustain appreciable RCW damage before its function is impaired; other times, loss of performance immediately results from the first spall. For example, a guide roller in a hot metal bar-handling system may sustain considerable RCW, but this wear may be unimportant as long as the component continues to function adequately. In the case of ultraprecision ball bearings for missile guidance systems, however, a very small spall may cause the center of mass of the rapidly spinning bearing to shift, resulting in significant guidance errors.

Rolling contact is frequently accompanied by slip or sliding. The complex motions experienced by tribocomponents in many types of rolling contact situations produce at least a small percentage of slip or sliding. Pure rolling is probably the exception rather than the rule in the diverse applications of rolling components. For example, Fig. 1 is a schematic profile of meshing spur gears. When the gear teeth first touch, there is a measure of sliding plus rolling. When the contact point coincides with the pitch circle, there is pure or nearly pure rolling (depending on the accuracy of gear alignment or lateral vibration). Past this point, slip again occurs between tooth surfaces; it reaches its second maximum just at the point where the surfaces separate. Slip can result in scuffing or adhesive wear damage to the mating surfaces if the lubrication is inadequate. Therefore, proper lubricant and surface treatment selection is important to minimize the deleterious effects of slip in many types of rolling contact arrangements. Lubrication and wear of rolling-element bearings is discussed in the article "Friction and Wear of Rolling-Element Bearings" in this Volume.

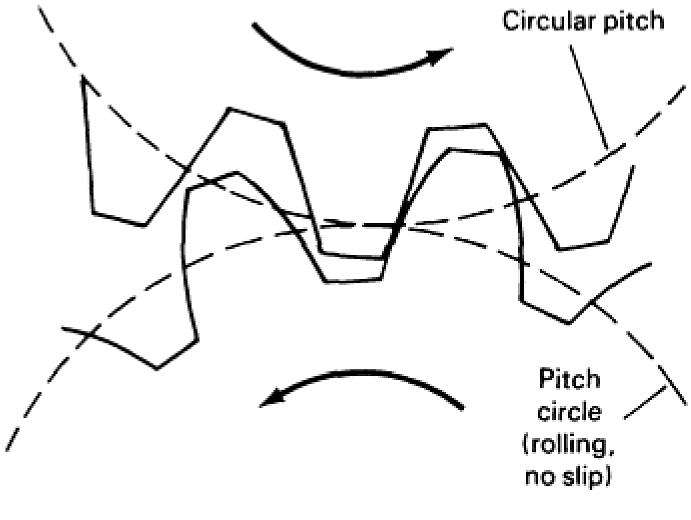

Fig. 1 Engagement of gear teeth in a gear set

Physical Signs of RCW

Gears and bearings are the components most commonly subjected to RCF and RCW. Rolling mill rolls also frequently experience RCW (see Ref 1 for a thorough discussion). Surface hardening, refinishing, or hard coating is sometimes used to attack the problem. Rolling contact wear is often manifested by defects on the rolled product that replicate the worn portions of the roller surfaces. See the article "Metalworking Lubricants" in this Volume for a discussion of lubricant selection.

Gears. As previously mentioned, the wear modes experienced by gears usually involve both rolling and slip or sliding. Dudley (Ref 2) has described the wear of gear teeth, noting that the relative amount of sliding increases as the number of teeth increases. Furthermore, the wear is not generally a function of the relative sliding velocity along a tooth face; however, at very high speeds, scoring can occur, and the friction losses in gear sets are strongly affected by sliding

velocity. Hypoid gears, worm gears, and spiroid gears can run relatively well even when appreciably worn; consequently, gear designers do not always use wear as a critical design parameter. Major considerations in gear design are that:

- Gear tooth stress does not exceed a critical value for desired life
- Gear materials are of the right kind and quality
- The form and finish are adequate
- The lubricant and lubrication system are adequate
- The system is adequately protected from rust and contaminants
- Pitting fatigue life versus contact stress and elastohydrodynamic lubrication conditions

However, determination of the size of the gear unit--that is, the pit

ch diameter, gear ratio, and the face width--often must involve consideration of the Hertzian conditions necessary to avoid pitting failure of the gear face within the design life. Several types of pitting are recognized with regard to gear surface fatigue failures:

- *Initial pitting.* Surface fatigue that usually occurs as a narrow band just below or at the pitch line at the beginning of component operation and that stops after the asperities have widened sufficiently (worn-in) to carry the load adequately
- *Destructive pitting.* Usually starts below the pitch line and spreads in number and size of pits until the gear shape is rendered unusable

Other terminology has been used for describing surface damage in gears. Terms include micropitting, surface origin pitting, subsurface origin spalling, subcase fatigue (also known as case-crushing), scuffing, and plastic flow.

Spalling is another type of wear mode that occurs in RCW of gear teeth. Spalling occurs sporadically, its frequency and exact location being statistical. The relatively large particles produced by surface spalling can cause damage if they embed in the contact surface or find their way into clearance-critical portions of gears or bearings. Dudley (Ref 2) states that both destructive pitting and spalling seldom happen at less than about 10,000 cycles, but notes that plastic flow (primarily in metallic or polymeric gears) can occur at a relatively low number of cycles if there is an overload on the contact surfaces. In summary, there generally are three types of gear wear: (1) normal or polishing wear, (2) moderate wear that is not necessarily destructive to gear life, and (3) destructive wear. For more details, see the article "Metalworking Lubricants" in this Volume.

Rolling-Element Bearings. As with gears, pitting, smearing, and spalling are important RCW manifestations in rolling-element bearings. The design and wear characteristics of rolling-element bearings are discussed in the article "Friction and Wear of Rolling-Element Bearings" in this Volume and in Ref 3. The depth of the spall tends to be related to the location of the maximum Hertzian shear stress below the surface. The fatigue spalling life of a bearing, *L,* is usually defined in terms of the first appearance of a spall and is generally based on the ratio of the equivalent dynamic load, *P,* to the load capacity, *C,* obtained from the manufacturer:

$$L = \left(\frac{C}{P}\right)^p \qquad \textbf{(Eq 1)}$$

The exponent p depends on the type of bearing. For ball bearings, $p = 3$; for roller bearings, $p = 10/3$.

In rolling bearings, the design and operating conditions significantly affect the location and rate of RCW damage. For example, a given bearing ball may experience a complex rotational path as it moves between the inner and outer bearing races. A given point on the surface of the ball may not be stressed once per revolution of the inner race, but rather, because of compound motions, may bear a Hertzian contact stress only occasionally. The center of the bearing race groove, on the other hand, is repeatedly stressed each time a ball rolls by. Therefore, the race tends to accumulate localized RCF damage cycles more rapidly than the balls.

Damage in rolling-element bearings can result from a complex combination of radial loads, axial loads, eccentric loads, thrust loads, and internal (cage/retainer) loading effects. A thorough treatment of the failure of rolling-element bearings, including not only rolling contact wear but also fracture, may be found in the article "Failures of Rolling-Element Bearings" in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook,* (Ref 4). The mechanisms of surface distress are also discussed in a collection of papers published in 1985 (Ref 5). Widner and Littmann (Ref 6) also provide a comprehensive treatment of bearing damage analysis.

Rolling Contact Fatigue Testing

Because RCF is a primary process for the production of RCW, some of the methods that investigators have developed to test the response of materials to RCF conditions similar to those they may experience in service are of interest. A particularly useful reference is *Rolling Contact Fatigue Testing of Bearing Steels* (Ref 7). In the introduction to this book, the editor states, "In building any moving machine, it is of primary concern to obtain a long endurance life of the rolling bearing. In designing a bearing life test, on the other hand, a long testing time should be avoided. The test must be accelerated so that results can be obtained within a reasonably short period of time. Unfortunately, the shorter the test becomes, the farther the simulation departs from real conditions of application."

Twenty-one papers in this collection describe testing machines, methods, and effects of processing and microstructure on RCF damage. Table 1 provides a guide to the RCF testing methods described in Ref 7 and 8 and Fig. 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 illustrate the testing arrangements listed in the table. A variety of RCF machines have been developed, ranging from one-of-a-kind research instruments to commercially manufactured bearing test rigs.

Table 1 Summary of RCF testing methods

Method	Description	Ref
NASA five-ball testing apparatus (Fig. 2)	Four lower balls, freely rotating 90° apart in a separator, simulates the kinematics of a thrust-loaded bearing; the contact angle can be varied; vibration sensor detects failure in unattended tests; low-(cryo) and high-temperature testing (to 1000 °C, or 1830 °F)	7[(a)]
Flat-washer testing apparatus (Fig. 3)	16 retained balls rolling in a circle on a flat washer with a 75 mm (3 in.) OD, 50 mm (2 in.) bore, and 6.4 mm ($\frac{1}{4}$ in.) thickness; 4.17 GPa (605 ksi) contact stress; 1500 rev/min; filtered lubricant delivery system; piezo sensor detects vibration	7[(b)]
Unisteel testing apparatus (Fig. 4)	Flat washer on retained balls; hanging dead-weight load; contact stress approximately 4.5 GPa (650 ksi); 1500 rev/min; drip feed of lubricant; vibration detection system; thermocouples monitor temperature (typically 50-60 °C, or 120-140 °F)	7[(c)]
Rolling contact testing apparatus (Fig. 5)	Two hemispherically ground, toroidal rollers loaded against a round bar; 40:1 ratio of roller diameter to bar diameter; 2.7-5.5 GPa (390-800 ksi) contact stress; 12,500 rev/min; drip-feed lubrication; velocity-vibration sensor	7[(d)]
Ball-rod testing apparatus (Federal-Mogul) (Fig. 6)	Three 12.5 mm ($\frac{1}{2}$ in.) balls loaded against a rotating 9.5 mm ($\frac{3}{8}$ in.) OD center rod; 3600 rev/min; spring load on opposing tapered retaining rings; accelerometer coupled with a shutdown device; drip-feed lubrication; stress per ball typically 6 GPa (870 ksi)	7[(e)]
Cylinder-to-ball testing apparatus (Fig. 7)	Symmetrical arrangement of two 19 mm ($\frac{3}{4}$ in.) balls rolling on a 12.5 mm ($\frac{1}{2}$ in.) OD captive cylinder; coiled-spring load through a multiplying lever; small cylinder rev/min = 22,677; splash lubrication; maximum contact stress, 5.8 GPa (840 ksi)	7[(f)]
Cylinder-to-cylinder testing apparatus (Fig. 8)	Symmetrical arrangement of two 12.5 mm ($\frac{1}{2}$ in.) cylinders on two 20 mm (0.8 in.) OD captive cylinders; coiled-spring load through a multiplying lever; small cylinder, cpm = 20,400; splash lubrication; maximum contact stress less than 4.4 GPa (640 ksi); vibration sensor terminates test	7[(g)]
Ring-on-ring testing apparatus (Fig. 9)	Crowned rings rolling on their peripheries; ring diameters of 50 and 53 mm (2 and 2.1 in.) provide "no-slip" condition, but various degrees of slip are possible by changing ring diameters; typically 2000 rev/min; contact ratio measured by electrical resistance; contact stress range typically 0.98-3.9 GPa (140-570 ksi)	7[(h)]
Various types	See review article of RCF and full-scale bearing testers	7[(i)]
Multiple bearing testing apparatus (Fig. 10)	Deep-groove ball bearing design; typically 3000 rev/min; four bearings on a single center shaft; maximum contact stress, 2.9 GPa (420 ksi); accelerometers on the outer housing monitor failure	7[(j)]
Rolling four-ball testing apparatus (Fig. 11)	Top ball drives three lower balls in a tetragonal arrangement; lower balls free to rotate in the cup; all balls 12.5 ($\frac{1}{2}$ in.) diam; upper ball spindle speed, 1500 rev/min; 5.9 kN (1325 lbf) load applied vertically	7[(k)]
High-speed four-ball	Same arrangement as above, but speeds of 15,000-20,000 rev/min; operating temperatures often exceed	7[(k)]

testing apparatus (Fig. 11)	100 °C (210 °F) (Plint machine)	
"AOL" vertical testing apparatus (not shown)	11 retained balls clamped between two flat washers; thrust load; recirculating lubricant system	7[k]
Inclined ball-on-disk testing apparatus (Fig. 12)	Spindle-held 20.5 mm (0.8 in.) ball rolling on a disk; up to 800 °C (1470 °F); ball speed up to 7200 rev/min; disk speed up to 3600 rev/min; variable slide/roll ratios; traction measurements; designed for ceramics	8

Mechanisms of RCW

Dowson (Ref 9) describes some of the earliest studies of the mechanisms of bearing fatigue and wear failure performed by Goodman in the late 1800s and early 1900s. Goodman introduced the terms pitting, flaking, scratching, and peeling to the wear failure analysis vocabulary, and in a 1912 review paper introduced the concept of surface fatigue thusly: "The speed-effect on the balls has possibly some relation to the well-known effect of very rapid reversals of stress."

Hershey (Ref 10) describes the history of understanding the mechanisms of subsurface fatigue, beginning with groundbreaking work in the mid- to late 1930s that established the manner in which intersecting, subsurface fatigue cracks formed surface pits in rolling elements. It is now known that the mechanisms of rolling contact wear involve far more than subsurface fatigue. Rolling contact wear can involve mild abrasion from contaminants in lubricants, it can be affected by water or acids in lubricants, it may be exacerbated by transfer of cage material, and in addition, the contributing combination of mechanisms may change over time.

Much of the research done on the mechanisms of RCF and RCW has been based on metals and alloys; consequently, relatively little is known about the detailed behavior of ceramics and composites in similar situations. When new metal rolling components are first started up, a surface-conditioning process normally occurs. In this process, subtle changes take place in both the surface roughness and the subsurface microstructures to reach the steady-state, running condition. Initially, the surface material may be stressed beyond its elastic limit, causing some plastic deformation. As repeated rolling contact occurs, a condition may eventually be reached wherein no further plastic deformation occurs. This process is called shakedown and has been analyzed in detail by Johnson (Ref 11).

The processes of RCF and RCW generally involve the following steps:

1. Accumulation of dislocations caused by repetitive stressing of the subsurface microstructure; a dislocation cell structure may be formed
2. Nucleation of voids or microcracks in regions of maximum Hertzian stress or nearby discontinuities in the microstructure, such as grain boundaries, preexisting porosity, or inclusion/matrix interfaces
3. Propagation of the microcracks in the subsurface
4. Linking of the cracks and movement of the crack tip toward the free surface
5. Creation of flakes, pits, and/or spalls
6. Spread of the damage to adjoining portions of the surface
7. Initiation of major fatigue cracks from surface or subsurface defects, sometimes causing catastrophic fracture

A bearing or rolling component is often considered to have "failed" at the first appearance of a spall (step 5). In some systems, RCW will go undetected until step 7. As mentioned above, lubricants may accelerate step 3 by helping wedge cracks to open. The ceramic bearing industry has made a significant investment in materials development to improve the fracture toughness of their materials and to reduce the proclivity toward catastrophic failure. Composite materials are under consideration because they contain internal crack stoppers or crack-branching, energy-dissipating internal interfaces.

Associated damage processes derive from the movement of wear particles spalled from the surface of fatigued rolling elements or their counterfaces. The particles may embed in the surfaces of the rollers, score the mating surfaces, or act as third-body abrasives to alter the surface roughness and thus the lubricant flow characteristics in the interface.

The reader is referred to several reviews of RCF and RCW mechanisms. Zwirlein and Schlicht (Ref 12) discussed RCF damage mechanisms in bearing steels, including the development of "white bands" in the near-surface regions of bearings in conjunction with the decay of the martensitic structure. For 52100 bearing steel, the morphology of the white bands depended on the combination of contact pressure and number of loading cycles. Olver *et al.* (Ref 13) reviewed wear in rolling contacts with small amounts of slip and drew comparisons with Suh's delamination theory of water (Ref 14). Several differences were noted between their observations and the predictions from the delamination theory. In particular, Olver *et al.* found that cracks nucleated at or near the surface, rather than below the surface. Also, cracks tended to run obliquely to the surface in a direction opposite to that of the tractive stress, rather than parallel to the surface. Finally, the wear was dependent on the relative hardness of the contacting bodies, not on sliding distances, as stated in the delamination theory. Even with relatively small amounts of slip relative to rolling, unacceptable wear was obtained if the lambda ratio, λ(the ratio of the elastohydrodynamic lubrication film thickness to the composite surface roughness), was

small. Improved wear life can be produced by ensuring that the lubricant has adequate load-bearing capacity, in order to maintain a higher λ ratio in operating bearings.

The effect of retained austenite on the RCF of a steel containing 0.18% C, 1.5% Cr, 4.25% Ni, and 1.0% W was reported by Zhu *et al.* (Ref 15). Using carburizing followed by carbonitriding to increase the amount of retained austenite in surface layers of the steel, they conducted RCF tests with crowned 50 mm (2 in.) diam rollers. They found that the greater the retained austenite content, the greater the contact fatigue resistance, and reasoned that increased toughness from the austenite enhanced the microstructural resistance to crack propagation.

Common ferrous materials for rolling-element bearings include AISI 52100 steel, 440C stainless steel, and M-50, M-50 Nil, M-1, M-2, and M-10 tool steels. The temperature limit for 52100 and 440C is about 250 °C (480 °F), and molybdenum-containing tool steels such as M-1, M-2, and M-10 may be used up to about 500 °C (930 °F). High-reliability bearings are also made from vacuum degassed and vacuum induction melting/vacuum arc remelting (VIM/VAR) steels. Advanced silicon nitride ceramics, such as Norton Company's NBD 200, offer higher temperature capabilities and excellent RCF properties, but are considerably more expensive than steel rolling-element bearings.

A key to improving the RCF of ceramic bearings was to reduce the porosity and inclusion content of the materials so that crack-initiating microstructural features would be absent from the near-surface regions where Hertzian contact stresses are maximum. High-performance aerospace and military applications will continue to drive the development of high-temperature ceramic materials for rolling-element bearings, and commercial applications of ceramics in advanced automotive and truck engines are gradually appearing. Single-piece cam roller-followers made from silicon nitride ceramics are replacing more complicated steel parts that contain needle bearings on their inside diameter. The cost of the parts, particularly the cost of machining, will affect the rate at which they are introduced into mass-produced automobiles and trucks. The goal of producing truck engines that will run for 750,000 to 1,000,000 miles will also spur the use of ceramics, which have demonstrated outstanding reliability in engine tests.

Hybrid bearings that contain ceramic rolling elements and metallic races and retainers are also under development for military and high-performance applications. Lubrication is a major problem at elevated temperatures, and various types of solid lubricants have been developed. Solid lubrication poses the problem of ensuring a continual supply of the lubricant. See the article "Solid Lubricants" in this Volume for a more complete discussion.

The most common gear material is steel, but a variety of other materials--nonferrous, plastic, and ceramic--have also been used. The material must be able to be fabricated into the proper contour and finish for effective operation, yet possess the hardness necessary to resist wear and deformation. Generally, hardness is a major factor in the selection of gear materials, but temperature and corrosion resistance may also be important in specific applications. Surface treatments such as case hardening are used after gear profiles have been machined from softer stock. Proper selection of a compatible counterface material is also important. Table 2 provides a summary of common ferrous gear materials, their typical heat treatments, and range of surface hardnesses.

Table 2 Typical ferrous gear materials

Material	Surface treatment	Minimum surface hardness	
		HRC	**HB**
Steel			
A-1 through A-5	Through-hardened and tempered	. . .	180-400
	Flame- or induction-hardened	50-54	. . .
	Carburized and case-hardened	55-60	. . .
AISI 4140	Nitrided	48	. . .
AISI 4340	Nitrided	46	. . .
Cast iron	As-cast	. . .	175-200
Nodular iron	Annealed, quenched and tempered	. . .	140-270
Malleable iron (pearlitic)	. . .	. . .	165-240

Impact Wear

Peter A. Engel, Department of Mechanical and Industrial Engineering, State University of New York at Binghamton

Introduction

IMPACT WEAR can be defined as the wear of a solid surface that is due to percussion, which is a repetitive exposure to dynamic contact by another solid body. This somewhat restricted definition detaches "erosive" phenomena by jets and streams of particles from the subject of study (Ref 1). Volume (or mass) removal of material, either at or under engineering contact stress levels, is discussed in this article, as opposed to permanent indentations cause by plastic deformation.

Many industries employ processes that lead to impact wear. Machine components, cams, and gears mate with a certain dynamic component. Typical applications occur in electromechanical printers; a prime example is that of typefaces, which are expected to hold definition, thus assuring high print quality, often for billions of cycles. Separable electrical connectors must make repeated contact without excessive removal of highly conductive noble or seminoble films. In drilling devices applied to a variety of media, ranging from computer boards to oil-shale, tool wear is a concern of economy. In the chattering of tubes carrying liquid wastes from nuclear reactors, safety and reliability are most important.

In most of the above applications, impact occurs with a component of sliding, compounding the relative normal approach. Thus, the term "compound impact wear" has been coined. Another consideration for the mode of contact involves the intensity, of frequency of participation, for mating surfaces. "One-body wear" is generated on one repeatedly exposed surface, as in the case of a printer typeface that is regularly impacted against continually renewed paper. However, in some devices, such as relays, the same neighboring surfaces are continually mated. If one of the mating surfaces is prone to more wear than the other, and if it is the surface of primary concern, then it could still be viewed in terms of one-body wear. If the wear of both surfaces needs to be monitored, then the situation is termed two-body wear.

The various percussive wear mechanisms include adhesive, abrasive, surface fatigue, corrosive, and thermal wear. These pure forms correspond to those that occur in sliding and rolling contacts. The fundamental differences have been sought in the nature of pressures and the friction coefficients that arise in those contact modes (Ref 2). Hybrid wear mechanisms, which combine several of the above, are frequent. An example is the fretting that occurs on the back-printer device of a hammer striking against a print band (Ref 3, 4).

The wear mechanism strongly depends on the combination of mated materials used. For example, thermal wear can occur in polymers. The contact stress range can also influence the wear mechanism. If impact speed is increased, severe adhesive wear can succeed the low-stressed fretting wear. The wear mode, such as the relative size of the sliding versus normal impacting speed component, often makes an essential difference. The worn surfaces of aluminum projectile specimens subjected to compound impact cycles, upon repeatedly impacting a steel plate rotating at different speeds, are shown in Fig. 1.

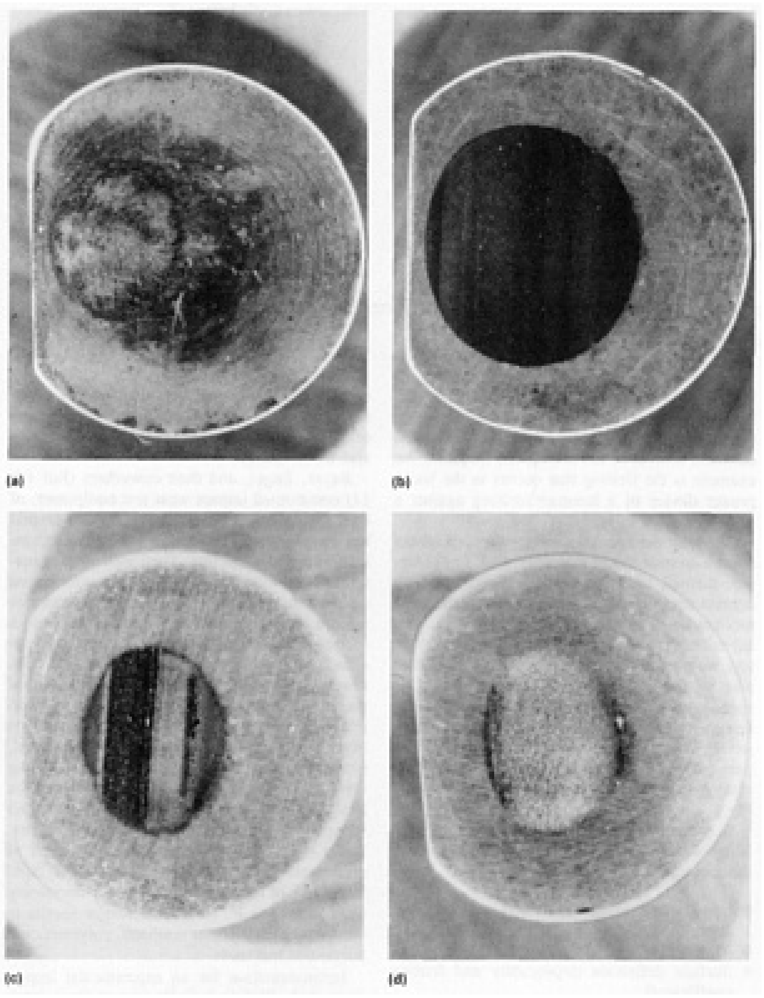

Fig. 1 Impact-worn surfaces of spherical-headed aluminum 2024-T4 projectiles, 15×; the 0.5 g (0.018 oz) projectiles (for which δ = 1.1 μm, or 44 μin., and *R* = 41 mm, or 1.6 in.) repetitively impacted an alloy steel target plate at *v* = 1.7 m/s (68 in./s), $q/\sigma_0 \approx 0.8$. (a) *v* = 0, *N* = 1.5 × 10^7. (b) *v* = 250 mm/s (10 in./s), *N* = 1.5 × 10^7. (c) *v* = 1.25 m/s (50 in./s), *N* = 10^4. (d) *v* = 3.0 m/s (120 in./s), *N* = 10^3

In order to systematically study the subject, it is helpful to divide variable parameters into these categories:

- Loads (for example, mass and speed components)
- Materials (elastic and strength data)
- Surface definition (topography and friction coefficient)
- Wear coefficients

A rational, semi-empirical impact wear theory (Ref 1), which embodies all the above ingredients, is outlined in this article.

Experimental Background

From a long line of experimental impact wear studies, several that underlie the variety of industrial needs are described below. Examining vibrational contact for nuclear engineering materials, De Gee *et al.* (Ref 5) wore sintered aluminum powder (SAP) hemispheres against SAP planes, and Ko (Ref 6) investigated the chattering of heat-exchange tubes against annular supports. Wellinger and Breckel (Ref 7) studied the wear of the plastically deforming contacts of a great variety of metal specimens subjected to repeated normal impact. Montgomery (Ref 8) correlated and modeled wear that was caused by rock drill bits. The work of Sorokin (Ref 9), one of several Soviet industrial wear investigators, is also worth citing.

Bayer, Engel, and their coworkers (Ref 10, 11) constructed impact wear test equipment, of both the ballistic projectile (Fig. 2a) and pivotal hammering type (Fig. 2b), out of electromechanical printer mechanisms. They used various material combinations, stress range, lubrication conditions, and other parameters to optimize various machine contacts. Rice (Ref 12) built a reciprocating impact wear tester and investigated, with his coworkers, a range of wear relationships (Ref 13, 14) that were dependent on metallurgy, such as grain structure. Sugita *et al.* (Ref 15) dealt with effects of impact wear on MgO single crystals, a typical brittle material. Fretting wear that was due to repeated impacting was studied by Levy and Morri (Ref 16). Sare (Ref 17) investigated wear-resistant materials subjected to abrasion in ore-crushing hammers. Bayer (Ref 18) found that the impact wear of elastomers typically exhibits two stages: a rapid initial are of deformation, with ever-decreasing rates following it. He found similar results in thermoplastic polyester urethane, polyester, and polyamide materials.

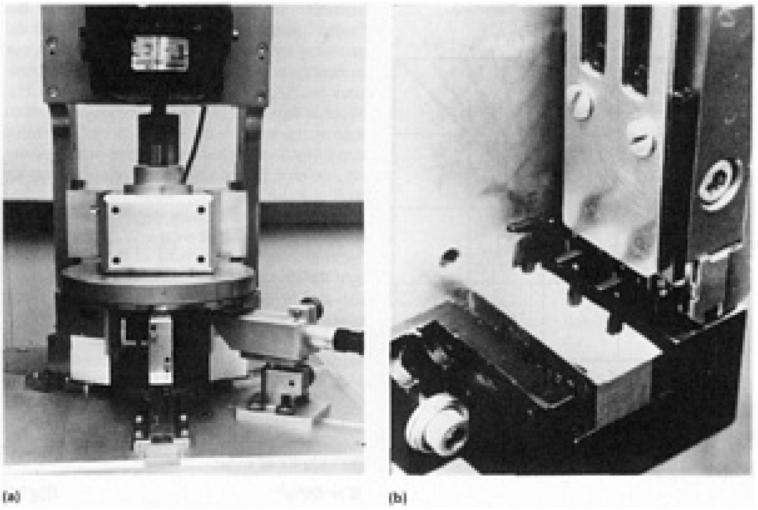

Fig. 2 Impact wear testing apparatuses. (a) Ballistic impact wear tester with three projectile bays located 120° apart. (b) Pivotal hammering tester, where three hammers impact a polymer sheet

Instrumentation for an experimental impact wear study (Ref 1) includes impact force measurement devices (such as piezoelectric transducers) that calibrate force versus speed relations. The contact stress for either a projectile or hammer that strikes a known material at known speed can be calculated by analytical or numerical (finite-element) methods. This

information, which is related to the Hertz contact theory, turns out to be important in terms of the wear theory outlined in this article.

The wear scar can be measured by removing the worn specimen and topographically scanning it. It can then be repositioned for more load cycles if an accurate method is available (Ref 19). Scanning electron microscopy (Ref 20) is commonly used to check the wear mechanism, the wear scar shape, and any idiosyncrasies of the process. The worn surface must be characterized for hardness (for example, by a Rockwell, Vickers, or Knoop microhardness test) (Ref 1, 21).

Model for Compound Impact

To model compound impact (Ref 22), Fig. 3 shows a projectile of mass, *m*, approaching a target plane with a normal relative speed, *V*. Subsequent to striking (at time, *t*, equated to 0) the plane that is moving in the tangential *x*-direction at a speed, *v*, the projectile is accelerated by friction in the *x*-direction. Because friction is impending, the equation of motion of the slipping projectile includes the Coulomb friction term:

$$\frac{d\dot{x}}{dt} = \mu P(t),\ t > 0 \quad \textbf{(Eq 1)}$$

with the initial conditions

$$t = 0,\ x = 0,\ \dot{x} = 0 \quad \textbf{(Eq 2)}$$

Approximating the impact force pulse as a sinusoidal of peak force, P_0, and duration, t^*:

$$P(t) \approx P_0 \sin\left(\frac{\pi t}{t^*}\right) \quad \textbf{(Eq 3)}$$

integration of Eq 1 yields the speed to which the mass is accelerated by time, *t:*

$$\dot{x} = \frac{\mu P_0 t^*}{\pi m}\left(1 - \cos\frac{\pi t}{t^*}\right) \quad \textbf{(Eq 4)}$$

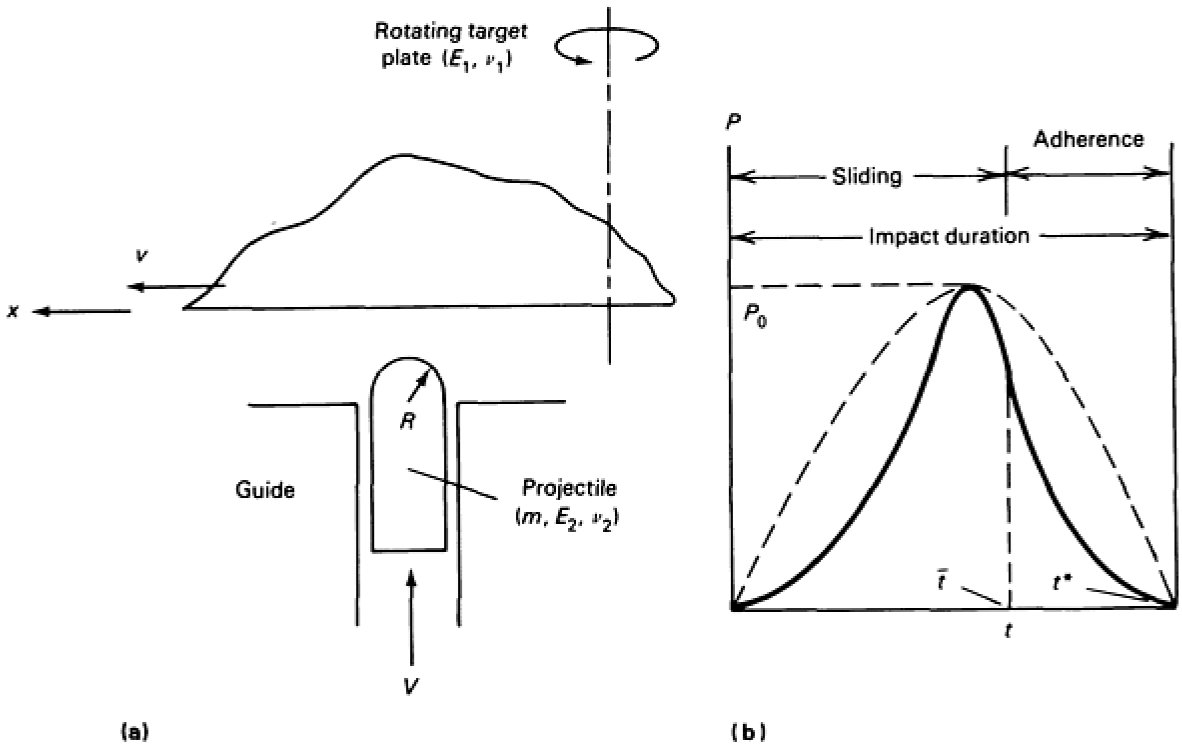

Fig. 3 Model of compound impact, where projectile strikes a tangentially moving plate. (a) Projectile approach. (b) Impact pulse and sinusoidal approximation

If the impacting mass is to catch up with the plane at some time, $\bar{t} < t^*$, then the slipping time, $\bar{t}$, can be calculated from Eq 4, by setting $\dot{x} = v$ at $t = \bar{t}$, obtaining:

$$\bar{t} = \frac{t^*}{\pi} \cos^{-1}\left(1 - \frac{\pi m v}{\mu P_0 t^*}\right) \qquad \textbf{(Eq 5)}$$

It is understood that after $t = \bar{t}$, the projectile is adhered to the plane and no longer slips against it. The negative component of the arc cos function is characteristic of the slipping properties of the system, and is called the slip factor,

$$f = \frac{\pi m v}{\mu P_0 t^*} \qquad \textbf{(Eq 6)}$$

the numerical ranges of which are also important for wear considerations:

- $f = 0$ is normal impact
- $0 < f < 2$ is moderate sliding speed; slipping gives way to adherence at time $\bar{t}$ during the impact; $\bar{t}$ is real valued in Eq 5, $\bar{t} < t^*$
- $f > 2$ is high sliding speed; slipping persists throughout the impact contact time, and is imaginary in Eq 5

If a spring, *k*, is restraining the mass in the *x*-direction (Fig. 4a), then a force $k \cdot x$ will act on the projectile, tending to increase the slipping time. The latter is calculated from a transcendental equation corresponding to Eq 5:

$$\cos\omega\bar{t} - \cos\phi\bar{t} - f\left(1 - \frac{\omega^2}{-\phi^2} = 0\right) \quad \textbf{(Eq 7)}$$

where $\omega = \sqrt{k/m}$ and $\phi = \pi/t^*$. Figure 4(b) shows the effect of spring restraint.

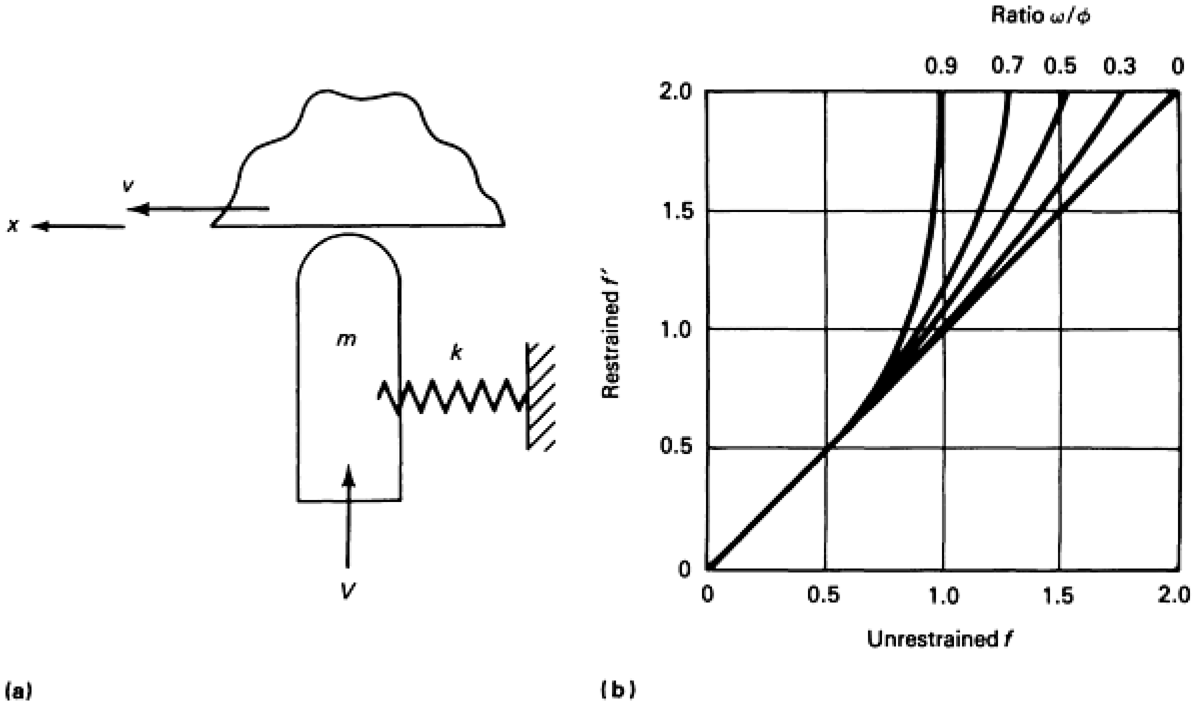

Fig. 4 Spring-restrained projectile model. (a) Impact. (b) Corrected slip factors for restrained projectiles

If rotation of the impacting projectile is considered in addition (Fig. 5), then an inertial couple, $I\ddot{\theta}$, must be added to the free-body diagram of the projectile. The slipping time is obviously shortened by this additional degree of freedom, because adherence to the target is easier to achieve. Now $\bar{t}$ is calculated from the equation

$$\frac{\cos\omega\bar{t} - \cos\phi\bar{t}}{1 - (\omega^2/\phi^2)} + \frac{mL^2}{I_{cg}}(1 - \cos\phi\bar{t}) = f \quad \textbf{(Eq 8)}$$

which corresponds to Eq 5 of the unrestrained, unrotating case of the impacting projectile. The sliding restraint and rotational capacity can be used to more accurately model pivotal hammering devices.

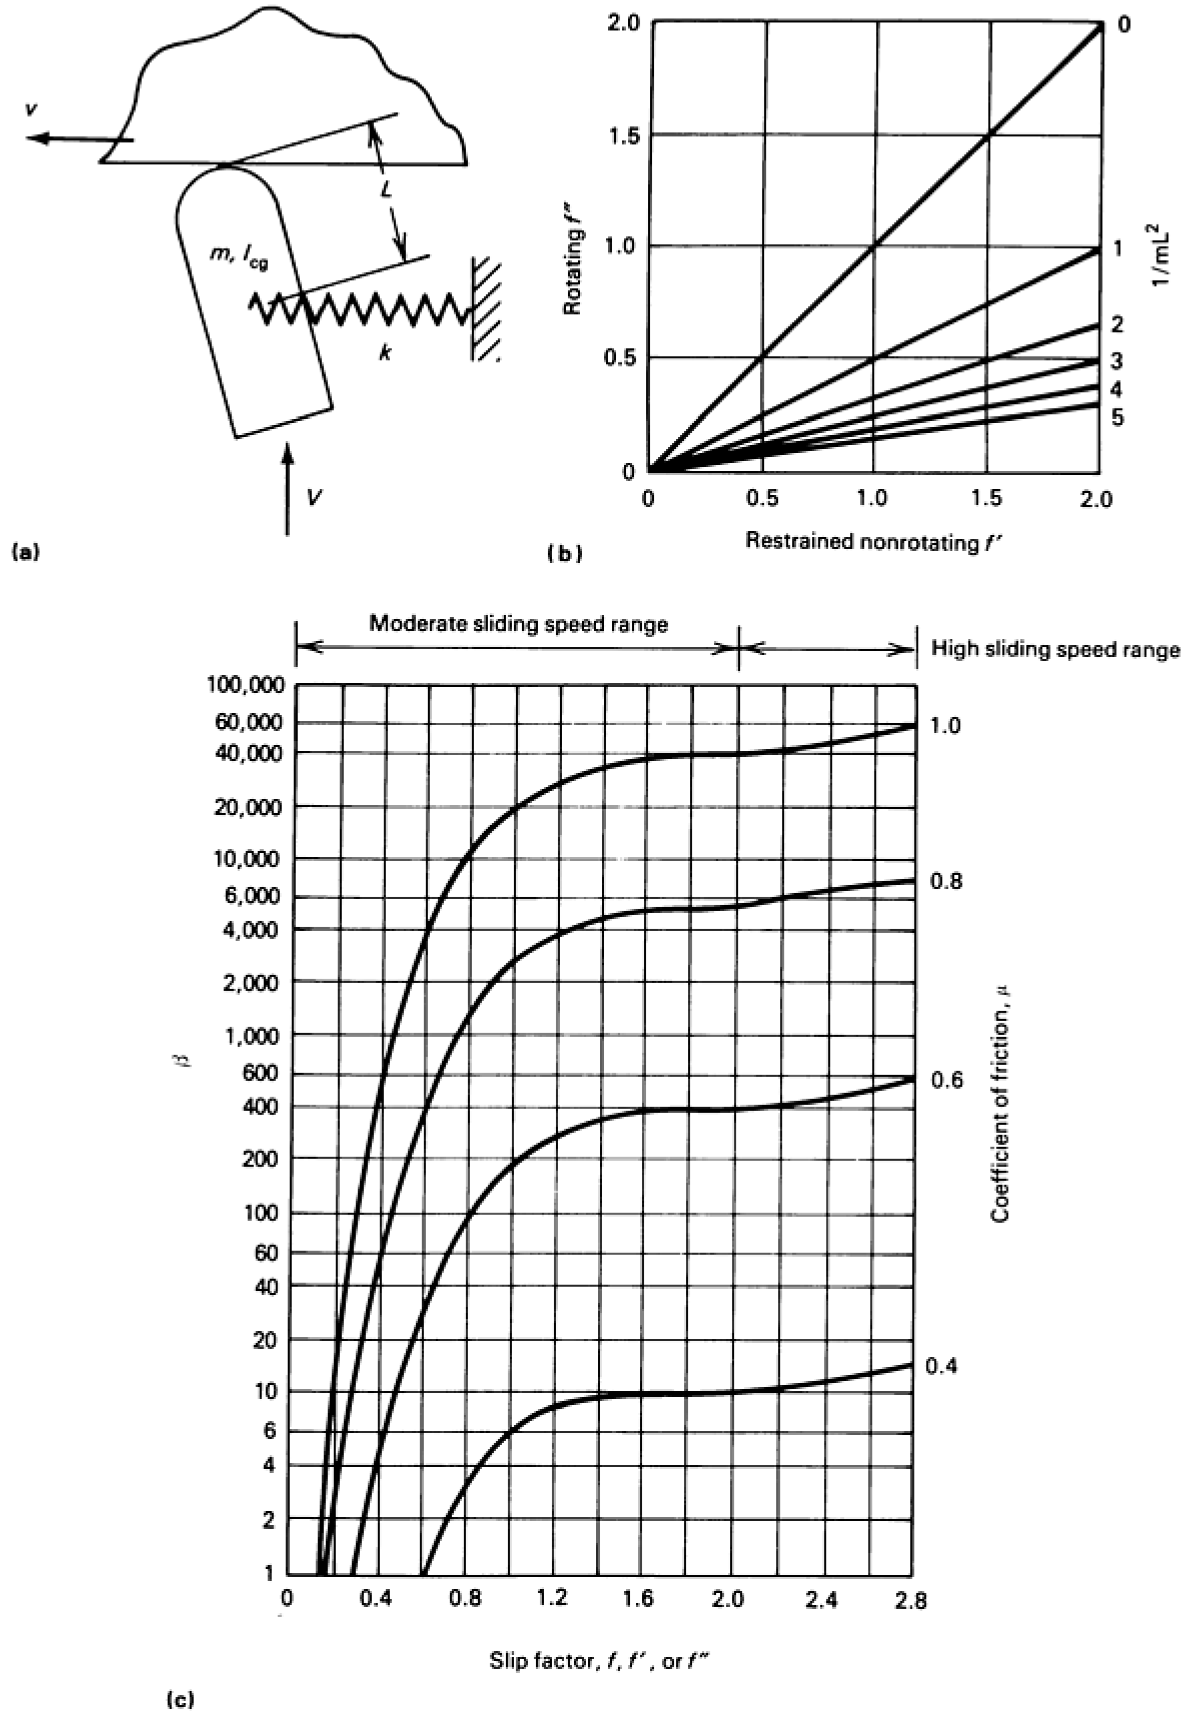

Fig. 5 Spring-restrained projectile rotating during impact. (a) Impact schematic. (b) Corrected slip factors for restrained rotating projectiles. (c) Plots of β versus *f* and μ

Linear Impact Wear

Two cases were found to be of great practical importance in repetitively impacted contacts. Discussed first is a linear wear mechanism that occurs in print heads.

Consider the linear wear mechanism that is characteristic of an abrasive sliding process:

$$W = \frac{KPX}{H} \quad \textbf{(Eq 9)}$$

where K is the wear constant for the material pair, P is the normal contact force, X is the sliding distance, H is the hardness of the wearing body, and W is the volume worn away. When a contact, such as a print head that strikes, paper, undergoes a cycle of compound impact, the one-body wear of the print head per differential time, dt, during a single impact cycle, at time, $t < \bar{t}$, can be evaluated. After adherence takes place, no more wear generation is assumed (Ref 1). Thus,

$$dW = KP(t)dX(t) \quad \textbf{(Eq 10)}$$

where x is the print head displacement, and X is the slip of the print head with respect to paper:

$$X = vt - x \quad \textbf{(Eq 11)}$$

having nonzero values in the slip region $0 < t < t < t^*$ (see Eq 5). Differentiating Eq 11,

$$dX = (v - \dot{x})dt \quad \textbf{(Eq 12)}$$

Integrating over the time $0 < t < \bar{t}$, the wear per impact cycle becomes, for the moderate sliding speed range ($f < 2$), by integration of Eq 10:

$$\Delta W = \frac{Kvt^*P_0}{\pi H} C(f) \quad \textbf{(Eq 13)}$$

$$C(f) = \frac{f}{2}, f < 2 \quad \textbf{(Eq 14)}$$

Likewise, for the large sliding speed range ($f > 2$), integration over the whole pulse yields Eq 13 with

$$C(f) = 2\left(1 - \frac{1}{f}\right), f > 2 \quad \textbf{(Eq 15)}$$

Thus, $C(f)$ is a two-part, but continuous, function converging to $C(f) = 2$ at $f = \infty$(Fig. 6).

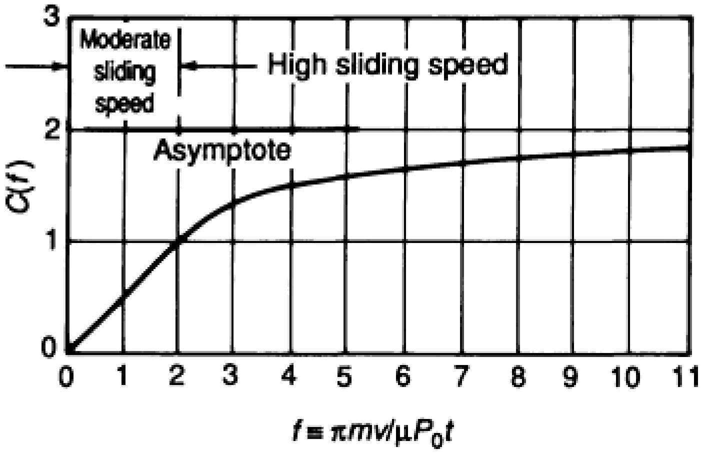

Fig. 6 Function *C*(*f*) relating abrasive impact wear to slip factor

The above wear process is termed "linear," because the wear per pulse, ΔW, is independent of the number of cycles, or of the geometry of the wear scar as consecutive impacts are incurred. A similar analysis was also applicable to computer print wires, which were observed to wear in a "pencil-sharpener" mode (Ref 1).

Abrasive wear constants, *K*, were taken from the wheel tester invented by Roshon (Ref 23), and adopted as an ASTM standard to grade computer paper for abrasivity. A wide ribbon is stretched on the cylindrical surface of a ***d*** = 1.2 m (4 ft) diameter steel drum, against which a cantilevered bob made of the print head material of known hardness, *H,* is squeezed, producing a controllable normal force, *P*, on the contact. The bob is given a slight tangential speed perpendicular to the sliding direction, so that the paper surface tends to be renewed with subsequent wheel rotations. Wear volume measurements at the contact point of the bob after a known number, *n,* of wheel revolutions at constant speed finally yield the wear constant from Eq 9:

$$K = \frac{HW}{\pi d n P} \qquad \textbf{(Eq 16)}$$

Impact Wear of Machine Contacts

The repetitive impacts that take place in metallic machine contacts tend to create a wear scar, which appears after a certain incubation period in the wear life. This means that within a period of initial cycles, N_0, called the zero-wear limit, the contact spot maintains the original surface median or root mean square (rms) height, δ.

Figure 7 shows a set of wear curves, ***h*** versus *N*, for carbon steel ballistic impact wear projectiles (*m* = 1.27 g, or 0.05 oz, Rockwell hardness (HRC) = 20, *R* = 140 mm, or 5.5 in., head radius) impacted against an alloy steel plate at the common normal approach speed, *V* = 1.73 m/s (68 in./s). The target disk rotation was varied, however, producing the relative sliding speeds, *v* = 0, 0.25 m/s (10 in./s), 1.27 m/s (50 in.s/s), 3.81 m/s (150 in./s), and 7.62 m/s (300 in./s).

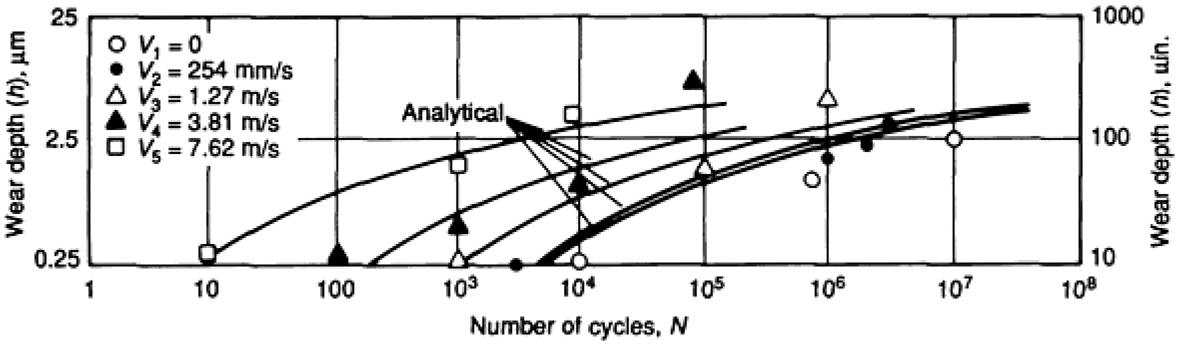

Fig. 7 Compound impact wear of carbon-steel projectiles tested in ballistic impact wear apparatus. Projectiles are carbon steel, HRC = 20, V8 ($\delta \simeq 0.5$ μm, or 20 μin.), *m* = 1.27 g (0.045 oz), *R* = 140 mm (5.5 in.), *V* = 1.7 m/s (68 in./s); target disk is alloy steel 4140, HRC = 40 to 45, V16, μ= 0.62

Projectiles were inspected for wear at logarithmic intervals. It was observed from the experimental measurement points that the wear process became "measurable" at earlier cycle numbers as the *v*/*V* ratio was increased, that is, the sliding contribution was increased with respect to the normal impact contribution.

Zero-Wear Limit. In order to establish the zero-wear limit as a quantitative, semi-empirical relation, an extension of the Bayer-Ku zero-sliding-wear theory (Ref 24) was made. The latter has, for the number of passes, *N*, denoting zero wear:

$$N_0 \left(\frac{\tau_{max}}{\gamma_r \tau_y} \right)^9 = 2000 \qquad \text{(Eq 17)}$$

In impact wear, it is sensible to consider subsurface damage, D_1, which is caused by the maximum shear stress that occurs in the depth of a contact without any shear tractions attending, and surface damage, D_2, which is due to shear traction caused by superposed sliding effects that occur during the slipping time of compound impact cycles.

The damage contributions (Ref 1) are defined as integrals of the representative maximum subsurface and surface stresses over an appropriate interval of the impact pulse. Thus,

$$D_1 = \int_0^{t^*} \tau_{max}^9 (t) dt \qquad \text{(Eq 18)}$$

is integrated over the whole pulse, but

$$D_2 = \int_0^{\bar{t}} [\mu \sigma_{z,max}(t)]^9 \, dt \qquad \text{(Eq 19)}$$

is integrated only over the slipping time, $\bar{t}$. Note that in evaluating the damage factors D_1 and D_2, the sinusoidal impact force pulse of Eq 3 can be used for a simpler calculation.

Defining the surface damage contribution factor

$$\beta \equiv \frac{D_2}{D_1} \qquad \text{(Eq 20)}$$

the zero-wear law is now formulated analogously to Eq 17:

$$N_0 \left(\frac{\sigma_{z,\max}}{\gamma \sigma_y} \right)^9 = 2000 \quad \text{(Eq 21)}$$

which has a coefficient γ that is to be determined via experiments.

From many sets of experiments conducted on various steel and aluminum projectiles, γ was found to be close to 1.1. Note that an essentially constant γ_r is another feature of the Bayer-Ku sliding wear theory. The relationship of these two constants is discussed in Ref 1.

Approximate expressions (Ref 25) of β for common metals (Fig. 5c) are:

$$\beta = \left(\frac{\mu}{0.31} \right)^9 (1.23) \int_0^{\cos^{-1}(1-f)} \sin^9 \zeta \, d\zeta, f < 2 \quad \text{(Eq 22)}$$

$$\beta = \frac{f}{2} \left(\frac{\mu}{0.31} \right)^9, f > 2 \quad \text{(Eq 23)}$$

Measurable Wear. Past the zero-wear limit, a wear scar becomes evident, and its dimensions undergo a growth process. Only symmetric quadratic (spherical or cylindrical) contact surfaces subjected to repetitive impacts are considered here. It is assumed that throughout the wear history, either the impact momentum or peak impact force remains constant. However, it is recognized that because of changes in contact geometry that are due to wear, the contact area and, thus, the Hertz contact stress state per impact, will vary. Figure 8 illustrates the descriptors relevant to measurable wear.

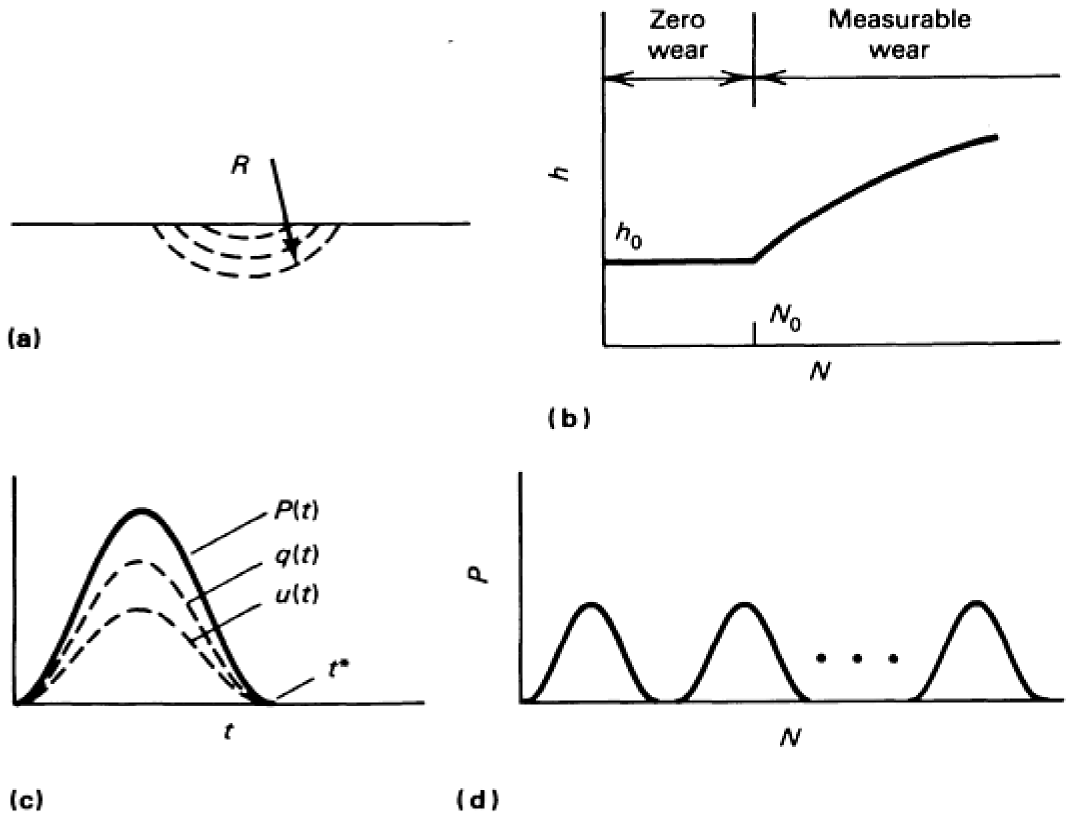

Fig. 8 Concepts relevant to measurable wear. (a) Wear formation. (b) Wear history. (c) Impact history (pulse). (d) Loading history

It is useful to establish the concept of the instantaneous wear state, which includes the geometry of the worn contact, and the Hertzian contact stresses arising in this contact, which are due to the prescribed impact cycles. The instantaneous wear state at the peak of the *N*th impact would include the instantaneous peak contact radius, *a*, peak maximum pressure, *q*, and others.

The common experience with moderately stressed machine contacts is the tendency of wear scars to evolve toward conformance of the two mating surfaces. Figure 9 shows an originally plane spring steel target gradually conforming to the outline of a tool steel pivotal hammer. In one-body wear processes, the "softer" partner progressively wears toward the geometry of the nonwearing, "harder" partner (a greater resistance to wear is meant here by hardness because it is usually proportional to *H*). Wear is dependent on the instantaneous contact area at any stage of the wear history. The initial condition to this phase is the zero-wear geometry, defined by the quadratic surface belonging to $N = N_0$, $h = \delta/2$.

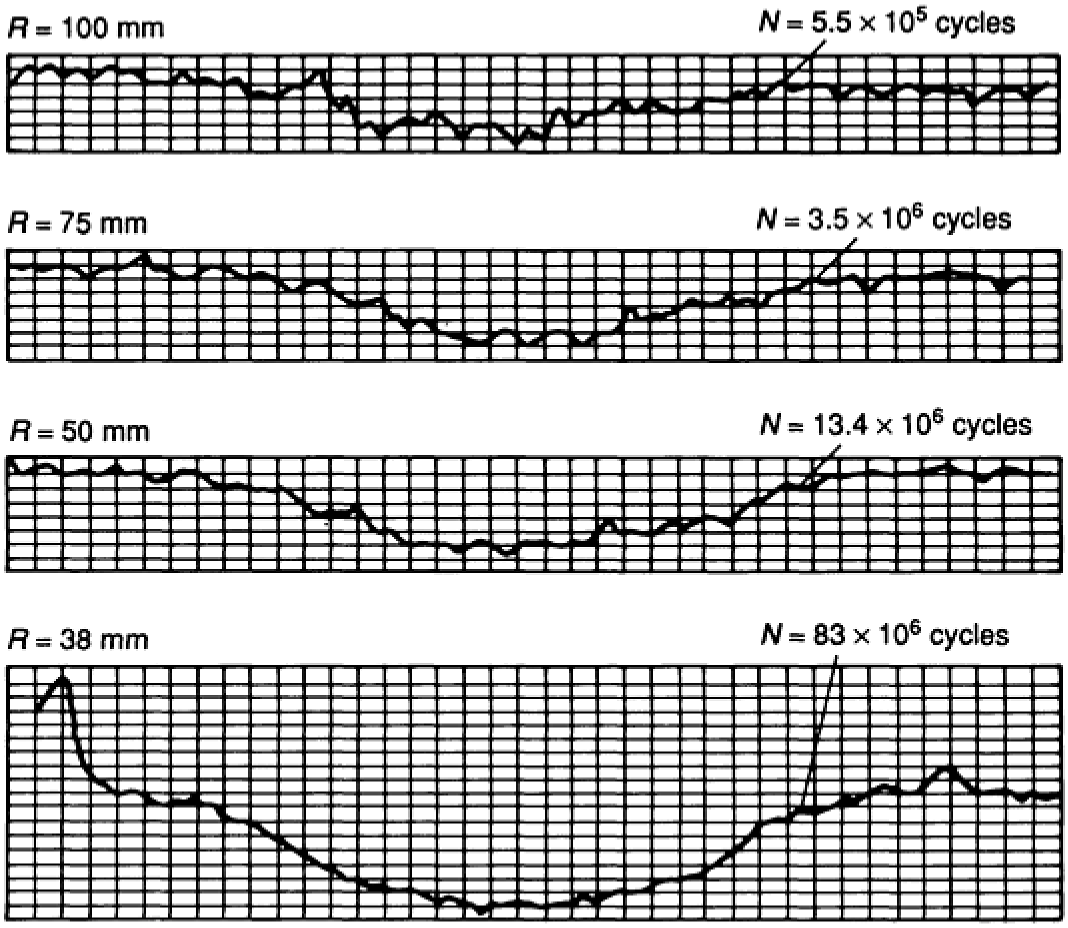

Fig. 9 Process of changing curvature on flat blued spring steel target (AISI-C1095, 48 TO 51 HRC) surface impacted by hard cylindrical hammer (Carpenter extra, air-hardened tool steel, HRC = 62 to 64, *r* = 35 mm, or 1.38 in.). In terms of scale, each vertical division is 0.508 μm (20 μin.) and each small horizontal division is 50.8 μm (0.002 in.).

In the measurable wear stage of the wear history, the growth of the wear scar can be followed by observing the deepening of the wear scar, *h*, and the change of the radius of curvature, *R*. It can also be described by the instantaneous peak contact radius, *a*, or peak contact pressure, *q*, because *a* and *q* are uniquely related by Hertz theory to the shape of the contact area defined by *h*. It is also argued (Ref 1) that *a* coincides with the instantaneous radius of the wear crater.

Let the mathematical expression of the wear mechanism be written in the following form for the volume of wear:

$$W = KN^b q^{3c} \quad \textbf{(Eq 24)}$$

The differential form of the above, in terms of both the number of cycles and the instantaneous peak pressure:

$$dW = \frac{\partial W}{\partial N} dN + \frac{\partial W}{\partial q} dq \quad \textbf{(Eq 25)}$$

Letting $b = 1$, and inserting Eq 25 into Eq 24, the differential relationship becomes:

$$dW = \frac{W}{N} dN + \left(\frac{3cW}{q}\right) dq \quad \textbf{(Eq 26)}$$

The above equation can then be integrated for particular geometries characterizing the percussive wear. Two such simple geometries are a soft ball wearing against a hard plane and a soft plane wearing against a hard ball. In the methods of solution described below, the object is to solve for nondimensional wearing geometries. These can be converted into physical geometric parameters through multiplication by the appropriate constants.

Solution Methods for Measurable Wear

Example 1: Soft Ball Worn by Hard Plane.

The ball wears from the original radius R_1 to a radius $R > R_1$. With reference to Fig. 10, the wear is the difference between two paraboloids

$$W = \pi[R_1(h_1 + h)^2 - Rh_1^2] \quad \textbf{(Eq 27)}$$

with

$$h_1 = \frac{a^2}{2R_1} \quad \textbf{(Eq 28)}$$

where the wear scar radius a was equated with the edge of the peak contact radius at the stage, N, of wear history. For the depth of wear from this geometry:

$$h = \frac{a^2\left(1 - \frac{R_1}{R}\right)}{2R_1} \quad \textbf{(Eq 29)}$$

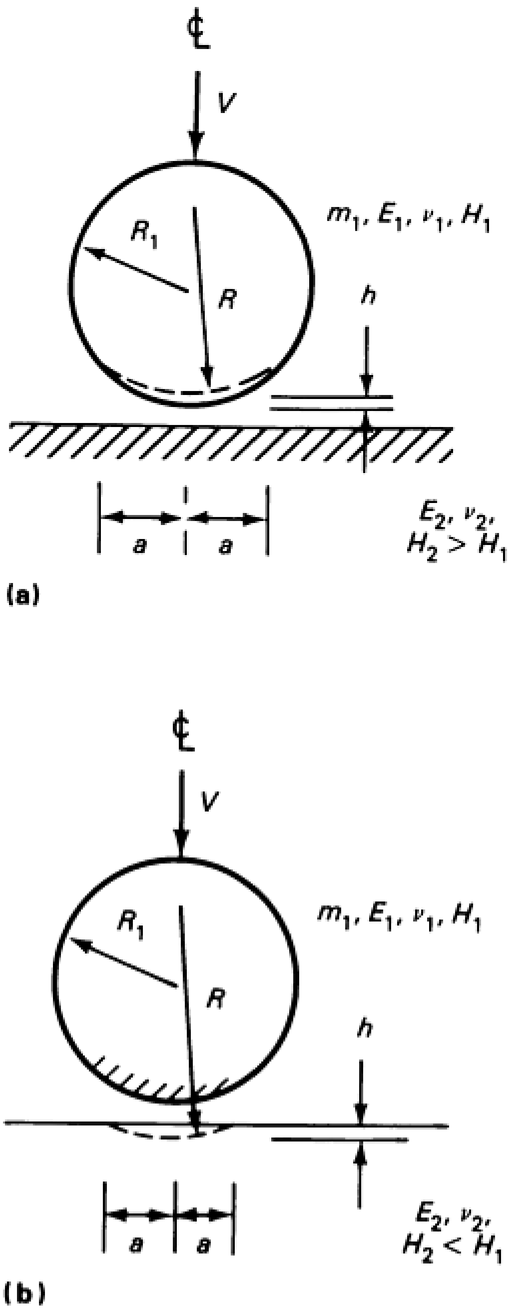

Fig. 10 Percussive wear schemes. (a) Wear of soft ball versus hard plane. (b) Wear of soft plane versus hard ball

Introducing the nondimensional curvature of the wear scar:

$$\lambda \equiv \frac{R_1}{R} \qquad \textbf{(Eq 30)}$$

Hertz contact analysis yields the following expressions for *q*, *a*, and *W* in terms of λ:

$$q = K_1\lambda^{3/5} \qquad \textbf{(Eq 31)}$$

$$a = K_2\lambda^{-2/5} \qquad \textbf{(Eq 32)}$$

$$W = \frac{\pi K_2^4}{4R_1}(1 - \lambda)\lambda^{-8/5} \qquad \textbf{(Eq 33)}$$

where elements of the Hertz impulse

$$P_0 = 0.811(V^6 m^3 R_1 E_r^2 \lambda^{-1})^{1/5} \qquad \textbf{(Eq 34)}$$

$$t^* = 4.525(V^{-1} m^2 R_1^{-1} E_r^{-2} \lambda)^{1/5} \qquad \textbf{(Eq 35)}$$

were used to obtain the constants

$$K_1 = 0.1258(V^2 m R_1^{-3} E_r^4)^{1/5} \qquad \textbf{(Eq 36)}$$

$$K_2 = 1.2411(V^2 m R_1^2 E_r^{-1})^{1/5} \qquad \textbf{(Eq 37)}$$

Substituting into Eq 26, the ordinary differential equation for wear is obtained:

$$\frac{(3 + 9c)\lambda - (8 + 9c)}{5\lambda(1 - \lambda)}\,d\lambda = \frac{dN}{N} \qquad \textbf{(Eq 38)}$$

For a value of $c = 3$, found to be practical, there results:

$$\frac{6\lambda - 7}{\lambda(1 - \lambda)}\,d\lambda = \frac{dN}{N} \qquad \textbf{(Eq 39)}$$

The wear depth, *h*, is related to λ as

$$h = C\lambda^{-4/5}(1 - \lambda) \qquad \textbf{(Eq 40)}$$

where the factor *C* has the dimension of displacement, and connotes the severity of the impact:

$$c = 0.77(V^4 m^2 R_1^{-1} E_r^{-2})^{1/5} \qquad \textbf{(Eq 41)}$$

In order to express the initial condition at the zero-wear limit, Eq 40 can be solved for $\lambda = \lambda_0$. Figure 11 facilitates the conversion from dimensional to nondimensional variables, *h* to λ, and vice versa. Note that Fig. 11 also includes cylindrical geometries, for which the wear equations can be found in Ref 1.

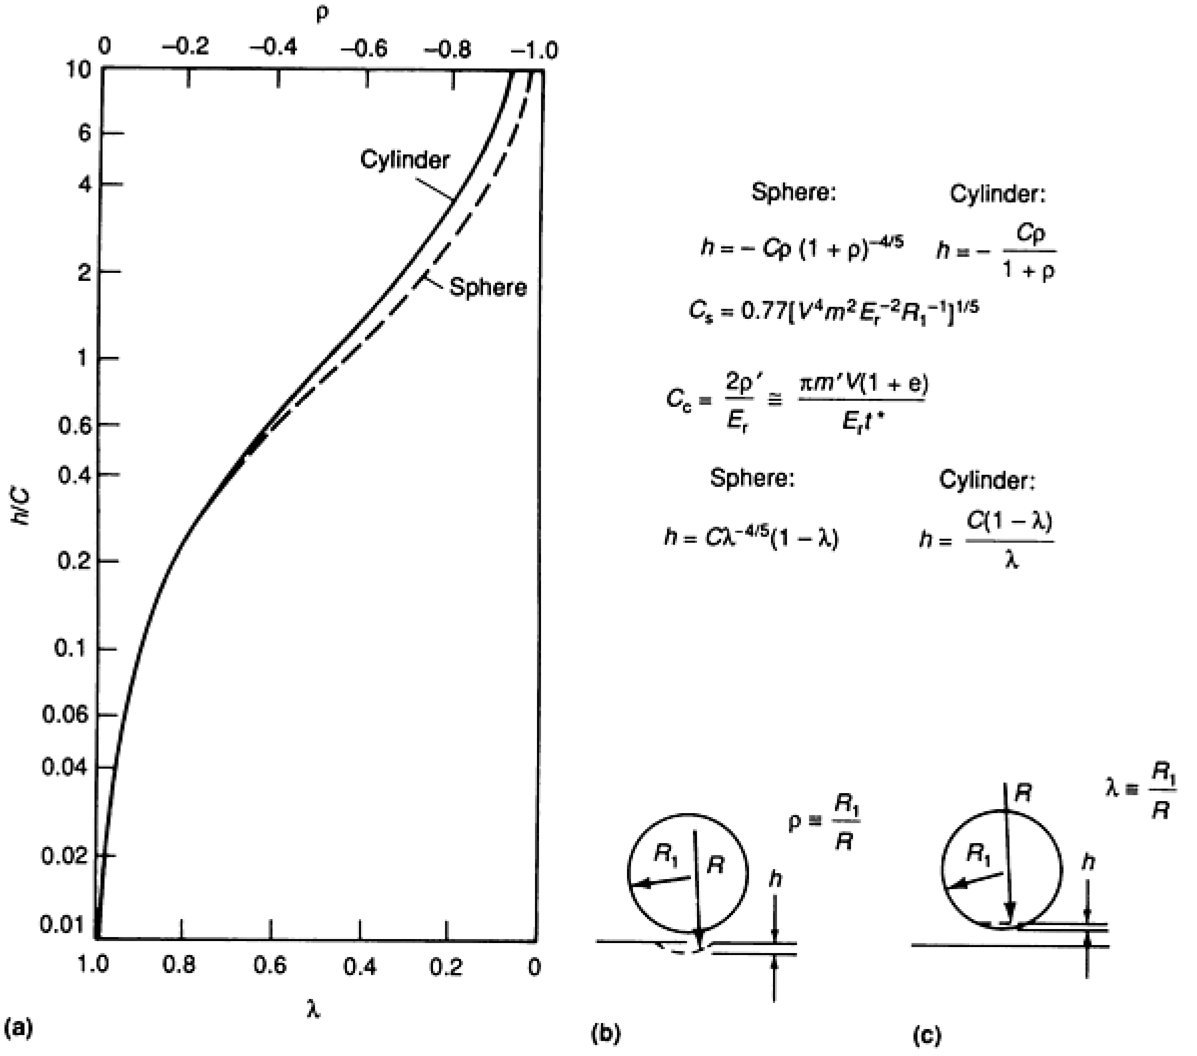

Fig. 11 (a)*h*/*C* variation versus λ and ρ for spherical and cylindrical contacts. (b) Hard sphere or cylinder wearing down soft plane. (c) Soft sphere or cylinder wearing against hard plane

Example 2: Soft Plane Worn by Hard Ball.

Figure 10(b) shows the geometry of the deepening wear scar of the plane, attending a continuously sharpening negative radius, *R.* The nondimensional curvature is taken as

$$\rho \equiv \frac{R_1}{R} \qquad \textbf{(Eq 42)}$$

All of the mathematical treatment given above for the wearing ball will apply if $\lambda = \rho + 1$ is inserted.

Computational Procedures. The differential equations of dimensional percussive wear (for example, Eq 38 and 39) for the cases treated here, and for several others (such as two curved bodies, cylindrical impact), admit the "master curve" solution technique (Ref 1) (Fig. 12). A master curve (Fig. 13) is first constructed for a fixed initial condition, such as $\overline{N}_0 = 1$, $\overline{\lambda}_0 = 0.99$ (or $\overline{\rho}_0 = -0.01$, corresponding to $\lambda_0 - 1$).

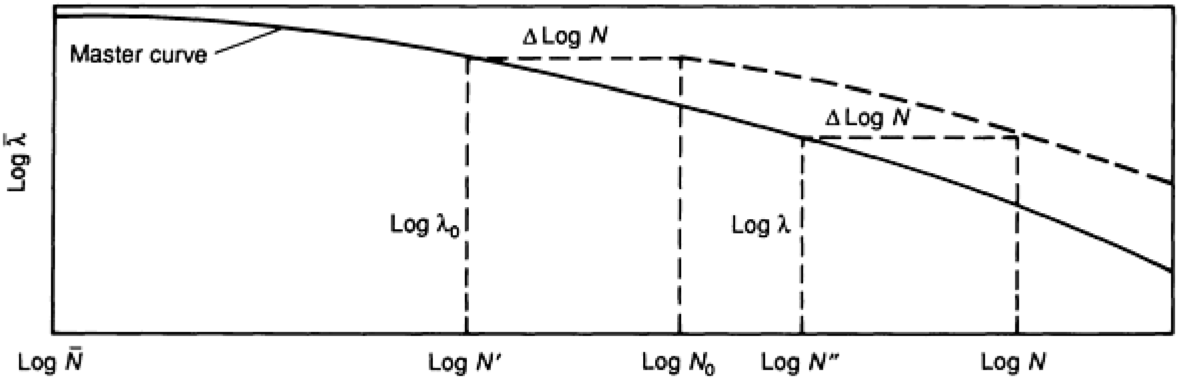

Fig. 12 Master curve shift procedure

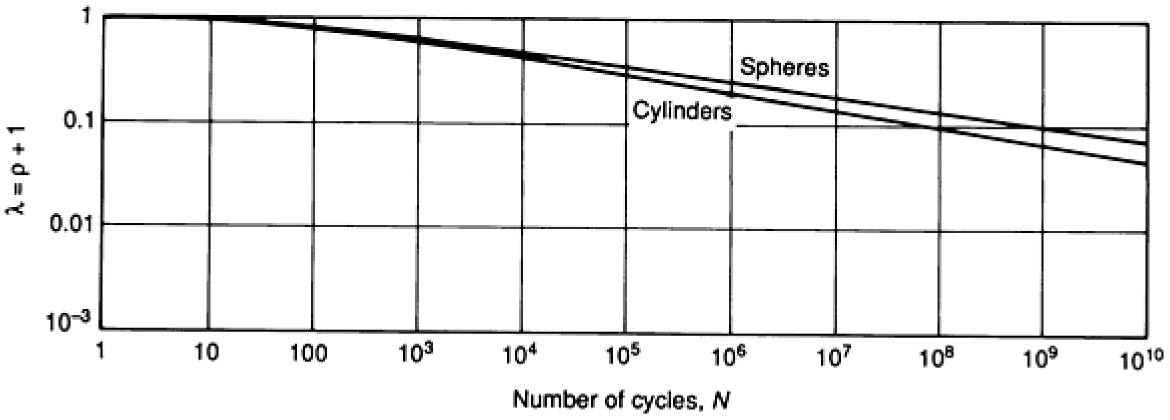

Fig. 13 Solution for impact wear in terms of nondimensional curvature parameters with initial conditions of N_0 = 1, ρ_0 = -0.01 or λ_0 = 0.99

In order to obtain the desired solution belonging to the given set of initial conditions (N_0, λ_0), we intercept the master curve at λ_0, obtaining the abscissa *N*'. Now, the master curve can be shifted from *N*' to N_0, and on this shifted portion of the master curve, the solution λ for any *N* desired can be found.

Besides the master curve method, an exact solution of Eq 39 can also be obtained for *N:*

$$N = \frac{N_0 \left(\frac{1-\lambda}{1-\lambda_0} \right)^{T-U}}{(\lambda/\lambda_0)^T} \quad \textbf{(Eq 43)}$$

where for a constant-impulse process, $T = (8 + 9c)/5$, $U = (3 + 9c)/5$.

Note that the compound nature of the impact (sliding component) is included in the zero-wear limit, and no further amendment of the computational apparatus is required. Several geometries that are more complex, and the case of two-body impact wear, treated in Ref 1. The calculation of hardness for a composite multilayered surface is treated in Ref 26.

Plotting a Wear Curve

By way of example, consider the wear of an originally plane, massive carbon steel machine platen, subjected to repetitive compound impact by a hard, nonwearing spherical-ended (*R* = 140 mm, or 5.5 in.) steel alloy (62 HRC) component of *m* = 1.2 g (0.04 oz) mass, at an approach speed of *V* = 2.0 m/s (78 in./s) and sliding speed of *v* = 1 m/s (40 in./s). The wearing surface has a roughness of $\delta/2 = 0.25\ \mu$m, and hardness of 20 HRC, with a yield stress, σ_y, of 500 MPa (75 ksi). The modulus of elasticity, *E,* of steel is 207 GPa (30×10^6 psi), and its Poisson's ratio, *v,* is 0.3. The friction coefficient, μ , for the unlubricated surfaces is 0.6.

Calculating the wear curve for nonlinear wear, the zero-wear limit is first established. The Hertz impact yields

$$P_0 = 929.4\text{N}$$

$$t^* = 9.494\ \mu\text{s}$$

$$K_1 = 245.9\ \text{MPa}$$

The slip factor is

$$f = \frac{\pi(1.2 \times 10^{-3})2}{(0.6)(929.4)(9.494 \times 10^{-6})} = 1.42$$

for a moderate range.

The β surface contribution factor is, from Fig. 5(c), $\beta = 320$, so that for the zero-wear limit, using $\sigma_y = H/3$ and $q = K_1$:

$$N_0 = \frac{1}{1 + 320}\left[\frac{(1.1)(500)}{245.9}\right]^9 2000 = 8743$$

and

$$h_0 = 0.25\ \mu\text{m}$$

Solving Eq 41 for *C*, 3.345 μm (130 μin.) is obtained, so that from Fig. 11, for $h_0/C = 0.0747$, the values obtained are $\lambda_0 = 0.93$ or $\rho_0 = -0.07$.

For the measurable wear range, the wear coefficient *c* = 3 will be used. Because the wear of a "soft plane" is being calculated, the nondimensional geometric wear parameter, $\lambda = \rho + 1$ will be computed. Equation 43 is now written:

$$N = 8743 \left(\frac{1 - \lambda}{1 - 0.93}\right) \ / \ \left(\frac{\lambda}{0.93}\right)^7$$

to be solved for $\lambda = 0.9, 0.8, 0.7, 0.6$, and so on, delineating the wear curve, Fig. 14. Conversion from nondimensional to dimensional wear depth, *h,* is made by use of the wear severity factor *C,* once again.

Corrosive Wear

Brent W. Madsen, U.S. Department of the Interior, Bureau of Mines

Introduction

CORROSIVE WEAR is defined as the degradation of materials in which both corrosion and wear mechanisms are involved. The combined effects of wear and corrosion can result in total material losses that are much greater than the additive effects of each process taken alone, which indicates synergism between the two processes. This article focuses on the corrosion-wear synergism in aqueous slurry and grinding environments. Examples of corrosive wear problems encountered in industry are provided, and the effects of environmental factors on corrosive wear are discussed. Related articles can be found in this Volume. The article "Forms of Mechanically Assisted Degradation" in *Corrosion: Fundamentals, Testing, and Protection,* Volume 13A of *ASM Handbook,* is also relevant.

Occurrences in Practice

Corrosion and wear damage to materials, both directly and indirectly, costs the nation hundreds of billions of dollars annually. Although corrosion can often occur in the absence of mechanical wear, the converse is rarely true. Corrosion accompanies the wear process to some extent in all environments, except in a vacuum and inert atmospheres. Corrosion and wear often combine to cause aggressive damage in a number of industries, such as mining, mineral processing, chemical processing, and energy production. Corrosion and wear processes involve many mechanisms, the combined actions of which lead to the mutual reinforcement of their effectiveness. Seventeen synergistic relationships between abrasion, impact, and corrosion that could significantly increase wear damage in wet and aqueous environments have been identified (Ref 1).

Slurry Handling. The movement of materials as a slurry is an efficient means of transportation that is used in many industries. However, the movement of these slurries can cause significant corrosive wear. Pumps, elbows, tee junctions, valves, flotation cells, and hydrocyclones are parts of slurry handling systems that are subject to corrosive wear. The periodic replacement of worn parts often results in costly process downtime. Pipe rotation has been considered good practice for those pipes that are subject to localized wear, but careful monitoring is necessary to prevent failure of the worn parts because of corrosion (Ref 2). Turbulence and eddies are promoted either where fittings or valves project into the mainstream flow or when the diameter of a pipe changes. The momentum of the particles is sufficient to cause

abrasive damage to the side walls of the pipe in its curves or elbows, where the change in direction does not produce eddies. Slurry particles can impart damage to the bottom of the pipe by tumbling or sliding in straight pipe sections.

Sliding wear can occur, for example, in an ore chute in a minerals processing plant, where moist ore particles slide on an inclined platform, chute, or screen. Figure 1 shows a worn wire cloth screen in a minerals processing plant. Another example is a submerged valve that opens and closes to control the flow of material. Here, the parts are subjected to metal rubbing, as well as to the abrasive and corrosive nature of a slurry. Other, more common corrosive wear problems occur in equipment such as automobile brakes an engines (Ref 3), fillings used in dental applications, and tapes rubbed by recording heads in electronic video and audio equipment. Each of these wear examples has a corrosive component that results from exposure to reactive environments.

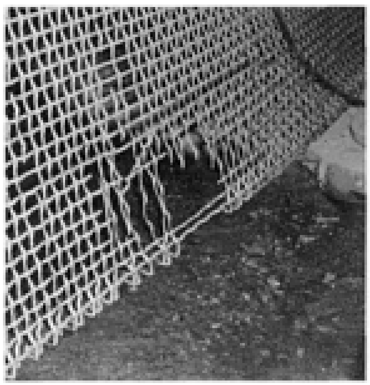

Fig. 1 Worn wire screen in minerals processing plant showing effects of sliding wear in moist environment

Crushing and Grinding. Corrosive wear is prevalent in the grinding of mineral ores. The annual cost of grinding media frequently approaches or exceeds the cost of energy in some processes (Ref 4). Figure 2 shows ball mill liner plates in both new and worn conditions. Figure 3 shows a cone crusher liner that wore completely through after only three months of use.

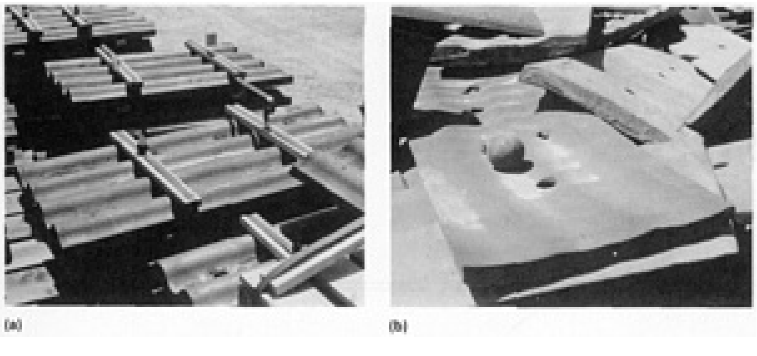

Fig. 2 Ball mill liner plates. (a) New condition, before installation. (b) Worn condition, with partially worn grinding belt

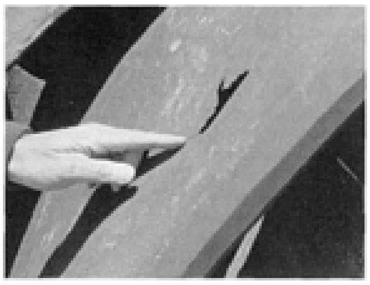

Fig. 3 Worn cone crusher liner after 3 months of use

Corrosion and wear damage arising from comminution is equivalent to 12% of more than 30 billion kW · h of energy consumed annually by U.S. industry for crushing and grinding purposes, whereas contributions from minerals account for 50%; cement, 25%; coal, 13%; and agricultural products, 12% (Ref 5). The development of more efficient mining, transportation, and processing systems has allowed exploitation of many large, low-grade ore bodies, which involves the crushing, grinding, and treatment of huge volumes of abrasive material to satisfy modern demand for materials (Ref 6). This trend will increase the future consumption of grinding media in an industry where over 0.9 Mg (1×10^9 tons) of ore are crushed annually (Ref 5).

Wear debris and corrosion products that are formed during comminution affect product quality and can adversely affect subsequent beneficiation by altering the chemical and electrochemical properties of the mineral system (Ref 4, 7, 8, 9). Electrochemical interactions between minerals and grinding media can occur, causing galvanic coupling that leads to increased corrosive wear. Corrosion and wear are also important in nonmining industries, such as the pulp and paper industry, where physical processing steps such as the grinding of wood chips are increasingly being substituted for chemical processing steps in order to reduce water-treatment requirements and fulfill regulatory standards.

High-Temperature Processes. Many chemical processes take place at elevated temperatures and involve corrosive wear. A process such as coal gasification involves hot gases with entrained solid particles that impinge on the containment vessel surface. Several studies have been conducted to describe the wear-corrosion synergism that takes place during the oxide formation and subsequent removal by abrasive particles (Ref 10, 11, 12).

Power-generation plants use processes that occur without any particles present and involve only the transport of solutions or steam. In these cases, liquid forces on the solid surface, which are due to turbulence or droplet impacts, mechanically remove protective layers of corrosion products, thus exposing more base material to corrosive action. An example of this type of process is the erosion-corrosion of steam turbines. Other systems may involve the dissolution of the protective oxide layer, because of a continual flow of liquid past the surface. Cavitation is also a problem where the high-speed flow of liquid is present. This subject is discussed in the article "Cavitation Erosion" in this Volume.

Effect of Environmental Factors on Corrosive Wear

Environmental factors affect corrosive wear in materials handling systems. Some of the more important factors that influence the material losses in slurry transport and grinding operations in aqueous media and ambient conditions are discussed below.

Slurry Particle Impingement on Two-Body Corrosive Wear

Slurry particles that strike the target material under the influence of their own momentum and that of the carrier fluid impart two-body wear damage to component parts. They are not constrained by another solid, as distinguished from grinding, which is discussed later.

Dependence on abrasive particle shape, density, size, and hardness, as related to wear rate, is discussed below.

Particle Shape. Until recently, no investigation had directly reported the effect of particle shape on wear in slurry handling systems. However, it was commonly agreed that the angularity of the slurry abrasives was important in determining the wear rate of materials where corrosion was not dominant. When slurries are recycled in a closed slurry

pot system, the wear rate can decrease dramatically with time (Ref 13, 14, 15). This is due to the microscopic rounding of the abrasive particles. The difference in wear rates for recycled and flow-through slurries is shown in Fig. 4 for type A514 steel in a water/silica sand slurry containing 50 × 70 mesh particles.

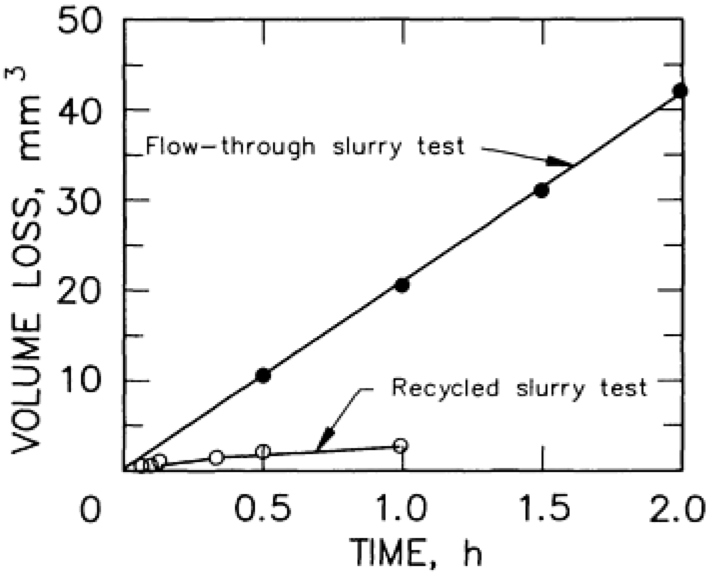

Fig. 4 Comparison of slurry wear for the flow-through and recycled slurry systems using a low-alloy steel in a 2% silica sand slurry. Source: Ref 13

Figure 5 shows the worn surfaces of the steel that resulted from the two tests. The specimen exposed for 1 h in the flow-through test (top photograph) had many fine grooves over its entire surface, typical of cutting wear. The bottom photograph shows the smooth, wave-type pattern that developed after 1.67 h with a recycled slurry, indicating a deformation wear mechanism.

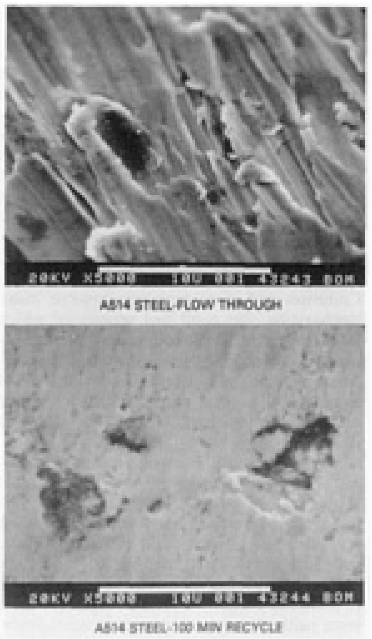

Fig. 5 Comparison of wear surfaces for low-alloy steel specimens worn in flow-through (top) and recycled (bottom) slurry tests for 1 h and 1.67 h, respectively. Source: Ref 13

The angularity of a particle depends on the radius of each protruding point on its surface, relative to its average radius. Bitter (Ref 16) has shown that the more angular a particle, the higher is its apparent density (Fig. 6). This effect results in a lower maximum velocity at which impact between the particles is purely elastic. If the predominant mode of material loss is corrosion, the angularity of the particles may not be such an important consideration.

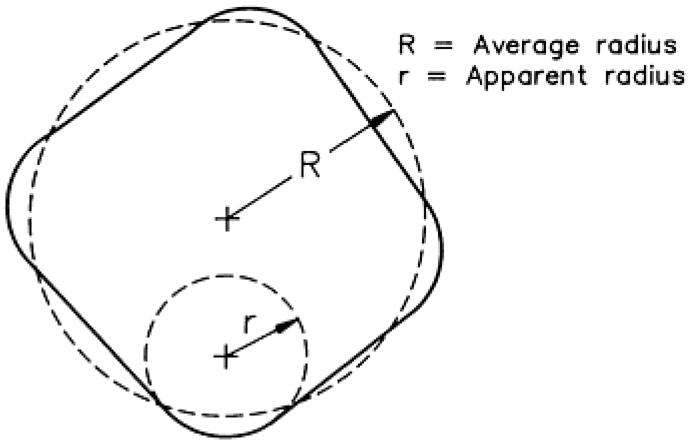

Fig. 6 Relationship between angularity and apparent density of a particle. Apparent density is $(R/r)^3$ × real reactive density. Source: Ref 16

Particle density is an important parameter that influences the corrosive wear caused by slurries. For a particle of a given angularity, the denser the particle, the more likely it is to cause either deformation or cutting wear on impact. This is a consequence of the dissipation of more energy in the same volume.

Particle Size. Because of their greater kinetic energy, particles of the same density and angularity in slurries with the same nominal velocity impart greater wear losses to materials as their size is increased. A recent study (Ref 17) has shown that larger particles have a higher collision efficiency and a higher impact velocity than smaller particles. These factors contribute to increased wear rates as slurry particle size increases.

Particle Hardness. The wear of materials has been shown to dramatically increase when the slurry particles are harder than the material being worn. However, increases in the hardness of the abrasive, above a critical hardness value, do not appreciably increase the wear rate. Likewise, when extremely hard abrasive particles are present in the slurry, moderate increases in the hardness of the worn material do little to retard the wear rate.

Dependence on slurry velocity, angle of attack, and solids concentration is discussed below in terms of wear rate.

Velocity of the slurry is the single most important factor that controls the rate of wear. The wear rate is an exponential function of velocity; exponents are reported to range from 1.6 to 4.8, but are generally between 2 and 3 (Ref 18). The velocity of the slurry not only affects the rate of mechanical damage of a material, but the corrosion rate, as well. Above a threshold velocity, corrosion products can effectively be stripped from an alloy, thus making available a new surface that is susceptible to corrosive attack.

The angle of attack of slurry particles on a material determines, to a large extent, the role that the abrasives will play in corrosive wear. In straight pipelines where the flow of slurry particles is basically parallel to the walls of the pipe, little damage to the underlying metal results from direct contact between the abrasive and alloy (Ref 19). The abrasives, along with the solution, serve to slowly remove the corrosion products and enhance the corrosion rate. The extent of this removal process is controlled by the particle size, angularity, and slurry density.

On the other hand, when a curvature in the pipe is present, the slurry particles tend to wear the pipe as depicted in Fig. 7. In this condition, the slurry particles are more likely to not only remove any corrosion products, but to directly impart mechanical wear damage to the alloy. If the alloy is one that normally passivates (such as a stainless steel), the abrasive

can continually remove the protective film and allow corrosion to proceed at a much higher rate than if no abrasive particles were present. The removal of the base metal depends on the type of material being worn.

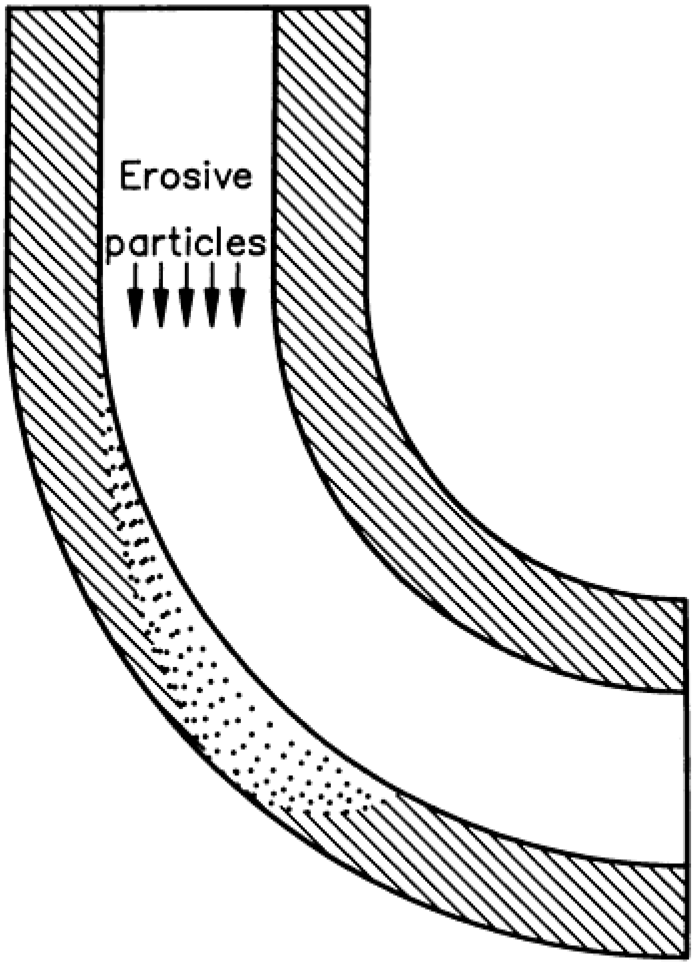

Fig. 7 Changing pattern of wear and, hence, changing angle of impingement, at bend in pipe. Source: Ref 16

Generally, ductile alloys wear greatest at shallow angles of attack, from 10 to 30°, whereas brittle materials wear greatest at 90°. The reason for these differences is the type of wear that occurs. Cutting wear is dominant for low angles of attack with ductile material, whereas deformation wear is greatest at larger angles of attack.

Solids Concentration. Increasing the solids concentration in a slurry generally increases the wear rate. The increase is only proportional to the solids concentration for dilute slurries. For denser slurries, particle-particle interaction tends to decrease the dependence of the wear rate on slurry density (Ref 14, 20).

Dependence on Hydrodynamics. Recent work (Ref 21, 22) on the trajectories and impact velocities of particles during slurry erosion has shown that not all of the particles directed at a target will impact it. The fraction of slurry particles that impact the surface of the target material is controlled by fluid velocity and viscosity, as well as the size, shape, and density of the slurry particles.

Flow-dependent corrosive wear typically occurs at geometrical irregularities, such as fittings, valves, and weld beads, where the flow separates from the wall of the containment vessel. Flow separation and reattachment produces high turbulence intensity and particle-wall interactions that lead to high corrosive wear rates (Ref 23, 24, 25). Figure 8 shows streamlines in a pipe for flow contraction and flow expansion.

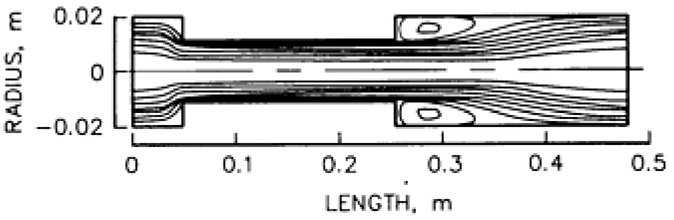

Fig. 8 Streamlines for water in pipe of variable diameter. Source: Ref 24

Blatt *et al.* (Ref 23) and Nesic *et al.* (Ref 24) have correlated material losses with the local, near-wall intensity of turbulence in single-phase (liquid only) flows. It was hypothesized that intensive near-wall turbulence disrupted the protective corrosion product and disturbed the mass transfer layer, thus enhancing oxygen transport to the metal surface and corrosion rates.

Corrosion products and the mass transfer of oxygen play an important role in the total material losses encountered in straight sections of a carbon steel pipeline. Work done by Postlethwaite *et al.* (Ref 19 and 26) shows that the material loss rate is under oxygen mass transfer control, with corrosion being the dominant mode of metal loss. The magnitude of the erosion-corrosion can be estimated using well-established mass transfer correlations for oxygen diffusion.

In aqueous solutions of near-neutral pH, mechanical wear prevents the formation of a rust film that completely covers the interior of a pipe. By providing a barrier to oxygen, this rust film in carbon steel pipes is responsible for corrosion rates of <1 mm/year (<0.04 in./year). When abrasive solids are present, coverage of the metal by the rust film is incomplete, and the islands of bare metal that are present can act as efficient cathodes and result in substantially increased rates, such as >10 mm/year (>0.4 in./year).

Grinding Wear: Impact and Three-Body Abrasive-Corrosive Wear

The wear of grinding media and crushers in mineral processing systems is caused by the combination of abrasion, corrosion, and high-energy impact of ore and metal components. The increased size of modern crushing and grinding equipment greatly increases the kinetic energy at metal/ore interfaces, which results in high wear rates. The crushed ore particles participate in three-body abrasion by virtue of being confined between two solid surfaces.

Dependence on Force. The strong effect of impact severity on the grinding media wear rate was reported by Dunn (Ref 1) for dynamic loading conditions. He showed that the wear rate was four times greater in an 8.5 m (28 ft) semiautogenous grinding (SAG) mill (8.30 kgf, or 18.3 lbf, balls) than that attained in a 2.9 m (9.5 ft) ball mill (1.81 kgf, or 4 lbf, balls). The ball velocities in the two mills were calculated to be 9.14 m/s (30 ft/s) and 5.33 m/s (17.5 ft/s), respectively. However, under conditions of a static load, Kotlyar *et al.* (Ref 27) found that the total wear rate of a metal alloy was approximately linear with load. They used a rotating metal alloy specimen between two ceramic anvils submerged in an abrasive slurry.

Dependence on Abrasive Type. Abrasive wear rates for steels and irons generally increase with an increase in mineral hardness. When the metal-to-mineral hardness ratio is greater than 0.6, marked improvement in the ability to resist abrasive wear is shown (Ref 28). In order to achieve this favorable hardness ratio, hard $(Fe,Cr)_3C$ carbides found in low-alloy nickel-chromium irons and harder $(Fe,Cr)_7C_3$ carbides found in high-chromium white cast irons are used.

Dependence on Galvanic Interaction between Minerals and Metal Alloys. Electrochemical interactions between ore materials and grinding media can occur. Mineral particles with potentials that are nobler than those of steel grinding media become galvanically coupled and result in accelerated corrosive wear (Ref 6). In recent studies (Ref 29, 30), it has been reported that the relative contributions from corrosive and abrasive wear are highly variable from one mineral-metal system to another, and are largely dependent on the mineral slurry characteristics, as well as the properties of the grinding media. In the presence of surface abrasion, and corrosion resistance, hardness of the grinding media, pH and conductivity of the pulp, and oxygen content influence the magnitude of galvanic currents between minerals and grinding media. Jang *et al.* (Ref 31) also found that galvanic currents exist between ferritic and martensitic phases in a microstructure of steel grinding media, as well as between sulfide minerals and these two phases.

Role of Localized Corrosion in Grinding. In the study of high-carbon low-alloy (HCLA) steel grinding media, Kotlyar and Wadsworth (Ref 27) found that localized electrochemical cells existed between strained and unstrained regions of the alloy. This resulted in preferential anodic dissolution in microgrooves, which promoted pitting. The overall corrosive wear rates of the steels were found to be strongly dependent on the localized corrosion.

Experimental Measurement of Corrosion-Wear Synergism

Quantitative measurements of corrosion, mechanical wear, and wear-corrosion synergism have been made using various experiments. The combined effects of wear, *W*, and corrosion, *C*, often result in total damage rates that are much greater than the additive effects of each process taken alone, indicating a strong synergism between wear and corrosion. The synergistic component, $S_{(C,W)}$ is that part of the total damage that results from the interaction of corrosion and wear processes. The total material loss, $T_{(C,W)}$, is related to the synergism by

$$T_{(C,W)} = W_0 + C_0 + S_{(C,W)} \qquad \textbf{(Eq 1)}$$

where W_0 is the wear damage in the absence of corrosion, and C_0 is the corrosion damage in the absence of mechanical wear. Equation 1 implies that corrosion can affect mechanical wear, and that mechanical wear can affect corrosion. Most researchers who have studied this type of system have measured *T* under conditions of corrosive wear, measured W_0 by conducting another experiment under conditions designed to minimize or eliminate corrosion during the wear process, and performed a third experiment to obtain the corrosion rate during the wear process. The rate obtained in this manner is usually higher than the corrosion rate C_0 because of mechanical wear interaction, and is designated as C_w. Using this notation, an equation similar to Eq 1 can be written as:

$$T_{(C,W)} = W_0 + C_w + S'_{(C,W)} \qquad \textbf{(Eq 2)}$$

where $S'_{(C,W)}$ is the increase in the mechanical wear losses when corrosion is present. Changes in the corrosion rate that are due to wear-corrosion synergism are included in C_w, which is the sum of all electrochemical corrosion processes occurring on the material during wear. The term W_0 can be obtained either by conducting the experiment under cathodic protection conditions or by using corrosion inhibitors.

The value C_w can be measured by performing polarization measurements with the specimen of interest as the working electrode. The electrochemical corrosion rate can be determined by making measurements of the current density within ±20 mV of the open-circuit corrosion potential. The current density versus polarization potential curves were fitted to the following theoretical equation that characterizes a reaction which contains only two processes under activation energy control:

$$I = I_c \left[\exp\left(2.203\frac{\phi}{\beta_a}\right) - \exp\left(-2.303\frac{\phi}{\beta_c}\right)\right] \qquad \textbf{(Eq 3)}$$

where *I* is the measured current density, I_c is the corrosion current density, ϕ is the polarization potential, and β_a and β_c are the anodic and cathodic Tafel slopes, respectively.

Equation 3 is suitable for describing the behavior of many alloys in aqueous solutions. A nonlinear regression technique can be used to determine I_c, β_a, and β_c, and values for the corrosion current can be converted to units of volume loss per area per hour to give C_w in Eq 2.

Another method used to obtain the corrosion rate is the polarization resistance method, in which the slope of the potential versus the current density (that is, the polarization resistance, R_p) is measured at potentials that are very close (±5 mV) to the open-circuit potential. The corrosion current, i_c, is calculated according to:

$$i_c = \frac{\beta_a \beta_c}{2.3(\beta_a + \beta_c)} \cdot \frac{1}{R_p} \quad \text{(Eq 4)}$$

The value I_c can then be calculated by dividing i_c by the electrode area. C_w (in units of material volume loss per area per unit time) is obtained after multiplying I_c by the appropriate conversion factors. In this case, β_a and β_c can either be measured graphically from Tafel plots of the potential versus log *i* or estimated from tabulated values for similar alloys.

Examples that show how these measurements have been made in slurry particle impingement systems and experiments that simulate ore-grinding environments are described below. Mechanisms for corrosive wear have been proposed, based on the cited studies.

Slurry Particle Impingement Systems

Various types of slurry wear tests designed to measure corrosive wear are reported in the literature and include slurry pot, jet impingement, and pipeline configurations. The experiments described in this section involve the wear condition known as low-stress, two-body abrasive wear. Madsen (Ref 13, 14, 32, 33) utilized a slurry pot that was capable of using either recycled or flow-through slurry. Pitt and Chang (Ref 34, 35) conducted experiments with a jet-impingement apparatus, and Postlethwaite *et al.* (Ref 26) used electrodes in a closed-loop pipeline to measure both wear and corrosion rates.

Slurry Pot Experiments. A slurry wear test developed by the Bureau of Mines (Ref 32, 33) was used to measure both wear and corrosion rates during slurry wear in order to establish the relationship between the wear and corrosion of metal-alloy specimens. Figure 9 depicts the slurry wear apparatus.

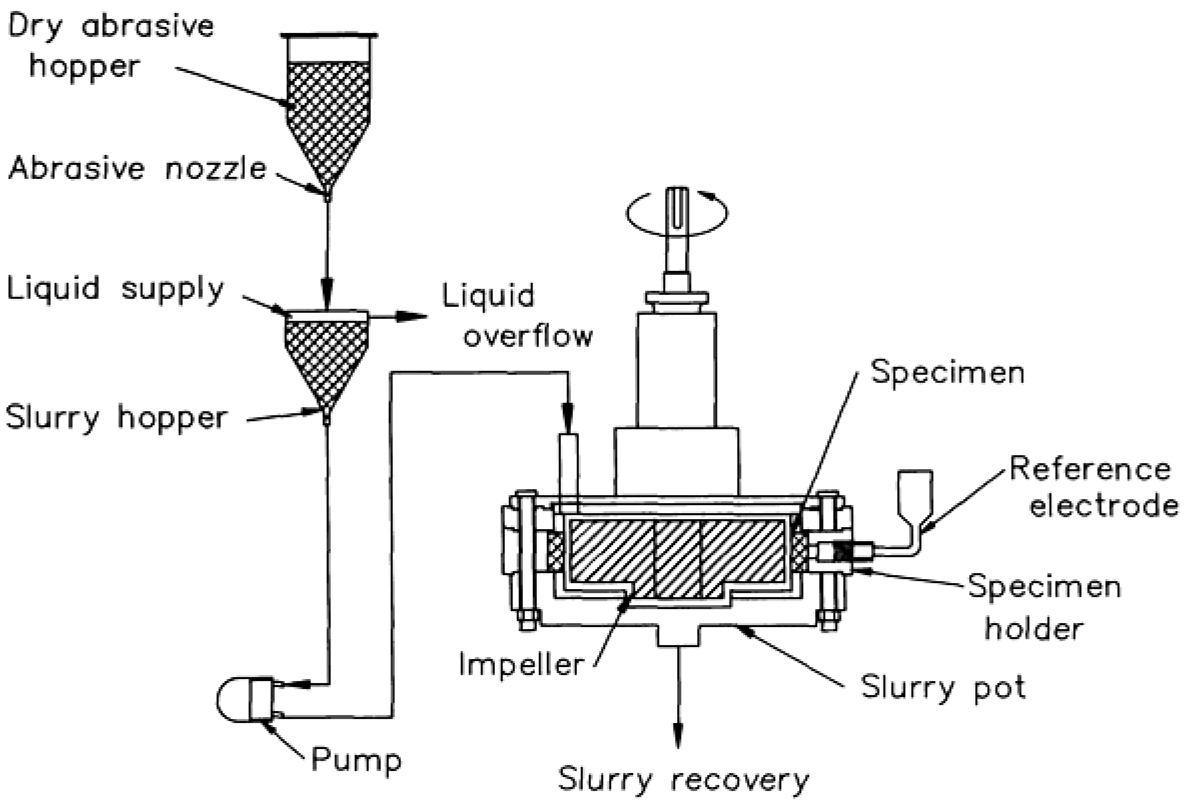

Fig. 9 Flow-through slurry wear apparatus. Source: Ref 13

Three types of tests were conducted to determine the terms in Eq 2. The total material loss, $T_{(C,W)}$, was determined from weight losses and densities during an experiment conducted at open circuit. The wear rate that was due to mechanical wear only was determined while cathodically protecting the specimens to eliminate corrosion.

These experiments showed that mechanical wear had a dramatic effect on the polarization curves of passive alloys, such as stainless steels. The results showed that the combined effects of wear and corrosion resulted in total wear rates that were much greater than the additive effects of each process taken alone. Figure 10 shows the polarization plots for 316 stainless steel that was exposed to a silica sand slurry at various slurry concentrations and impeller velocities. It is noted that the anodic current density increases with an increase in percent solids and speed, indicating that more of the passive film is removed because of the higher frequency of particle impacts. The oxide film on the stainless steel is apparently adherent and fast forming. In contrast, the polarization curves and corrosion rates of low-alloy steels were not affected to any extent because they freely corrode and do not form tightly adhering passive films.

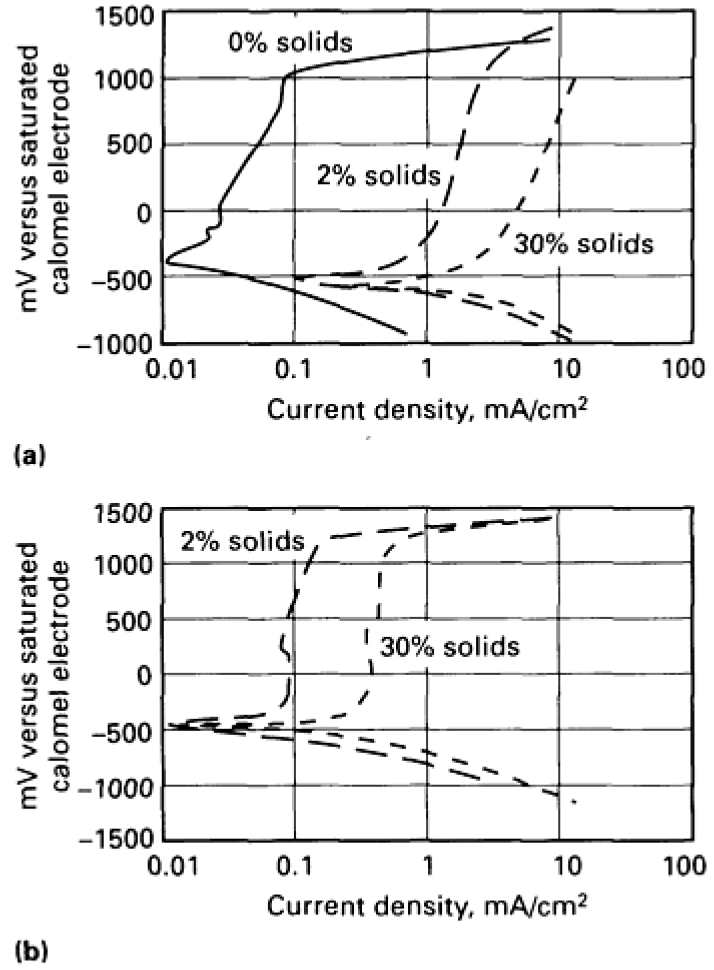

Fig. 10 Polarization curves for 316 stainless steel showing the effect of percent solids and impeller speed in a silica sand slurry. (a) Impeller velocity, 15.6 m/s (52 ft/s). (b) Impeller velocity, 5.8 m/s (19 ft/s). Source: Ref 33

The corrosive attack on the specimen surface can aid the mechanical wear processes, allowing the meal to be removed more easily by the forces that result from the abrasive action. In a 2% silica sand/water slurry, with impeller speeds of 5.8 and 15.6 m/s (19 and 51 ft/s), the $S'_{(C,W)}$ in Eq 2 accounted for 62% and 37%, respectively, of the total material losses, T. The synergistic effects are therefore very important in regard to the slurry wear of metal alloys.

Jet-impingement experiments were conducted in which Pitt and Chang (Ref 34, 35) used an electrochemically instrumented jet slurry apparatus. A hardened stainless steel nozzle with a 3.81 mm (0.15 in.) diam orifice delivered a slurry jet stream that impinged on the working electrode, which was 3 mm (0.12 in.) away from the orifice.

The corrosion currents were determined according to Eq 4 by using the polarization resistance technique described previously. $T_{(C,W)}$ was calculated from weight losses during corrosive wear. W_0 was determined from weight losses during experiments in which the working electrode was cathodically protected at a potential of -1.5 V versus the saturated

calomel electrode. This system used a recycled slurry that was replenished with fresh slurry periodically to minimize the effects that were due to slurry particle rounding.

At jetting speeds ranging from 9.3 to 21.5 m/s (30.5 to 70.5 ft/s), the $T_{(C,W)}$ from both a high-carbon steel and a high-chrome cast iron impinged by a quartz slurry were mainly influenced by the $S'_{(C,W)}$. This synergistic effect accounted for 8.3 to 54.9% of the total material losses, with the greatest effect occurring for larger particles and higher jet velocities.

Closed-Loop Pipeline Experiments. Postlethwaite *et al.* (Ref 26) measured the electrochemical corrosion rate of steels in a closed-loop pipeline experimental apparatus. He mounted electrode specimens flush with the pipe wall. The test section of pipe was a 38 mm (1.5 in.) diam vertical leg of the test loop. The vertical orientation of the pipe eliminated any effects of gravity on the solids concentration in the pipe.

The value for $T_{(C,W)}$ was obtained by weight losses, whereas C_w was obtained by polarization resistance techniques. The values obtained for W_0 (during cathodic protection of the electrode) were less than 5% of the total material losses, and $S'_{(C,W)}$ varied between 2.8 and 40.9% of the total material losses.

Most of the material losses from a commercial carbon steel pipe were due to electrochemical corrosion. Depending on the slurry flow rate, C_w varied from 56 to 92% of the $T_{(C,W)}$. It was shown that the erosive effect prevented the formation of a rust film that normally stifles the diffusion of oxygen to the corroding surface.

Grinding Wear Systems

The abrasive wear in grinding is different from that experienced in slurry particle impingement systems, because the abrasive particles from the crushed ore participate in three-body abrasion between two solid surfaces.

Rotating Cylinder/Anvil Experiments. Kotlyar, Pitt, and Wadsworth (Ref 36) used a rotating cylinder/anvil apparatus to measure the corrosive wear of a HCLA steel. The apparatus consisted of a rotating cylindrical specimen that rotated between two opposing abrasive anvils that were applied to the cylinder to a controlled load. The specimen served as a working electrode in a three-electrode system. Values of $T_{(C,W)}$ were determined by weighing the specimens before and after an experiment. To estimate W_0, cathodic protection was applied to the sample by fixing the voltage at -1.7 V versus a saturated calomel electrode (SCE). The electrochemical corrosion rate was determined using a linear polarization technique. In experiments using HCLA steel rotating cylinders in a 15 wt% quartz slurry (pH = 9), total material losses were higher by a factor of four when quartz, rather than HCLA, anvils were used.

As shown in Fig. 11, the increase in total material loss, T, was linear with applied load; corrosion, C_w, was nearly constant with load; the purely mechanical wear, W_0, increased and then leveled off as a function of load; and $S'_{(C,W)}$ was large and variable (Ref 37). The synergistic contribution of corrosion to abrasion increased markedly with loads higher than 65 N (6.6 kgf). This may result from the initiation and propagation of microcracks, assisted by anodic corrosion. The surface cracking caused by pitting and subsurface cracks (Ref 38) also has been observed after wet grinding in laboratory ball mills. The synergistic effect was found to decrease linearly with respect to pH in the range from 7 to 10. Above a pH of 10, pitting is retarded, and the metal loss that results from synergism decreases.

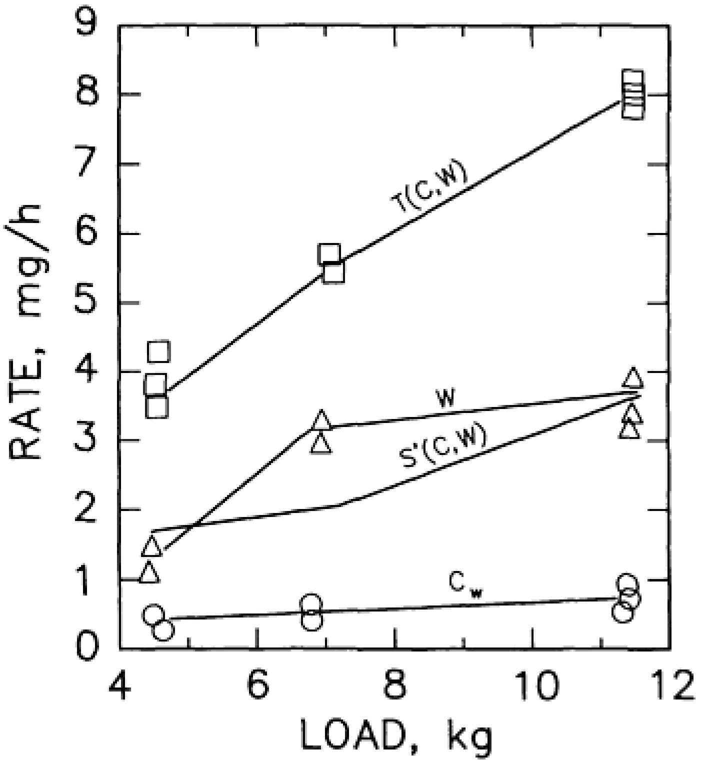

Fig. 11 Total wear rate, $T_{(C,W)}$; mechanical wear rate, *W;* corrosion rate during wear, C_w; and the synergistic term, $S'_{(C,W)}$, for HCLA steel using quartz anvils in a 15% quartz slurry at pH 9.0 as a function of load. Source: Ref 37

When localized corrosion is present, the corrosion component is small, whereas the synergistic component can be as high as 50% of the total material losses. The large synergism is accounted for by macroscopic removal of metal, resulting from localized corrosion.

Rotating Ball-on-Electrode Experiments. In investigations of the electrochemistry of complex sulfide-grinding systems, the galvanic currents of pyrite, pyrrhotite, and mild steel electrodes were determined in short-circuit connections under abrasive and nonabrasive conditions (Ref 39, 40). The device shown in Fig. 12was developed for the tests performed under abrasive conditions. It consisted of a porcelain ball rotating against three fixed electrodes of pyrite, pyrrhotite, and mild steel. Quartz slurries prepared with mild steel balls were used, and the galvanic current for each electrode was separately and alternately monitored via a switch with a zero-resistance ammeter.

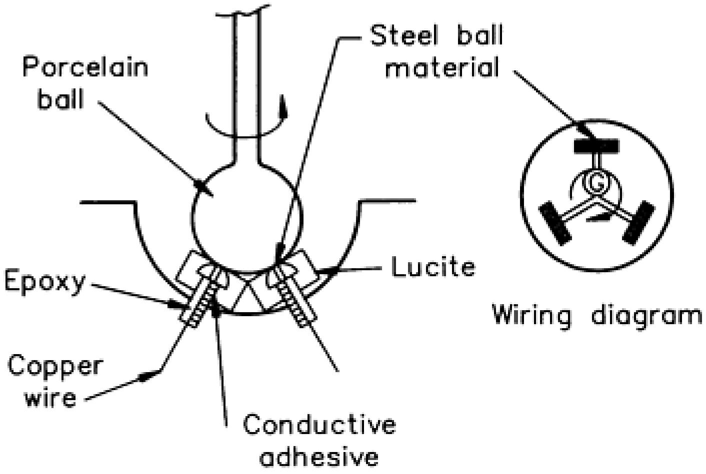

Fig. 12 Experimental ball-on-electrode device to measure galvanic currents between minerals and alloys. Source: Ref 38

Figure 13 depicts an electrochemical model for a two-sulfide/grinding media system according to the corrosion theory for a multielectrode galvanic cell (Ref 41). In this system, the noblest electrode is generally a sulfide mineral that is cathodic. The grinding media is usually more active than the sulfide minerals and is anodic. The other sulfide mineral develops an intermediate cathodic or anodic behavior, depending on its rest potential, the electrochemical characteristics of the electrodes, its surface area, and the material that it contacts.

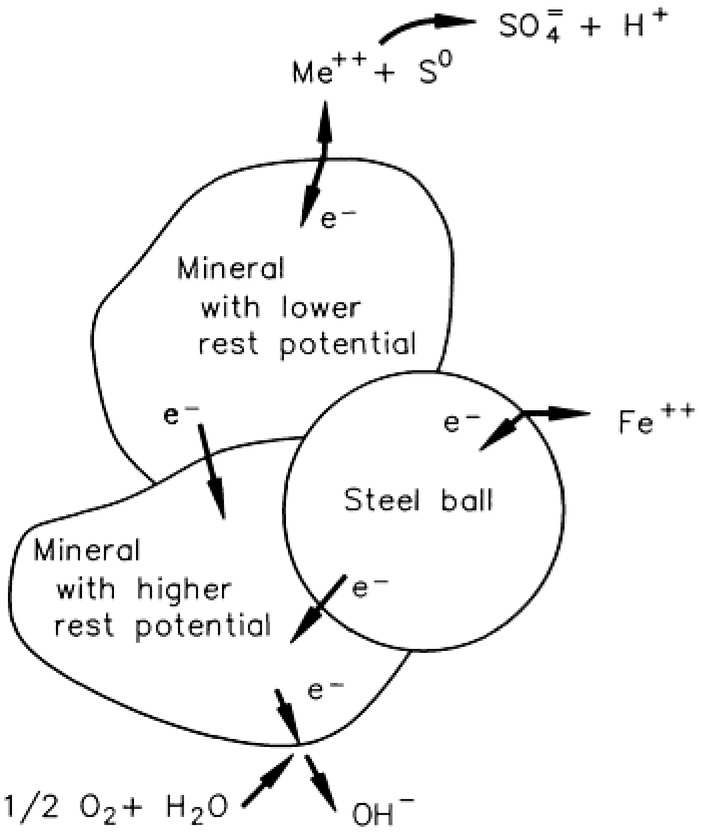

Fig. 13 Model of galvanic interactions among two minerals and grinding media. Source: Ref 39

Major reactions that are thought to take place at the surface of the respective mineral or steel electrode are (Ref 39):

$$\frac{1}{2}O_2 + H_2O + 2e^- = 2OH^- \text{ (at cathodic mineral)} \quad \textbf{(Eq 5)}$$

$$MeS = Me^{2+} + S + 2e^- \text{ (at anodic mineral)}; \quad S \rightarrow SO_4^{2-} + H^+ \quad \textbf{(Eq 6)}$$

$$Fe = Fe^{2+} + 2e^- \text{ (corrosion of steel media)} \quad \textbf{(Eq 7)}$$

$$Fe^{2+} + 2OH^- = Fe(OH)_2 \rightarrow \text{Fe hydroxides} \quad \textbf{(Eq 8)}$$

Dissociation of the minerals may also occur, but this is usually a slow process. The precipitation of other metal oxides is possible when dissolved metal ions from the minerals combine with hydroxide ions in a manner similar to Eq 8.

By using electrochemical and surface analysis techniques, Adam *et al.* (Ref 42) studied the pyrrhotite-grinding media system. They found a coating of hydroxide and/or sulfate species of iron on the pyrrhotite surface as a result of galvanic interactions (Eq 5, 7, 8) between the mineral and the grinding media. Similar findings were reported by Learmont and Iwasaki (Ref 43) for the galena-grinding media combination. The iron hydroxide coatings on pyrite produced by reactions (Eq 5, 7, 8) can impair floatability, whereas local pH changes that are due to acid formation via oxidation of elemental sulfur to sulfate and hydrogen ions at the pyrrhotite surface (Eq 6) can prevent the formation of the detrimental coating.

Corrosion currents that are due to the galvanic coupling between the sulfide minerals can be determined by obtaining polarization curves of individual electrodes under abrasive conditions, and by determining the point at which the cathodic curve crosses the anodic curve. These curves must be adjusted for the cathode/anode surface areas (Ref 44). Estimates based on this technique have shown good agreement with estimates from marked-ball water test data (Ref 9).

Mechanisms of Wear/Corrosion Synergism in Abrasive and Impact Wear

At stated earlier, Dunn (Ref 1) has indicated a number of mechanisms that account for wear/corrosion synergism in mineral processing systems. The following discussion applies the proposed mechanisms to various materials and handling systems.

Abrasion. The plastic deformation by high-stress metal-mineral contact causes strain hardening and susceptibility to chemical attack. This was shown by Kotlyar and Wadsworth (Ref 27), who demonstrated the existence of localized electrochemical cells between strained and unstrained regions of alloys, which promoted pitting. The abrasion mechanism itself can:

- Remove protective metal oxides and passive films to expose unoxidized metal to a corrosive environment. This is true for high-speed slurry wear of stainless steels (Ref 33). The corrosion rate of 316 stainless steel was shown to be as high as mild steel in the presence of only 2 wt% silica sand slurries
- Form microscopic grooves and dents that serve as sites for concentration cell corrosion. This can happen to many alloys, including HCLA steels, in which the formation of microgrooves and partial removal of oxide films lead to the initiation of pits that affect the total material losses (Ref 27)
- Increase the microscopic surface area exposed to corrosion, thus increasing the corrosion current
- Remove strain-hardened surface layers that are caused by repetitive impact. These layers are often more brittle than the underlying metal and do not adhere to the surface as well
- Crack brittle metal constituents, forming sites for impact hydraulic splitting. As corrosive liquids are trapped in cracks, forces on the metal surface seal the crack containing the liquid, and then hydraulically

split adjacent metal to propagate the crack.

Corrosion, as a mechanism, can:

- Produce pits that can be precursors to microcracking, which invites hydraulic splitting during impact
- Roughen the surface, thus leading to lower energy requirements to abrade the metal
- Produce hydrogen, which can embrittle the metal and lead to cracking (Ref 45)
- Selectively attack grain boundaries and less-noble phases of multiphase microstructure, weakening adjacent metal. This is especially true of white cast irons, where corrosion attacks the chromium-depleted zones that surround the hard carbides in the structure. This corrosion eventually promotes the premature removal of the harder carbide phases, thus accelerating material losses

Impact. Plastic deformation can make some constituents more susceptible to corrosion. The impact mechanism itself can:

- Crack brittle constituents and tear apart ductile constituents to form sites for crevice corrosion and hydraulic splitting
- Supply the kinetic energy to drive the abrasion mechanism, thus accelerating the abrasive component of wear. In ore processing, some minerals are driven into the softer steel grinding media, promoting the formation of galvanic corrosion cells
- Pressurize mill water to cause splitting, cavitation, and jet erosion of metal and protective oxidized material
- Pressurize mill water and gases to produce localized temperatures and phase changes in the liquid
- Heat grinding media, mill liners, ore, and fluids to increase corrosive effects

Means for Combating Corrosive Wear

Research and engineering efforts in wear, corrosion, and materials science are being pursued to combat corrosive wear in aqueous environments. The areas of investigation described below include materials selection, surface treatments, and handling environment modifications.

Materials Selection. The selection of the right material for a particular corrosive wear environment can lead to extended life of component parts, less costly downtime, and other economic advantages.

One approach is to place a number of materials in actual service and to compare the material losses of each over a given time. This technique can give the best solution to materials selection, but is time consuming. It also limits the number of materials that can be tried, and does not often result in the application of scientific principles to obtain the most cost-effective material for the given life of a process. However, actual field service should be used as a concluding step before final choices of materials are made.

Another approach is to adapt laboratory tests to field situations. Isaacson *et al.* (Ref 46) used a method in which electrodes were mounted at the ends of mill liner bolts, and polarization curves of the media material electrodes were obtained by a telemetry-radio system. Although the data were often noisy, correlations with laboratory corrosive wear tests were made.

Madsen (Ref 47, 48) used a test developed in the laboratory in a field experiment. He converted a laboratory slurry pot test to a portable model that could be transported to the field for use with slurries there. This approach enabled the testing of a large number of candidate materials in a relatively short time, because this slurry pot design allowed for the simultaneous comparison of 16 specimens.

The equipment could be useful in screening materials for further evaluation in actual service, thus shortening the time needed to determine the better material while offering a wider selection than actual field use could. This test is most

useful when the hydrodynamic and geometric parameters in the test chamber are similar to those experienced in the actual service conditions.

A more fundamental and scientific approach is to study the wear and corrosion characteristics of various materials in the laboratory and extrapolate these results to actual field use. A great deal of knowledge and modeling of wear, corrosion, 0and wear-corrosion synergism is needed, along with a detailed model of the hydrodynamics. This research is still in its infancy, but is making progress as the number of researchers who can recognize wear-corrosion synergism increases.

Surface Treatment. Rather than use the more-corrosive-resistant material to make the entire component, one may choose to use a thinner layer of a costly material on the surface of the more economical substrate material. Claddings, surface treatments such as hard facings and patching with welds, or replaceable liners have all been used. In pipelines where corrosion is a problem, it is sometimes economical to line the pipes with a smaller-diameter polymer that is more corrosion resistant, but lacks the strength to withstand high pressures on its own.

Modification of the materials handling environment can be effective in controlling the corrosive wear of component parts. Solution conditioning, such as adjusting the pH and deaeration, can reduce the amount of material losses in a corrosive-wear environment. Slurry conditioning is not economical for the short slurry lines used in mining operations unless some method of water separation and recirculation is used (Ref 19).

Use of Corrosion Inhibitors. Oxidizing inhibitors, such as chromates and nitrites, have been used to raise the potential of an alloy into passive regions and to lower their corrosion rates (Ref 49). These inhibitors form a surface film when used in high concentrations. Chromates also act as effective inhibitors when used at concentrations much lower than those required to produce active-passive transitions. At these lower concentrations, chromates act as cathodic inhibitors in neutral solutions. However, because chromates are toxic, alternative nontoxic inhibitors with a similar action should be considered. Many governments restrict the effluent limit to levels as low as 0.05 ppm chromate, which makes the choice of chromate inhibitors unacceptable. Progress in developing nonchromate inhibitors has been slow (Ref 19).

Slurry Parameters. Reduction of the slurry velocity is a major factor in controlling the rate of material losses if the mechanical wear, *W*, is important, because the wear rate generally varies with the velocity raised to exponents of 2, 3, or 4. For slurry pipelines that carry 20% silica sand (30 × 50 mesh), very little abrasive wear occurs below a velocity of 6 m/s (20 ft/s) (threshold value). Above this velocity, mechanical wear becomes more dominant as a means of material degradation.

Particle size can also be a factor in the wear of slurry handling equipment. The mechanical wear, *W*, will not be a problem if the particle size is sufficiently reduced so that the particles are fine enough to follow the streamlines of the solution, rather than impact the walls of the containment part. Postlethwaite points out, however, that fine slurry particles and low velocities may result in conditions mild enough to permit the growth of rust films and scale, which can lead to pitting (Ref 19).

The particle size and velocity combination should be maintained below the threshold value, where *W* is not a factor, but with a particle size that causes enough abrasion to maintain a rust-and scale-free pipe surface. In this condition, however, the pipe should be protected from corrosion by inhibitors and/or deaeration. This would eliminate the need for unnecessary size reduction.

Cathodic protection is a useful method for protecting short sections of slurry pipelines, pumps, elbows, and other equipment (Ref 50). However, the length of the protection must be kept sufficiently short to prevent overprotection and subsequent hydrogen blistering of the protected surface. The throwing power of cathodic protection, either by impressed current or galvanic anodes, is insufficient for this method to be used to protect the inside of slurry pipelines.

Sacrificial electrodes, such as zinc plugs in water or slurry pumps, have been used to cathodically protect the pump casting. This means of protection may be applicable to other instances where it is economically feasible.

Design of Pumps, Valves, Elbows. Research by Roco *et al.* (Ref 51, 52, 53, 54) and Ahmad *et al.* (Ref 55) has shown that computer modeling is becoming a tool for the design of wear-resistant slurry pumps. A computer code is used to carry out the numerical flow simulations within the pump channels, and an energy-based, wear-predictive model has allowed for the prediction of wear rates for various geometries.

The use of these types of models can extend the wear life of pumps by altering the geometry of the interior of the pump. This effectively removes the areas of high wear rates, and spreads the energy absorbed by the pump head evenly around its interior. This same type of modeling has been done by Postlethwaite (Ref 56) and Nesic and Postlethwaite (Ref 57, 58, 59) for areas of disturbed flow.

Other means of controlling corrosive wear are available, including:

- Increasing the pipe diameter in order to decrease the slurry velocity and help ensure laminar flow
- Increasing the thickness of materials in critical areas
- Inserting impingement plates or baffles to shield critical areas from high wear
- Directing the inlet flow of materials to avoid high particle velocities at the wall of containment vessels

Oxidational Wear

T.F.J. Quinn, School of Engineering and Applied Science, United States International University--Europe

Introduction

OXIDATIONAL WEAR is a form of wear that primarily occurs during nominally unlubricated conditions of sliding. It is usually, but not always, a beneficial form of corrosion in which oxide films that are approximately 3 or 4 μm (120 or 140 μin.) thick form on the real areas of contact at the relatively high "hot-spot" temperatures that often occur between sliding interfaces.

In many cases, tribological oxidation can reduce the wear rate by two orders of magnitude, compared with the wear of the same metals under an inert atmosphere. However, amelioration of the wear rate will only occur if the oxide layers are formed during sliding. It is not possible to artificially produce low-wear surfaces by preoxidizing the surfaces under static furnace conditions.

Oxidational wear can also occur under lubricated sliding conditions when the oil film thickness is less than the combined surface roughnesses of the triboelements, for example, under conditions of boundary lubrication. Oxidational wear is the "last defense" that a lubricated metal surface has against scuffing. It is also the only defense that some of the recently emerging ceramic tribosystems have against failure when running at high temperatures.

This article focuses on the dry, unlubricated wear of metals, particularly steels, because this reflects most of the work that has been conducted recently. Attention is also given to situations that could involve the mechanism of mild oxidational wear under conditions where oxide thickness increases parabolically with respect to time. The effect of the oxide thickness increasing linearly with respect to time is also discussed in view of the recent literature (Ref 1), which has shown that the wear of stainless steels may proceed in this way.

Theoretical expressions are given for the mild oxidational wear rate of a metal under conditions involving parabolic dependence of mass uptake of oxygen per unit area upon the time of oxidation, as well as conditions involving linear dependence. The parabolic oxidational wear rate is expressed in terms of a surface model that explicitly involves:

- The number of contacts, *N,* that constitute the real area of contact
- The equilibrium oxide film thickness, *TH,* beneath each of those contacts
- The temperature, *TF,* at the contacts
- The operating variables
- The parabolic oxidational constants of the metals being worn

On the other hand, the expression for the linear oxidational wear rate explicitly involves only the contact temperature, the operating variables, and the linear oxidation constants. This simplicity is only apparent, because the contact temperature is theoretically dependent on both the number of contacts and the thickness of the oxide beneath the contact.

It is difficult to confirm either of these expressions for the mild oxidation wear rate, because of the fact that the contact temperature is almost always impossible to measure directly. For most tribosystems, the contact temperature can only be deduced from direct measurement of the heat that flows away from the interface between each triboelement. If that is not possible, it can be deduced from theoretical analysis of the heat flow involving the number of contacts and oxide thickness.

Therefore, this article discusses the flow of heat from the sliding interface in terms of the same surface model that is used for the analysis of oxidational wear. Expressions are provided for the division of heat along the pin, *DTHP,* of a pin-on-disk wear configuration and for the excess temperature, *TE,* over the general surface temperatures of the pin, *TSP,* and of the disk, *TSD.* The *TE* is merely the difference between the *TF* and either the *TSP* or *TSD,* and is therefore not really independent of the expression for *DTHP.*

A selection of oxidational wear experiments is described, in which all of the tribologically important quantities (wear rates, frictional forces, divisions of heat, and general surface temperature) were determined experimentally using well-instrumented pin-on-disk wear machines with triboelements made of low-alloy steels. These steels are known to oxidize parabolically with time under both static furnace conditions and mild oxidational wear conditions (Ref 2).

The experimental wear rates and divisions of heat are then compared with the theoretical values predicted, respectively, by the parabolic oxidational wear equation and the equation for the theoretical division of heat along the pin. Because both equations depend on the same surface model of *N* asperity contacts (beneath which there is a critical oxide thickness, most of which has been formed at the contact temperature, which is itself dependent on *N* and oxide thickness), it should be possible to deduce values of the two unknowns, if one assumes that the static parabolic oxidation constants are relevant to tribological oxidation.

However, it has been found (Ref 3) that the only way to obtain a good correlation between the theoretical and experimental values of the wear rate and the division of heat is to assume that the tribological oxidation constants are different from the static oxidation constants. This article assumes that this difference resides entirely in the Arrhenius constant, *APT,* an assumption that might seem reasonable to make on purely physical grounds. However, there is a widely held belief, which is not necessarily correct, that the activation energy, *QP,* of oxidation in tribological contact is lower than that in the static furnace condition.

A computer program (FINDAP) is given in Table 1 for deducing the tribological Arrhenius constants from a selection of experiments using a low-alloy steel (En8). This program assumes that the static oxidation activation energies are the same as the tribological oxidation energies. Essentially, the program uses the method of "halving the interval" to obtain a value of *N,* which, when put into the equation for the division of heat, gives a value that is within 10^{-6} of the experimental value, *DE,* for a series of likely values of oxide thickness, *TH.*

These pairs of values of *N* and *TH* are then inserted into the mild oxidational wear equation to eventually provide a value of *APT* that, together with the value for *QP* that is appropriate for the calculated value of *TF,* is consistent with the experimentally measured wear rate.

With the tribological Arrhenius constants obtained from FINDAP, another numerical method is used as the basis of a computer program (OXYWEAR, Table 2) to deduce the critical oxide thickness, number of contacts, and contact temperature for a set of wear experiments with a different low-alloy steel. The basis of the numerical method is to: express *N, TH,* and *TF* in terms of the contact radius, *A;* obtain a quadratic equation in *A;* and thereby solve for *A* using a fully iterative technique. It turns out that the values obtained for *N, TH,* and *TF* are very similar to those arising from the FINDAP program, thereby indicating the credibility of the method.

This article concludes with a summary of the way to use the oxidational wear model to analyze practical tribosystems and an appraisal of the future direction of oxidational wear research as it relates to the interests of typical design engineers or metallurgists who want to understand ad make practical provision in their tribosystem for the changes in geometry brought about by wear and frictional heating.

Mechanisms of Wear

The recent paper by Lim and Ashby (Ref 4) discusses the various mechanisms of wear, with special reference to the sliding wear of cylindrical steel pins against steel disks. After careful analysis of the results and conditions used by several tribological research groups, these authors summarize their findings by means of a wear mechanism map for steels. Figure 1(a) shows the boundaries between seizure, melt wear, severe oxidational wear, mild oxidational wear,

delamination wear, and ultramild wear. The abscissa is the normalized velocity. U_n, and the ordinate is the normalized pressure, W_n, defined by:

$$U_n = \frac{(U)(RT)}{XK} \quad \textbf{(Eq 1a)}$$

$$W_n = \frac{W}{(A_n)(PP)} \quad \textbf{(Eq 1b)}$$

where U is the linear velocity at the pin surface, W is the applied normal load, RT is the radius of the cylindrical pin, A_n is the nominal, or apparent, area of contact between the pin and the disk, XK is the thermal diffusive of the underlying metal, and PP is the room-temperature hardness of the underlying metal of the pin. The contours of constant normalized wear rate, WR_n, are superimposed on the field, thereby showing the regimes of dominance of the different wear mechanisms. The normalized wear rate is defined by:

$$WR_n = \frac{WR}{A_n} \quad \textbf{(Eq 1c)}$$

where WR is the wear rate (in units of volume removed per unit sliding distance).

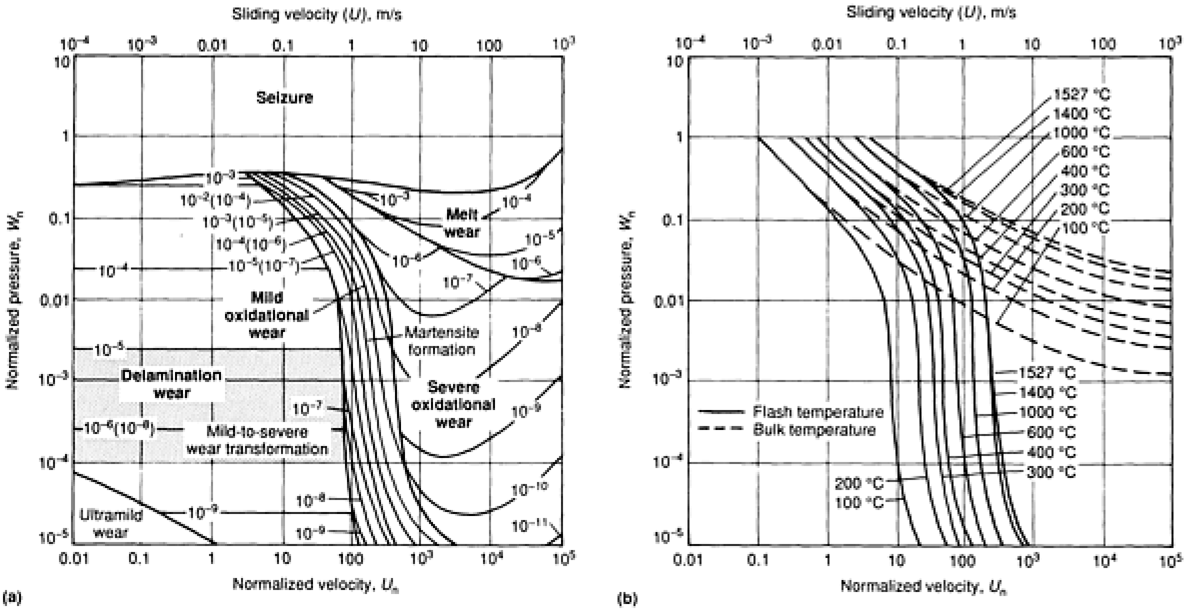

Fig. 1 (a) Wear mechanism map for steel sliding pairs using the pin-on-disk configuration. (b) Temperature map for steel sliding on steel in the pin-on-disk configuration

Figure 1(a) provides the design engineer with a useful guide to the wear rate to be expected in a steel-on-steel tribosystem, for given normalized velocity and normalized pressure. Lim and Ashby (Ref 4) have also produced another graph (Fig. 1b), which gives the designer some idea of the general surface temperature ad contact temperatures to be expected for given values of W_n and U_n.

It should be emphasized that these estimates are for a pin-on-disk system; are only very approximate, as far as the actual wear rates are concerned; and are somewhat lower than expected as far as contact temperatures are concerned (the surface temperatures are estimated to a much closer degree).

However, the particular strength of the wear mechanism map of Lim and Ashby is its all-inclusive nature, at least in terms of the wear of steels. For the first time, the work of the various tribological research groups has been brought together in a single schematic representation, which obviously will be useful for design engineers.

Mechanism of Mild Oxidational Wear

Our knowledge of the mechanism of mild oxidational wear has evolved gradually since the late 1960s (Ref 5, 6, 7, 8, 9) as a result of extensive microscopic and crystallographic analyses of worn surfaces and wear debris. In the initial stages of a wearing process, severe wear occurs. During this period, opposing surfaces achieve conformity, so that the real areas of contact consist of several large plateaus, the area of each being about the size of the real area of contact expected from the plastic deformation theory of Bowden and Tabor (Ref 10), namely *W/PP*, where *W* is the applied load and *PP* is the Brinell hardness (expressed in units of stress). At any given instant, one of these plateaus bears most of the load and becomes the site of considerable frictional heating. This causes the metal below the plateau surface to expand, in a manner similar to that described by Barber (Ref 11), and become the only region of contact until it is removed by wear. If the sliding speed is comparatively slow or the loads are so light that frictional heating is negligible, then the expansion of the contacting plateau will not be sufficiently large for it to become a preferred contact region. Furthermore, the rate of oxidation of the contacting plateau will not be very different from that of the remainder of the surface.

However, given sufficient frictional heating, the contacting plateau will oxidize preferentially, compared with the remainder of the surface. It will then oxidize at a temperature, *TF,* that is normally well in excess of the general surface temperature, *TS.* The surfaces of these plateaus tend to be extremely smooth, with fine wear tracks parallel to the direction of sliding. Typically, each plateau has an area of about 0.01 mm^2 (15.5 mil^2) and a height of about 3 or 4 μm (120 or 160 μin.).

The plateaus will sometimes exhibit cracks running at right angles to the sliding direction, somewhat similar to the fatigue crack systems found in fracture mechanics. It is possible, but not yet proven, that the intermittent heat and stress cycles suffered by the plateaus, as they enter and leave contact with their "opposite numbers," could bring about wear through the contact fatigue mechanism indicated by these crack systems. Typically, the surfaces surrounding these plateaus are rough and strewn with wear-debris fragments that are the remnants of previously existing contact plateaus.

The contacting plateau (on each opposing surface) is the site for all the asperity-asperity interactions between two sliding surfaces at any given moment. According to the mild oxidational wear mechanism, these asperities are the site for oxidation at the contact temperature. Because oxidation occurs by the diffusion of oxygen ions inward and, sometimes, by metal ions outward, one would expect the plateau to grow in height from the interface between the oxide and the metal beneath each asperity contact. In the course of many passes, it is reasonable to expect that the increases in height would be spread over the whole area of the contacting plateau. Upon reaching a critical oxide film thickness, the plateau becomes unstable and breaks up to form flakes and, eventually, wear debris.

The mild oxidational wear mechanism does not attempt to explain why the plateau breaks off at a critical thickness of a few microns. However, the theory does assume that when the contacting plateau finally breaks up, then another plateau elsewhere on the surface becomes the operative one. The virgin metal beneath the original plateau becomes free to oxidize at the general surface temperature. Without externally induced heating, the amount of oxidation at those parts of the surface that are not in contact (typically at a temperature of about 80 °C, or 175 °F) will be several orders of magnitude less than the oxide growth at a contacting plateau (at a typical temperature of 400 °C, or 750 °F).

Mild Oxidational Wear Theory

Any type of wear must involve the real are of contact, A_r, between surfaces in a state of sliding loaded contact. The original papers on mild oxidational wear began with the Archard wear law (Ref 12), which states that the wear rate is proportional to the real area of contact. This can be expressed mathematically as:

$$WR = (K)(A_r) = \frac{KW}{PP} \qquad \textbf{(Eq 2)}$$

where *K* is dimensionless constant and *PP* is the room-temperature hardness of the softer of the sliding pair.

Archard (Ref 12) interpreted this *K*-factor as the probability of producing, on the average, a wear fragment at each asperity encounter. This would mean that an average of 1/*K* encounters are needed to produce a wear fragment. Quinn (Ref 6) suggests that, for oxidational wear, this could also mean that 1/*K* encounters need to occur at a plateau in order for it to build up to the critical oxide thickness.

Using this interpretation, the following expression was evolved:

$$WR = \frac{2(A)(KP)(W)}{(TH)^2(RH)^2(F)^2(U)(PP)} \quad \textbf{(Eq 3)}$$

where *A* is the radius of each asperity contact, *RH* is the average density of the oxidized plateau, *F* is the fraction of oxide that is oxygen, and *KP* is the parabolic rate constant.

This constant depends on the temperature of oxidation through the expression:

$$KP = (AP)\exp\frac{-QP}{(R)(TF)} \quad \textbf{(Eq 4)}$$

where *AP* is the parabolic Arrhenius constant, *QP* is the parabolic activation energy, and *R* is the universal gas constant. Equation 3 can be written in terms of *N*, the number of asperity contacts, by inserting $A = \{(W)/[(\pi)(N)(PP)]\}^{1/2}$, thereby giving an equation for the wear rate in terms of: the surface model for oxidational wear (*N, TH,* and *TF*); various constants (*AP, QP, PP, RH, F, R,* and π); and the operating parameters (*W* and *U*).

More recent work by Hong, Hochman, and Quinn (Ref 1) uses an alternative derivation of the mild oxidational wear equation, which does not depend on the validity of the Archard (Ref 12) interpretation of the *K*-factor. The derivation is simply an equivalence between the total volume of wear and the volume of material (that is, oxide) formed on the real area of contact in the time required to build up a critical oxide film thickness, namely:

$$(A_r)(TH) = (WR)(U)(t) \quad \textbf{(Eq 5)}$$

One can now involve oxidation theory by assuming that the mass uptake of oxygen per unit area occurs either parabolically or linearly with respect to the time, *t.* The linear assumption produces the equation:

$$(RH)(F)(TH) = (KL)(t) \quad \textbf{(Eq 6)}$$

where *KL* is the linear oxidation rate constant. From these last two equations, and by replacing A_r with *W*/*PP,* an alternative expression for the wear rate is obtained:

$$WR = \frac{(KL)(W)}{(RH)(F)(U)(PP)} \quad \textbf{(Eq 7)}$$

where

$$KL = (AL)\exp\frac{-QL}{(R)(TF)} \quad \textbf{(Eq 8)}$$

and *AL* and *QL* are the linear Arrhenius and linear activation energies, respectively. Note that Eq 7 does not contain a term in *TH.* In fact, it is an expression with:

- One explicit surface model term, namely *TF*
- Several constants, namely *AL, QL, PP, RH, F,* and *R*

- The operating parameters, *W* and *U*

However, it should be remembered that *TF* is itself a function of both *N* and *TH*.

Whether one approaches the theory of mild oxidational wear from the Archard (Ref 12) interpretation of the *K*-factor or from the straight-forward equivalence between the volume of wear and the volume of oxide formed on the real areas of contact, one should end up with the same expression. It is a matter of pure algebra to show that both approaches give the same equations for linear oxidation, provided that one assumes the distance of a wearing contact, namely 2(*A*), is of the same order of magnitude as the thickness of the oxide. The same equivalence holds for parabolic oxidation.

Next, the heat flow aspects of oxidational wear are considered, because they lead to theoretical values for the division of heat, *DTHP,* and the contact temperature, *TF.*

Calculation of Heat Flow

Archard (Ref 13) calculated the heat flow between a moving and a stationary heat source, without taking into account the effect of oxides on both the pin and disk of his tribosystem. He also assumed that the general surface temperature of the pin was not different from that of the disk surface, so that he could apply the conventional thermal resistance analog for obtaining both the theoretical division of heat along the pin, *DTHP,* and the theoretical temperature excess, *TE,* at the real areas of contact over the general surface temperature (*TSP* or *TSD*) of the pin or disk, respectively, namely:

$$DTHP = \frac{TD}{(TD) + (TP)} \qquad \textbf{(Eq 9)}$$

$$TE = \frac{(TP)(TD)}{(TD) + (TP)} \qquad \textbf{(Eq 10)}$$

In these equations, *TE* is equal to (*TF* - *TSP*), *TD* is the fictitious excess temperature of the disk contact areas, assuming (for the sake of discussion) that all of the heat generated at the interface passes into the disk, and *TP* is the fictitious excess temperature of a pin asperity, assuming (again, for the sake of discussion) that all of the frictionally evolved heat passes into the pin.

A later modification of the Archard (Ref 13) expressions has been published by Quinn, Rowson, and Sullivan (Ref 2). These authors have included the oxide thickness on the pin, *TH,* in the expression for the theoretical division of heat along the pin, $DTHP_{qrs}$, and the theoretical contact temperature, TF_{qrs}, namely:

$$DTHP_{qrs} = \frac{(TD)_{qrs}}{(TD)_{qrs} + (TP)_{qrs}} \qquad \textbf{(Eq 11)}$$

where

$$(TP)_{qrs} = \frac{HT}{4(A)(KS)(N)} + \frac{(HT)(TH)}{(\pi)(A^2)(KO)(N)} \qquad \textbf{(Eq 12)}$$

and TD_{qrs} is given by one of two relationships, depending on whether *L* is greater or less than 5, where *L* is given by:

$$L = \frac{(U)(A)}{2(XK)} \qquad \textbf{(Eq 13)}$$

If $L > 5$, then TD_{qrs} is given by TDG, where:

$$TDG = \frac{0.85\ HT}{4(A)(N)(KS)\sqrt{L}}$$ **(Eq 14)**

If $L = 5$ or $L < 5$, then TD_{qrs} is given by *TDL,* where:

$$TDL = (-0.1021L + 0.8605)\left[\frac{HT}{4(A)(N)(KS)}\right]$$ **(Eq 15)**

The modified expression for the contact temperature, TF_{qrs}, can be written as:

$$TF_{qrs} = [(DTH)_{qrs}\ (TP)_{qrs}] + TSP$$ **(Eq 16)**

Some new variables have been introduced in the last few equations, namely *KO,* the thermal conductivity of the oxide, and *HT,* the total heat evolved through friction at the sliding interface, which is equal to [(*U*)(*FF*)]. With these theoretical heat-flow equations, and the mild oxidational wear equations given previously, theory can now be compared with the results from selected experiments with a low-alloy steel.

Theory and Experimental Results Comparison

In this section, the experimental values of wear rate and division of heat are used, together with the FINDAP computer program (details of which are given in Table 1), to deduce tribological oxidation constants that enable the use of theoretical expressions for the division of heat and the wear rate for similar tribosystems. Also used in this section are the values of the tribological oxidation constants described above, together with the OXYWEAR computer program (details of which appear in Table 2), to deduce consistent values of the radius of asperity contact, *A.* These values of *A* are, in turn, used to generate consistent values of the number of contacts, *N,* the critical oxide thickness, *TH,* and the contact temperature, *TF.*

First described are the relevant tables of data. Table 3 contains data for a series of experiments carried out with En8 steel at a speed of 2 m/s (6.5 ft/s), using a pin-on-disk wear machine that was fully instrumented for measuring the division of heat along the pin. This table was extracted from Table 1 of Ref 2. The symbols *TA, TB, TC,* and *H*1 relate to the thermocouple measurements and the heat flow calculated from these measurements for the pin-holder, as shown in Fig. 2.

Table 4 relates to the results obtained using the FINDAP computer program, in conjunction with the data in Table 3. The first few rows of Table 4 give the main constituents of the wear debris, as identified by x-ray diffraction. This identification enables one to select the appropriate oxidational activation energy, because Fe_3O_4 cannot appear in the wear debris unless the contact temperature, *TF,* is over 450 °C (840 °F), and FeO can only appear for *TF* values that are greater than 600 °C (1110 °F). This table shows that the tribological Arrhenius constants, *APT,* for this particular tribosystem are several orders more than the Arrhenius constants, *AP,* obtained from Caplan and Cohen (Ref 14).

Table 5 relates to data obtained from a series of wear tests with another low-alloy steel, En31, sliding against itself at a speed of 4 m/s (13 ft/s). This table is particularly interesting, because it gives the actual proportions of the various oxides in the debris. Later, it will be shown how this information can be used to overcome the problem of two or three different oxides of the metal being sandwiched within each of the contacting plateaus. Note that the debris for Experiment 1 was entirely alpha iron, indicating that this was not oxidational wear, so that the oxide thickness would be virtually zero. For the sake of later comparison, the variation of wear rate, *WR,* general surface temperature, *TS,* and the experimental division of heat, *DE,* with load, *W,* is shown in Fig. 3(a-c)

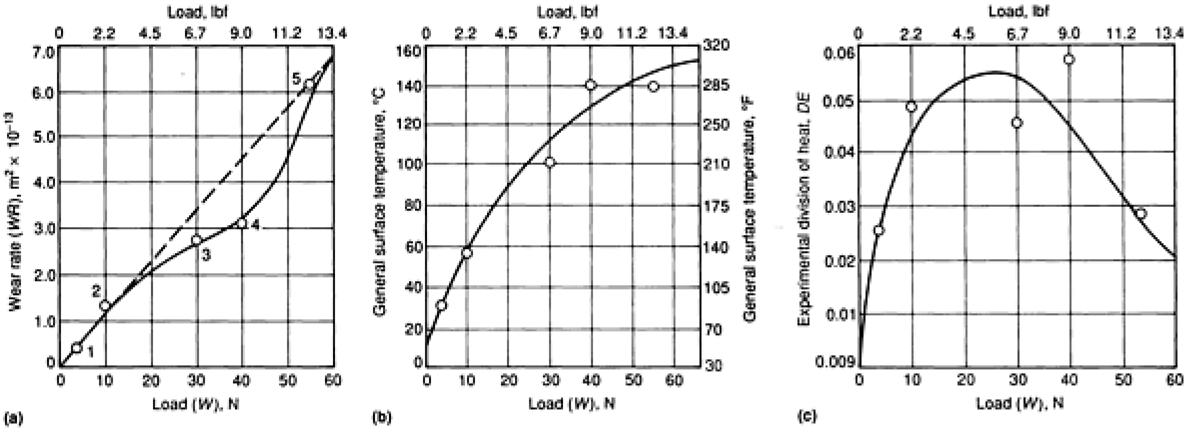

Fig. 3 Variation with load, *W,* of (a) Wear rate, *WR.* (b) General surface temperature, *TS.* (c) Division of heat along the pin, *DE,* for En31 steel sliding at 4 m/s (13 ft/s)

The wear rate versus load curve deviates from the expected linear shape for the experiments at 29.5 N (6.60 lbf) and 29.40 N (6.59 lbf), whereas the division of heat versus load curve shows an unexpected decrease in and reversal of slope at loads above approximately 20 N (4.5 lbf). The smooth shape of the general surface temperature versus load curve indicates that *TS* is unlikely to be connected with the deviant behavior of *DE* and *WR.*

If the general surface temperature is not the primary factor, perhaps the effect of changes in the type of oxide proportions should be considered, because it is well-known that Fe_3O_4 is a low-wear and low-friction material, compared with Fe_2O_3. In order to do this, the OXYWEAR computer program must first be used to deduce the values for *N, TH,* and *TF* for 100% Fe_2O_3, 100% Fe_3O_4, and 100% FeO. The results of this analysis are shown in Table 6.

Table 6 Expected values of *N, TH,* and *TF* based on the OXYWEAR computer program applied to the results of Table 3

Experiment number	At 100% Fe_2O_3			At 100% Fe_3O_4			At 100% FeO		
	N	***TH***	***TF***	***N***	***TH***	***TF***	***N***	***TH***	***TF***
1	181	1.95	396	97	2.62	523	44	3.80	743
2	305	2.07	387	150	2.83	495	50	4.43	722
3	219	2.72	387	105	3.70	492	31	5.74	716
4	786	1.20	372	422	1.60	450	116	2.81	692
5	778	2.90	406	286	4.56	560	110	6.80	769

For 100% Fe_2O_3 oxide plateaus, it is assumed that $APT = 6.12 \times 10^{12}$ and $QP = 208 \times 10^3$. For 100% Fe_3O_4, it is assumed that $APT = 0.87 \times 10^3$ and $QP = 96 \times 10^3$. For 100% FeO, it is assumed that $APT = 2.86 \times 10^7$ and $QP = 210 \times 10^3$.

Table 6 was compiled using the tribological Arrhenius constants obtained from the analysis of En8 steel applied to the results given in Table 5, assuming the three extreme cases described in the preceding paragraph. The OXYWEAR computer program, which was used to obtain these values, has already been published (in FORTRAN) (Ref 2). It uses a different approach to that used in the FINDAP program. In order to deduce values of *N, TH,* and *TF* that are appropriate to the experiments detailed in Table 5, the predictions of Table 6 must first be modified to reflect the fact that the wear debris for wear experiments 2 through 5 indicates that the contact plateaus must have oxidized at temperatures above 450 °C (840 °F), which is the temperature at which Fe_3O_4 begins to appear in the wear debris, but below 600 °C (1110 °F), which is the temperature at which FeO begins to appear in the wear debris. This modification is provided in Table 7, which has been constructed on the assumption that *N, TH,* and *TF* are linearly dependent on the proportion of Fe_3O_4 in the wear debris.

Table 7 Values of *N, TH,* and *TF* calculated from Table 4, assuming parameters are linearly dependent on proportion of Fe_3O_4 in wear debris

Experiment Number	Fe_3O_4, %	*N*	*TH*		*TF*	
			μm	**μin.**	**°C**	**°F**
1	0(a)	. . .	0(a)	0(a)	. . .	. . .
2	24	268	2.25	90.0	413	775
3	50	162	3.21	128	440	825
4	63	557	3.18	127	421	800
5	69	439	4.05	162	512	954

(a) Alpha iron was the only identified constituent of wear debris; hence, *TH* is probably close to zero.

Figure 4 illustrates how *TF, TH,* and *N* vary with the proportion of Fe_3O_4 in the debris, thereby permitting a ready comparison between these important tribological parameters. The curves in Fig. 4 are similar in shape to those of the wear rate versus load curve in Fig. 3(a), which shows that contact temperature, oxide thickness, percentage Fe_3O_4, and the wear rate are all directly related to one another. The smooth increase in the *N* curve is a mechanical effect of the increase in load, as could be shown by plotting *N* versus *W.*

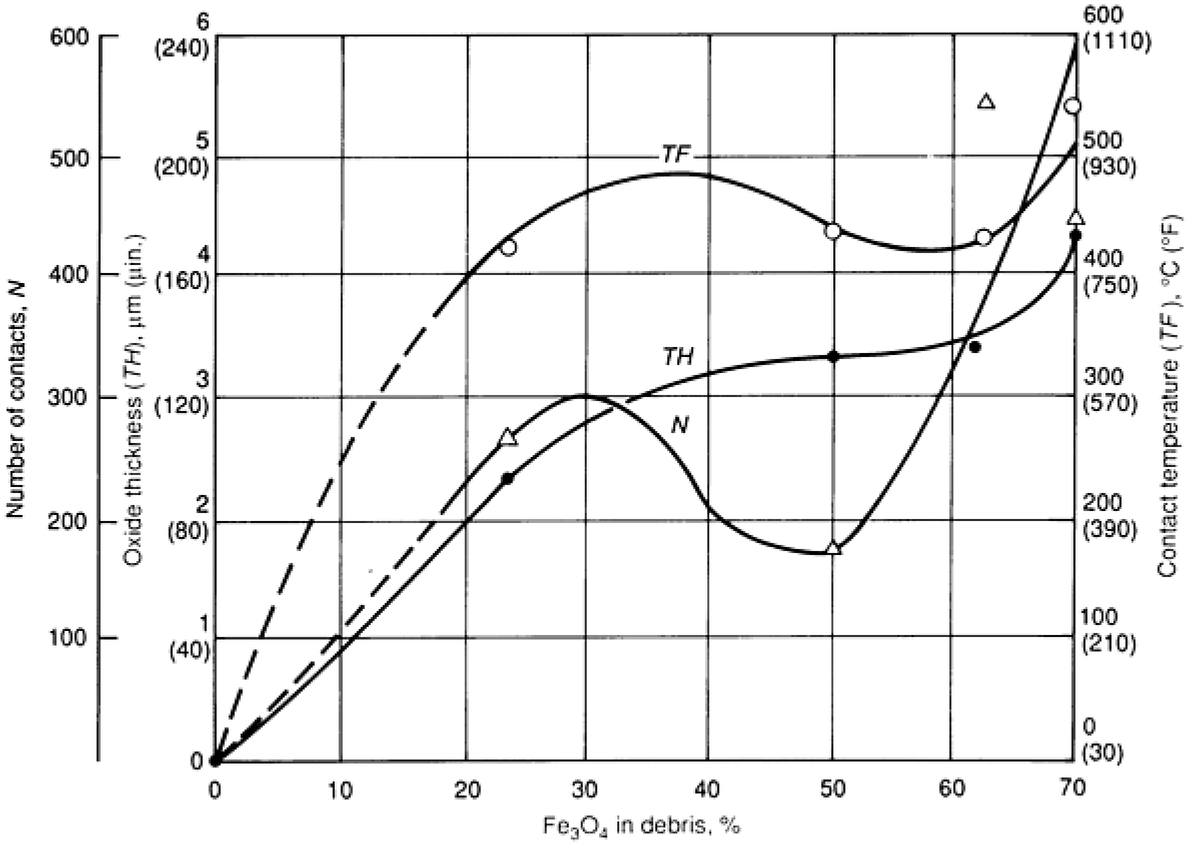

Fig. 4 Variation of oxide thickness, *TH,* number of contacts, *N,* and contact temperature, *TF,* with percentage of Fe_3O_4 in the wear debris from the wear experiments carried out with En31 steel sliding at 4 m/s (13 ft/s)

Although the model for oxidational wear and division of heat has been shown to yield interesting estimates of contact temperatures, oxide thicknesses, and numbers of asperity contacts, all of which can be shown to be of the right order of magnitude compared with values measured by electron microscopy, x-ray diffraction, infrared microscopy, thermometry, and heat-flow analysis, the model has yet to be applied to practical tribosystems. The next section in this article describes how the wear mechanism and temperature maps of Lim and Ashby (Ref 4) can be used, along with the ideas and results described in this review, to design a tribosystem that allows for the:

- Removal of oxidized surface layers from the triboelements over the proposed lifetime of the tribosystem
- Thermal expansion of the triboelements at *TS*
- Possible problems that could arise from very high contact temperatures

Application to Practical Tribosystems

The focus of the discussion below only concerns steel tribosystems that slide without any obvious lubrication (apart from the formation of oxidized surfaces). Nevertheless, there seems to be no reason why, in principle, the ideas and results discussed in this review should not be applicable to other metals that produce oxides under normal atmospheric conditions. Unfortunately, from a scan of the published literature, it appears that no metal other than iron or its alloys has received sufficient attention for it to be possible to devise a wear mechanism map similar to the one produced by Lim and Ashby (Ref 4). However, oxidational wear concepts have been applied to other metals, such as titanium, nickel alloys, and molybdenum. A broad program of research will be necessary to produce wear mechanism maps that are as all-inclusive as the steel wear mechanism maps for these metals and their alloys.

Assuming, therefore, that a particular tribosystem employs steels for its triboelements, one must first identify the wear mechanism and the relevant surface temperatures from Fig. 1(a) and 1(b). The normalized pressure, W_n, should not be

difficult to deduce, because it depends on the pressure and the room-temperature hardnesses of the triboelements. The normalized velocity, U_n, depends on the radius of the pin, as well as the thermal diffusivity of the disk. Clearly, the radius of the pin is related to the length of the area of nominal contact. Therefore, for a geometry different from that of a pin-on-disk, it is suggested that a characteristic length associated with the nominal area of contact of the stationary triboelement be used.

With these values of U_n and W_n, one can estimate the type of wear mechanism from Fig. 1(a), as well as the *TS* and the *TF* from Fig. 1(b). If the wear mechanism indicated by reference to these figures is mild oxidation wear, then one should be able to deduce the wear rate from Eq 3 and 4 using:

- The above estimates for *TF* and *TS*
- The values of *APT, QP, TH, RH,* and *F* given in this review for the relevant temperature ranges of the three oxides of iron
- The value of the load, *W,* from the pressure
- The value of the radius of asperity contact, *A,* taken to be approximately the same magnitude as the oxide thickness

Remembering that the wear rate is in units of volume removed per unit sliding distance, one can readily deduce a value for the thickness, or mass removed per unit distance of sliding or per unit time, for a particular tribosystem. Knowledge of the expected wear and the expected surface temperatures will help in the design of steel tribosystems to closer limits than heretofore, as well as avoid the use of materials, such as some solid lubricants, that will not function properly at high contact temperatures.

Future Trends

Although some research has been carried out on the connection between boundary lubrication and mild oxidational wear (Ref 15), this work has not been followed up. There is a clear need to take a similar approach toward understanding the competing chemical reactions of both the oxygen and the extreme-pressure additive in the oil with the wearing metal surfaces in a heavily loaded tribosystem. This situation calls for the application of the severe oxidational wear theory.

The theoretical aspects of severe oxidational wear have been known for some time (Ref 16, 17), but the theory still awaits experimental confirmation. However, it is very probable that, during the mid-1990s, the computer modeling methods described earlier will be successfully extended and applied to wear experiments carried out under elevated-temperature conditions. As soon as this modeling has resolved the problems involved in allowing for "out-of-contact" oxidation (Ref 18), the extension to heavily loaded tribosystems lubricated with extreme-pressure lubricants should be just a matter of time.

Surface Examination

K.C. Ludema, University of Michigan

Introduction

TRIBOLOGICAL SYSTEMS require extensive examination of their surfaces to isolate potential sources of wear. The systems are classified as "tribological" systems in order to encompass problems that include wear by sliding, wear by erosion, chemically enhanced loss of material, friction without significant wear, and any other mechanical interaction of two substances, whether lubricated or unlubricated.

Surface examination may require the use of several types of instruments. Generally, tribologists can usually solve two-thirds of their problems using a small magnet, a low-power optical microscope or hand-held lens, and surface roughness tracing. Few tribologists will need the more sophisticated instruments, and even fewer can be expected to know how to operate them.

Little is written on methods of surface analysis for tribological problems. Analysis involves human decision as well as instruments. The best method of analyzing surfaces begins with a good plan, and the plan should include several steps. In the following discussion, it will be assumed that a problem is known to exist. Perhaps a candidate material is operating in some new device and some judgment must be made of its suitability. Perhaps some surfaces are wearing too quickly or in some undesirable pattern, or the surfaces may be sliding in some undesirable manner, and the time has arrived to examine those surfaces. A procedure for surface analysis is given in the following paragraphs. The very first, and perhaps surprising suggestion is to *avoid dismantling the device or cleaning the surfaces* before performing the steps outlined below, either formally or informally.

Planning

Assemble a group of people (depending on the size of the problem) consisting of:

- Engineers and technicians who have responsibility for the product under discussion. Wear is influenced by the system surrounding a set of sliding surfaces in addition to the material composition of the sliding surfaces, and several skills should be brought into the discussion
- One or more persons with several years experience in general problems in friction, lubrication, and wear. These people serve as valuable buffers between product engineers,who need a "quick fix," and instrument specialists, who prefer to be more thorough
- Specialists in solid mechanics,fluid mechanics, lubricant chemistry, materials science, physics, and so on, should be consulted. These specialists must be selected with care, particularly if they are remote from practical problems. Surface scientists in particular, tend to concentrate on very fine detail, which *seems* sensible, but may not be. Their expertise is vital, however, and can best be applied when problems can be "broken down" into workable segments by people with broader experience in tribology

Develop a case history to gain a perspective on how the impressions or convictions were developed that the surfaces in question were judged to be operating either properly or improperly. Determine the conditions under which the surfaces seem to behave improperly. If the undesirable phenomenon appears periodically, determine whether this behavior is related, for example, to a change in supplier, a change in weather, a change in the "observer," or a change in the process sequence for making the original surface.

Develop a suitable expression for wear rate or performance problems of the surfaces in question. Are the surfaces wearing progressively, are they scuffing, is there vibration at certain times and not at others, and so on? Can these phenomena be quantified?

Decide between examining the wearing surfaces themselves or measuring the effect of wear (or uneven friction, and so on) on the functioning of the machine or component in question. It may be easier or more economical to redesign a machine component to accommodate a particular wear rate or frictional behavior than to find new materials to reduce wear rate or provide more predictable friction. Perhaps both will be necessary. The measurement of component function will probably involve measurement of changes in part clearances, friction, vibration mode, and so on. Accommodating a given friction or wear rate is a design question, which will not be discussed further.

If surface examination is necessary, it is useful to plan the steps leading to such examination, as discussed in the following sections of this article.

First Level of Surface Examination

Check Effect of Mechanical Test Sequence on Surface Chemistry. Determine, if possible, what effect there will be on the surfaces in question by stopping sliding (eroding, and so on) by dismantling the mechanical system containing the surfaces and by cleaning the surfaces. In some instances the surface chemistry will change with time after the machine is shut off, and surface chemistry will surely change during cleaning. In many instances a test device cannot be stopped, taken apart for examination, and reassembled without making some undesired change.

It is often important to preserve the wear debris on and near sliding surfaces for analysis. Observe the location of the buildup of debris, the flow patterns of debris, the particle size distribution, and so on. Obtain an oil sample and save any filters in the system that are replaced.

Dismantle the mechanical system in question in the presence of the personnel responsible for its performance. Note the practices of the persons doing the dismantling, and the possible effect of their practices on the surface condition of the workpiece.

Conduct a Preliminary Investigation by Human Senses. Use eyes, fingers, and nose to make a first judgment of the environment in which the surfaces are operating. There may be "gritty" substances or ridges of debris on or near the sliding surfaces, or there may be some particular pattern of marks, pits, or plowed ridges on the surfaces. A 10× eyepiece (magnifying glass) is probably the best aid at this stage.

Remove the surfaces to be examined and obtain some wear debris.

Observe the surfaces and debris in a binocular microscope that has a magnification range from about 2 to 40× (see the article "Optical Microscopy" in this Volume). Use a movable light source to light the target at all angles, from near-vertical to near-grazing angles. Rotate the specimens under the microscope to observe directional features of the surface.

Analyze Condition of Workpiece Surface. Surface materials may be worn away, rearranged, or built up by transfer. A perspective on these events can often be gained by surface tracing with a surface roughness tracer system (see the article "Wear Measurement" in this Volume) or other method of recording surface topography. Weighing of tribological components is sometimes useful. An important point is that the measurement of volume loss (or gain, as by material transfer) alone by any of the available methods is not sufficient. The shape of the worn region, the direction of scratching, the distribution of built-up material, and so on, must all be noted.

Repeat the above six steps for several specimens obtained from mechanical systems operated in various ways, with several different materials, and with different surface conditions, until every observer is sure of the sequence of surface change that is occurring and all agree on the scale of observation needed for full understanding of what is taking place. (See the section "Matters of Scale" in this article.)

It is important (albeit difficult) to obtain specimens in various stages of wear. When a tribological problem first appears, most investigators become very well acquainted with the failed state of the surfaces. However, before the final state, the surfaces had probably gone through several stages of change. The solution to problems often involves preventing the first stage of wear or change in behavior.

Proceed with patience. Interesting details of the debris and sliding surfaces are usually not obvious in the first hour of study, but with practice the eye eventually "sees" differences.

Develop a Hypothesis Concerning Surface Performance. The best hypothesis will arise from a group of people with the widest knowledge of tribological mechanisms. The hypothesis may contain elements that suggest the need for further analysis of some parts of the system, perhaps by an outside expert or vendor. For example, it might be postulated that the problem arises from vibration, may involve micropitting or hydrogen embrittlement (if the material is hardened steel), or may involve the buildup of compacted debris or chemical compounds from a lubricant.

Proceed with Laboratory Analysis or Conduct Modified Tests. With the hypotheses developed in the previous step, a choice may now be made between proceeding with laboratory analysis or proceeding with the further testing of practical parts. In most instances, further microscopic or chemical examination will not be as useful as empirically altering some part of the sliding system (for example, the materials, assembly practices, lubricants , and so on). However, if further examination is necessary, proceed to the next section.

Second Level of Surface Observation: Electron Microscopy

Scanning electron microscopy (SEM) is probably the most useful secondary analytical tool for surface analysis in tribology (see the article "Electron Microscopy" in this Volume). Most SEM units can cover a range of magnification from 20× to more than 30,000×. One major precaution in the use of the SEM system is that an effort must be made to retain perspective of size and scale. Perspective may be lost for two reasons. First, scanning electron microscopy has a depth of field that is ~300 times larger than that of the optical microscope at high magnification. This provides the advantage that most details on a rough surface will be visible, but it has the disadvantage that surfaces appear to be very much smoother than they actually are. Second, the great temptation in using SEM equipment is to focus on details that appear interesting, but that often turn out to be irrelevant.

Specimens for scanning electron microscopy must usually be small, typically $\leq$20 mm ($\leq$0.8 in.) thick and $\leq$80 mm ($\leq 3\frac{1}{8}$ in.) in diameter, depending upon the particular brand of SEM apparatus. They must be cleaned of volatile substances (unless the specimen can be cooled to cryogenic temperature in the scanning electron microscope) because the specimen will be inserted into a vacuum of better than 1.3 mPa (10^{-5} torr). If the specimen is a nonconducting material, it must be coated with carbon or gold so that an electron charge does not build up on the surface and deflect incoming electrons.

Images obtained with the SEM instrument do not correspond exactly with what is seen with the optical microscope. Scanning electron microscopy produces an images because the polarities across the specimen surface vary slightly.

Regions of positive bias appear dark and regions of negative bias (or with accumulated negative charge) appear bright. In contrast, the optical microscope produces an image of contrasting light intensities.

SEM units are often equipped with energy-dispersive x-ray analysis (EDAX) instrumentation (see the article "X-Ray Characterization of Surface Wear" in this Volume) for the purpose of identifying atomic elements in chosen regions on surfaces. In the most modern and automated instruments, interesting regions can be brought into the field of view, small details can be outlined within that field of view, and the elemental composition of the surface material within those outlines can be printed out directly.

Sometimes totally unexpected elements will appear in the analysis which do not relate to the specimen being examined. This occurs most often when scattered electrons in the specimen chamber impinge on the specimen holder or some other part of the instrument in the vicinity of the specimen, or it may due to a partially obstructed electron column.

The operation of modern SEM units equipped with EDAX instrumentation does not require high skill. However, skilled operator should be available to clean, align, and calibrate the instrument on occasion and to aid in the interpretation of some results.

Transmission electron microscopy (TEM) is a second type of electron microscopy (see the article "Electron Microscopy" in this Volume). It provides a view through a thin layer of solid material of ≤100 nm (≤1000 Å) thickness, depending on the voltage of the electron beam. Specimen preparation requires skill and patience because it is usually done by etching away unwanted material (usually with chemicals). Surface features of specimens can be observed with transmission electron microscopy, but this requires the making of replicas, shadowing, and several other time-consuming steps. TEM units have high-resolution capability, but require skilled personnel to operate the unit. Modern TEM instruments may also be equipped with electron diffraction instrumentation, which has several advantages over x-ray diffraction.

Selection of Chemical Analysis Instruments

The following steps must be taken to obtain tangible results using chemical analysis.

Isolate Specific Parameters to Be Investigated. Decide what information is desired from the surfaces under examination. This is necessary in order to choose the proper type(s) of instruments and to avoid a deluge of costly but superfluous information. The type of information needed may include the following (additional information is available in the section "Analysis of Data Collected"):

- Integrity of the original materials as indicated by surface cracks, loose grains, residual stresses, unexpected phases, inclusions, laps, and folds from surface processing, and so on
- Chemistry of "used" surfaces. Oxides, sulfides, organic compounds, decomposed lubricants, foreign matter, mixtures of phases from the original substrate materials, and so on, all influence sliding and wearing performance of machine components

Match Data Requirements with Instrument Capabilities and Limitations. Compare the capability of instrumentation with information needed from the instruments. This includes:

- The scale of depth and width. No practical sliding system that consists of material *x* sliding against, or eroded by, material *y* remains in its original state. After a short time each material is coated with other chemical species. If the coating is very thin (for example, 10 nm, or 100 Å) then the analysis of that coating must be done with an instrument that "penetrates" no deeper than the coating. On the other end of the scale, if the coating is thick (for example, 100 nm, or 1000 Å) and its composition varies throughout its thickness and over its expanse, then one instrument reading from the top three atomic layers over a target diameter of 10 atoms will provide data of very limited value
- Some analytical instruments identify elements only, and others provide information from which candidate compounds can be inferred. Most instruments operate within a limited range of the periodic table of the elements, but are, ironically, unable to identify the most common elements (namely,

hydrogen, carbon, and to a lesser extent, oxygen) on sliding surfaces. Time requirements, instrument charges, and operator expertise are usually proportional to the amount of information available from the instruments (as well as time required for the analysis)

- Several instruments operate with specimens confined in a vacuum. Volatile substances are usually not allowed into these instruments by the operator unless provision is made to cool the materials to a very low temperature. Nonvolatile substrates are usually rigorously cleaned before being placed into the vacuum. Unfortunately, this cleaning removes many of the coatings of interest

Define and Interpret Data to Provide Solution to Failure Analysis Problem. Develop a statement of precisely what data are to be obtained and how to interpret the results in a manner that is useful to the examination exercise. Instrument operators can explain results in terms of elements and compounds but not always in terms that are useful for solving a failure analysis problem.

Additional information about chemical analysis is contained in the article "Surface Chemical Analysis" in this Volume.

Analysis of Data Collected

The collected information must be studied with the intention of solving the problem. This seems obvious and trite to state, but the point is often forgotten in the information-gathering stage. It is often very tempting to explore in more and more detail. In most cases, it is better to "stand back" from the collected information and review the reason for the investigation underway. Check again to see whether or not the collected information answers questions on a macroscopic scale rather than on a microscopic scale. Check again to see whether or not some surviving parts (surfaces) have been investigated alongside the failed or failing parts. The first priority must be to solve the problem, the second to improve the product. Of course, an additional consideration might be to learn enough to publish a paper on the subject.

Matters of Scale

Size Scale of Objects. When examining specimens under a microscope, it is often useful to think about the scale of observation relative to the scale of size of various things. Figure 1 shows such a scale marked in SI units and in English units.

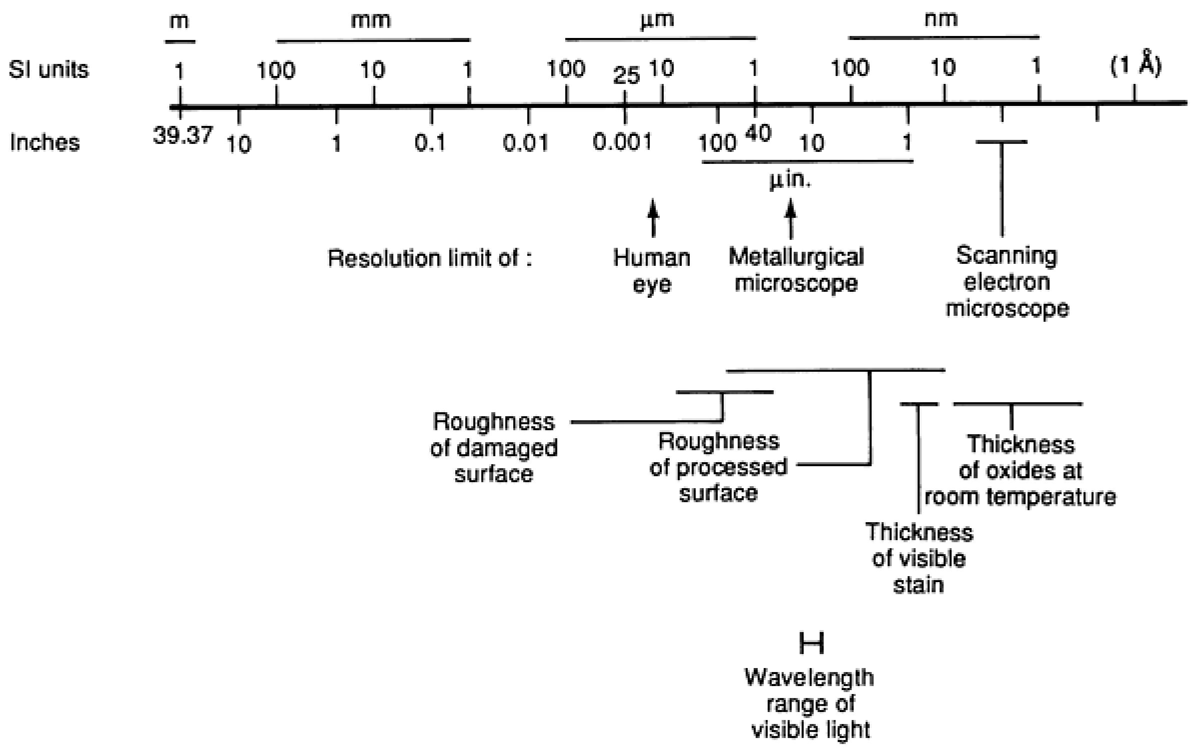

Fig. 1 Resolution ranges of selected surfaces and coatings relative to the viewing capabilities of various optical devices and the human eye itself.

Lateral Resolution Requirements to Discern Specific Features. For observing cracks, defects, inhomogeneities, plastic strains, and the details of surface damage, instruments with an appropriate lateral resolution must be selected. The question of appropriate resolution relates to the "need to know." For example, consider a crack, which nominally can be described as being in the shape of the letter V. At the crack tip, the size or spacing may be as small as atomic radii (~0.3 to 0.5 nm, or 3 to 5 Å), whereas at the other end it may be visible to the naked eye.

Very narrow cracks may constitute a minimal hazard in a structure, and thus may not be worth looking for. However, when a fatigue mode of wear is encountered, even the smallest crack is of interest.

Material defects approach a few atomic diameters and may be no more useful to observe than are crack tips. Material inhomogeneities are of the order of grain sizes (~1 μm, or 40 μin.), and are often a more important find.

The dimension of wear damage is often large relative to the lateral resolution of instruments. The contact diameter between two hard steel balls of 12 mm ($\frac{15}{32}$ in.) diameter pressed together with a load of 450 N (46 kgf) is about 0.52 mm (0.020 in.). The field of view of a high-power (2000× magnification) optical microscope is ~50 μm (~0.002 in.), whereas the field of view of an SEM unit at 20,000× is about 5 μm (200 μin.). What can be seen at such magnifications? The view can be compared with human observation of the landscape. A person may be living within an interesting geological area without realizing it. Assume that such a person is very familiar with a region within 16 km (10 miles) of his home. If that person could scan the region from a height of 32 km (20 miles), he might discern old lake beds and so on, but from an even higher altitude of 160 km (100 miles) he can detect ancient glacier movements. Similarly, observations at high magnification are likely to cause more confusion than enlightenment. It is best to first scan the entire surface and then to focus in on specific regions to obtain an accurate assessment of the surface.

To obtain maximum usage of the equipment used to examine a surface for flaws, a preliminary inspection of the entire surface should be conducted in order to not overlook isolated areas containing defects not specifically being targeted or sought.

Vibration Analysis

H.R. Martin, University of Waterloo

Introduction

ON-LINE MONITORING of wear conditions between surfaces is an important factor in maintaining efficient plant operation. The progression of wear in bearings, gears, and other surfaces that move relative to each other can lead to a wide range of failure conditions.

It is the interaction between surface asperities, which is due to relative motion, that induces vibrations in the surrounding structure. In turn, this presents a unique distribution, usually spectral, that often directly relates to the wear (damage) in progress. If there is sufficient energy transfer, then sensors placed on the external surfaces of machines can detect vital information regarding the running condition of the machine.

Wear, in a sense, can be categorized into three groups. The first group is undesirable wear that needs to be minimized, such as in bearings and gears. The second group is deliberate wear that results from the manufacturing process, such as grinding. The third group involves processes such as drilling and milling, which result in wear of the tool while metal is being cut away. In the case of the first and third groups, excessive wear will lead to reduced productivity or, in the extreme case, catastrophic failure.

Surfaces in Contact

Machined and even ground surfaces are neither perfectly flat nor smooth. In fact, only 0.1% of the nominal contact area actually touches, under normal loading conditions (Fig. 1). When these surfaces move, the asperity tips alternately weld and then break off. In addition, loading tends to increase the contact area and, hence, the number of tips in contact. Most surfaces in contact are lapped, honed, or ground, and therefore exhibit randomness in the direction of the machining process.

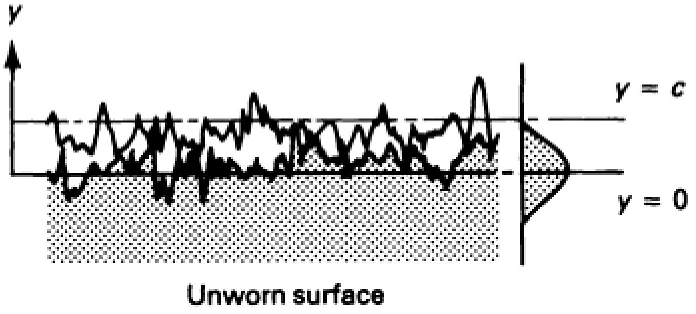

Fig. 1 Typical machine surface finish magnified to show asperity contact

Barwell *et al.* (Ref 1) showed that when the amplitude of the asperity heights was plotted on standard probability paper, a Gaussian distribution results. An example of this (Fig. 2a) shows a ground surface measured on a profiling instrument. For comparison, a surface cut in the form of a sine wave is shown in Fig. 2(b). Hence, it is not surprising that when two such surfaces either roll or slide over each other, vibrations are produced.

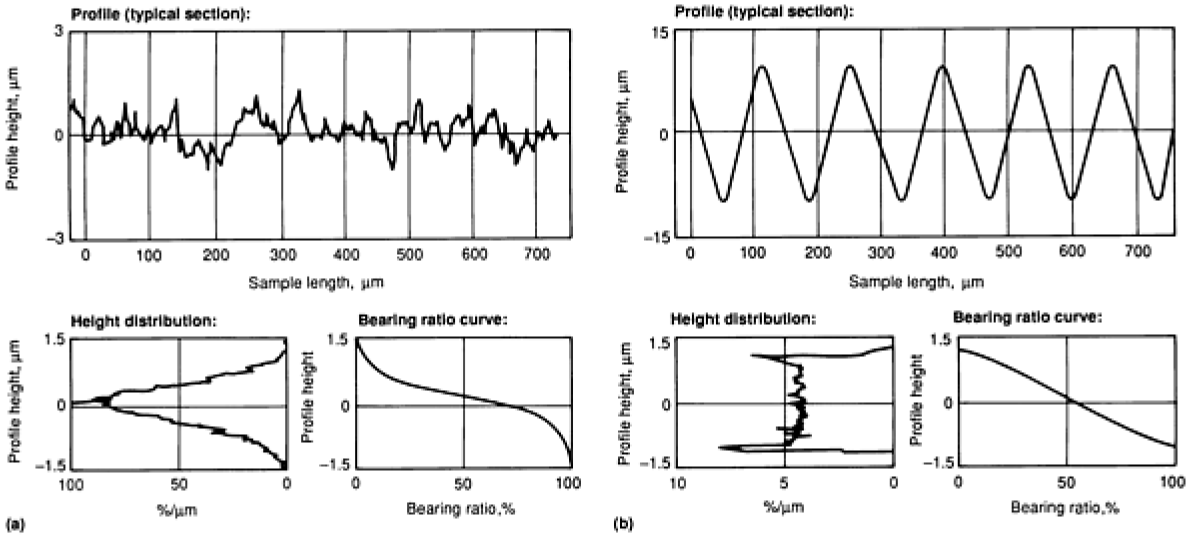

Fig. 2 Examples of statistical distributions for two surfaces. (a) Ground, single direction. Parameters (cut off = 0.8 mm, or 32 mils): R_a = 0.35; R_q = 0.45; R_{max} = 2.31. (b) Sinusoidal cut. Parameters (same cut off as above): R_a = 5.24; R_q = 5.99; R_{max} = 20.6. Source: Ref 2

The other aspect of surfaces in contact involves the deliberate removal of metal, as occurs in a lathe operation. Here, the interest is in monitoring the wear of the cutting tool, because a worn tool will not only reduce productivity, but will also affect the quality of the product. Again, vibrations that relate to the various stages of tool wear, up to breakage, are generated in the structure of the machine.

For example, as a drill becomes dull, it does not cut as fast as it is being pushed into the metal, which results in bending. The resulting "hits" on the side of the hole, which are due to the two lands of the drill bit, produce a spectral signature that is quite different from that of a sharp tool.

On-line too wear sensors are based on the frequency analysis of vibration signals. However, much progress can yet be made in this area (Ref 3). Current approaches still rely heavily on empirical analysis, in conjunction with some kind of database.

In wear monitoring, because the areas of interest in the vibrational spectra are primarily random in nature, the problem of normalizing the features to make them relatively machine-element independent is yet to be solved satisfactorily. Monitoring the trends of such extracted features can probably reduce the need for extensive databases.

Instrumentation

The availability and flexibility of instrumentation for vibration analysis has dramatically improved in recent years with the introduction of microcomputer technology. Transducers used in the measurement of vibration are commercially available. Their principles of operation are based on electromagnetic, electrodynamic, capacitive, resistive, and piezoelectric techniques.

Of these, piezoelectric devices are favored for most general vibration measurement applications, because of their ruggedness, light weight, small size, and ability to self-generate a signal. Additionally, it is possible to design these devices to be resonance-free over a wide frequency range and to be temperatures stable. Other advantages are that both velocity and displacement can be obtained by electronic integration of the signal, although there may be a loss in accuracy.

The accelerometer is an effective vibration transducer over a wide frequency range, but it is not as effective at low frequencies, because the signal magnitude is proportional to the square of the frequency. Below 10 Hz, it is better to use strain gages or other displacement measuring devices.

Another disadvantage of piezoelectric devices is the extremely low power level available, which is due to the nature of the quartz crystal or barium titanate material used. It is therefore essential that a conditioning amplifier with a very high input impedance be used, so that virtually no current is drawn from the sensor.

A popular choice is the charge-type conditioning amplifier, which satisfies this requirement and allows long cable lengths between the transducers and the amplifier, as well, Its disadvantage is poor performance at low frequencies. If, however, this type of performance is required, then the voltage amplifier has to be used with the piezoelectric transducer and the leads kept short.

Unlike the traditional piezoelectric materials, which are hard and brittle, polymeric piezoelectric film (Ref 4), has been available commercially. These polyvinylidene fluoride materials are tough, flexible, lightweight, and very corrosion resistant. The output charge level is about 20 times higher than conventional devices, and the manufacturer claims frequency bandwidths well into the acoustic emission range, that is, above 100 kHz (Ref 5). These developments point to some exciting possibilities for future research.

Modern digital oscilloscopes and analyzers usually have the facility for connection to microcomputers via various serial or parallel communication protocols. This allows great flexibility in data storage, and more extensive analysis.

Analysis Methods and Problems

The raw time-domain record of a random-type signal produced by surfaces in contact that move relative to one another is usually not very informative. Therefore, the traditional approach has been to convert to the frequency domain, either by filtering the signal or by processing using a Fourier transform. This allows the analysis of the vibration spectrum over the

range of frequencies of interest. Usually, the level of energy in a particular frequency band is monitored over time; a significant increase in magnitude is indicative of wear (damage).

The time-domain data collected by a transducer can be transformed faster using the fast Fourier transform (FFT) algorithm (Ref 6). Although this algorithm speeds up the process significantly, especially for large numbers of data points, it is necessary to ensure that anti-aliasing protection is implemented, and that the number of points in a data block is some power to two. However, there is at least one subroutine program that can take a data block with different numbers of points from some power of two.

Because the number of values calculated in the FFT analysis is equal to the number of data points in the original block, they can be paired to form a complex number, so that both amplitude and phase angle can be extracted. Hence, from a block of time-domain data, only half the number of spectral lines are produced in the frequency domain.

In random vibration, such as wear analysis, the phase angle has no meaning. Therefore, some advantage can be gained by using the Hartley transform. Because this algorithm only deals with the real part, some gain in processing speed can be attained. The square of the spectral line amplitudes produces the power spectrum of the data, which is also called the autospectrum. Some relationships that are useful are:

$$\text{Number of spectral lines} = \frac{1}{2} \times \text{number of data points in block}$$

$$\text{Frequency range} < \frac{1}{2}\ \text{sampling rate}$$

$$\frac{\text{Resolution}}{\text{Spectral line}} = \frac{\text{Frequency}}{\text{Number of lines}} = \frac{(2 \times \text{frequency range})}{\text{Number of data points}} = \frac{1}{\text{Block period}}$$

$$\text{Block period} = \text{Number of data points} \times \text{sampling interval}$$

Note that for the number of spectral lines, some commercial analyzers halve the number again, before presenting the video display. For the frequency range, a value of 2.56 is often used.

Most transducers produce analog signals at their outputs, but the computer needs each data point in binary coded form. This requires that the signal be sampled at equal time intervals and digitized. To reproduce the original signal, there are now only a finite number of data points available.

When a continuous signal from a sensor is broken up into a series of discrete numerical amplitude values at discrete intervals, it is called a time series. The process of obtaining the time series from a continuous function is called sampling. In order for the data to be meaningful in the frequency domain, the sampling rate must be greater than twice the highest frequency of interest. The frequency of the signal that corresponds to the minimum sampling rate is known as the Nyquist frequency. The corresponding allowable maximum time between samples is the reciprocal of this frequency.

An analog-to-digital (A/D) converter is needed between the transducer and the computer, where the sampled values are converted into equivalent numerical values by the A/D. Each value is represented by a finite number of states (0 or 1) is a series of steps. These binary coded steps always represent two raised to some integer exponent. Hence, for a 12 bit A/D converter with a full-scale deflection (FSD) of 10 V, the data will have 4096 steps of 0.00244 V. Each sample value is now rounded off to the nearest number of units in the range. This leads to a measurement error that may be as much as one half of the step interval.

The reason for keeping the sampling rate at greater than twice the highest frequency of interest is to avoid aliasing, which is a phenomenon that occurs because false information is generated when the process of interests is sampled (observed) often enough. As shown in Fig. 3(a), when the sampling rate is exactly twice the frequency of interest, no useful information can be extracted. Even if the sample is shifted in time, the correct amplitude of the original analog waveform cannot be fully described. In Fig. 3(b), the sampling rate is too low in relation to the frequency of interest.

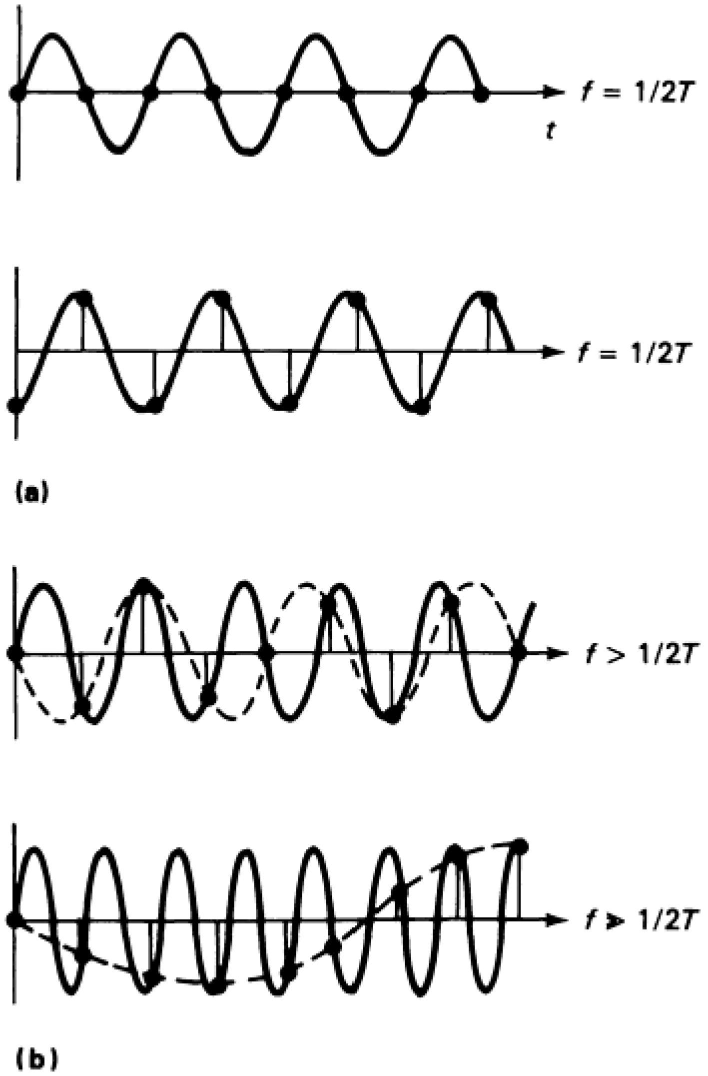

Fig. 3 Examples of aliasing. (a) Extraction of useful information not possible. *f,* frequency; *T,* time period in seconds. (b) Frequency created that does not exist in original data

In each case, the dotted lines show that a second waveform can be drawn through the same points. When processed through a spectral analyzer, this would result in spectral lines that did not exist in the original data. Aliasing is prevented by filtering the signal to a specific bandwidth consistent with the available sampling rate.

Leakage and Windowing

The FFT algorithm operates on the assumption that the collected time record from the sensor is continuous in time, as shown in Fig. 4(a). In the case of a sine wave, there are no problems provided that an integer number of cycles fits into the time-record block exactly. If the input is not periodic within the time block, then the FFT assumes a distorted input, as shown in Fig. 4(b).

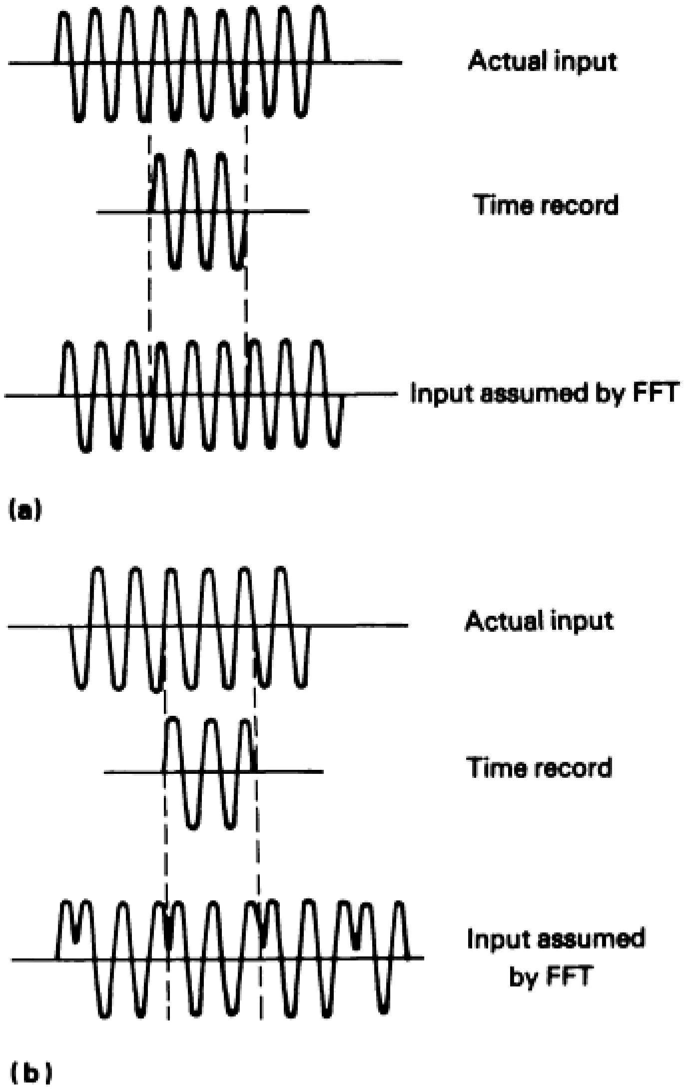

Fig. 4 Examples of signals within time record block. (a) Periodic. (b) Not periodic

In the frequency domain, the spectral energy is not a clean-cut spectral line (Fig. 5a), but is smeared throughout the frequency range (Fig. 5b). This effect is called leakage. It is therefore important to realize that leakage is due to the fact that the data is not periodic within the time block, and can be severe enough to entirely mask small signals close to the main component of interest.

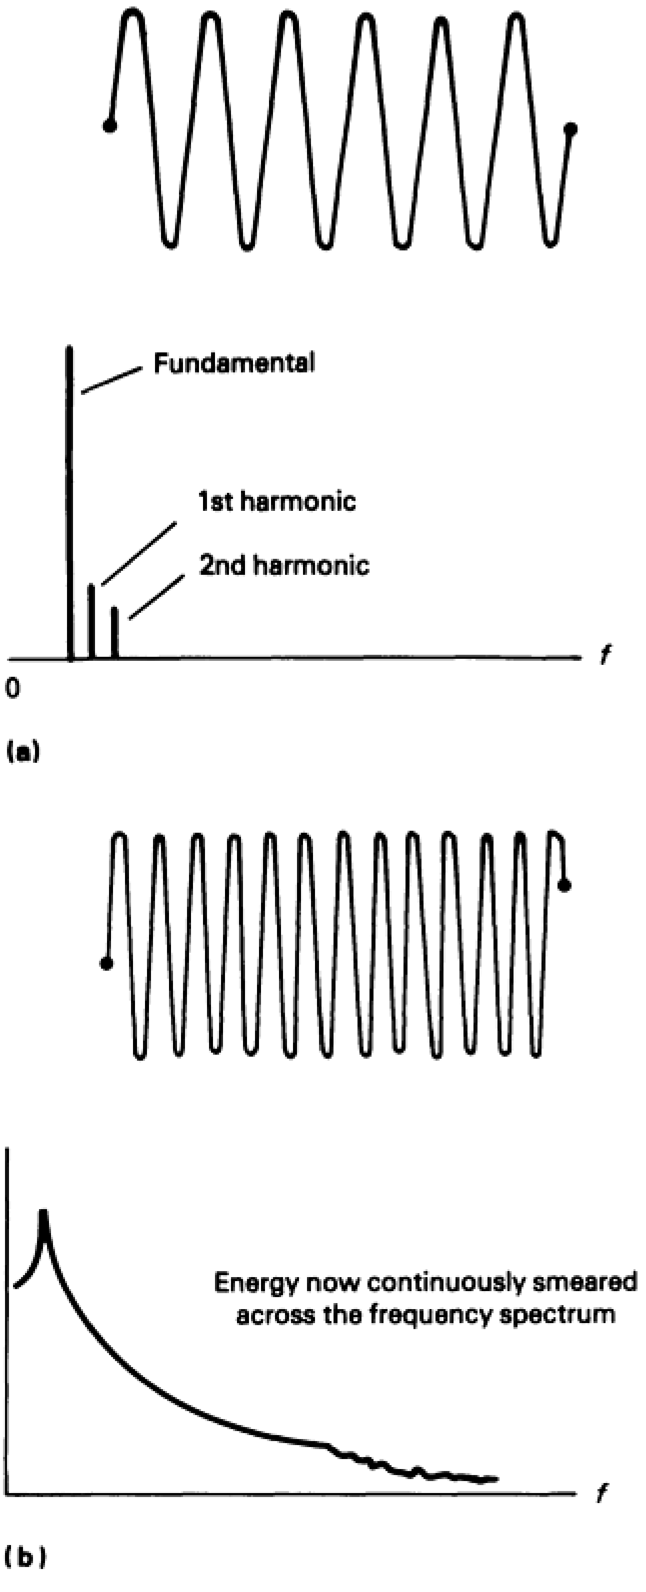

Fig. 5 Analysis results for extreme cases. (a) Data periodic in time block. (b) Data not periodic in time block

The method used to overcome the problem is the use windowing. Examination of Fig. 4(b) shows that most of the problem occurs at the edges of the time block. If the FFT could ignore the edges of the time block and concentrate on the middle portion, then the result should be much closer to the true spectral line. This can be achieved by multiplying the time record by a function that is zero at the ends and unity in the middle. Such functions are called window functions, and a popular one is the Hanning. Its effect on typical data is shown in Fig. 6 and 7. The Hanning window is extensively used for random-type data and therefore is the most useful in analyzing wear data.

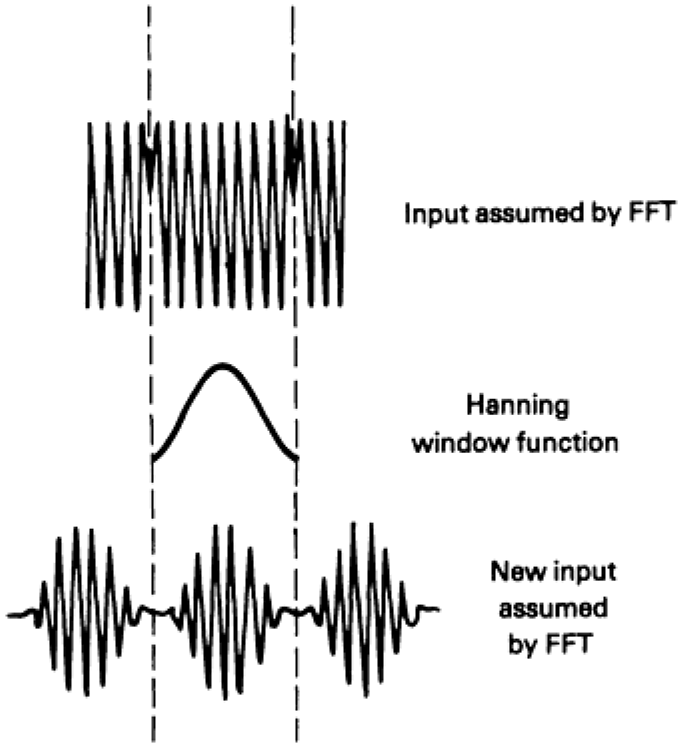

Fig. 6 Effect of windowing on time-domain signal

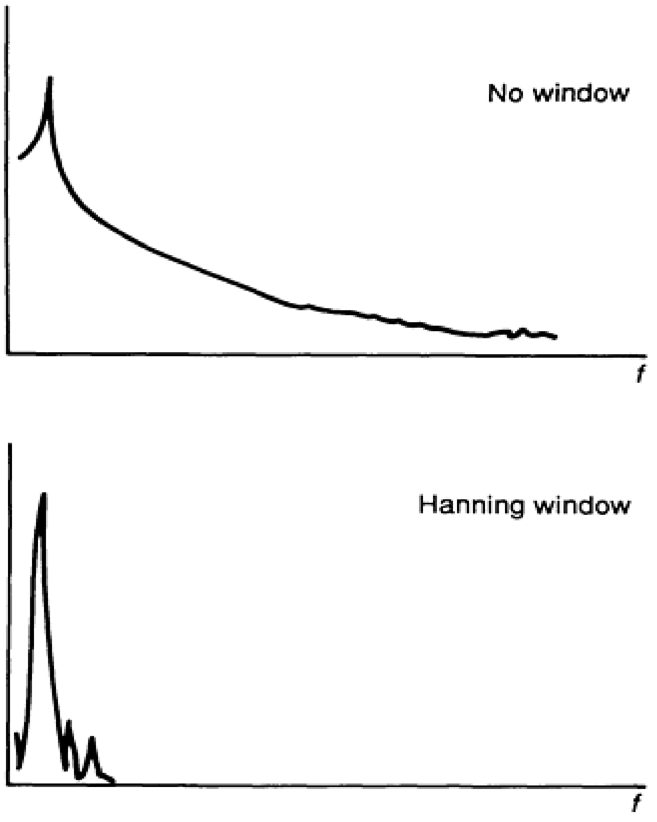

Fig. 7 Effect of windowing on spectrum

Averaging

In many practical situations, data collection has to be carried out in a noisy environment, which means that the signal to be analyzed is contaminated by unwanted signals from other sources. A commonly used method of attenuating unwanted signals is to limit the bandwidth by conventional filtering. Because the noise is usually broadband, this cuts off the extra bandwidth beyond the highest frequency of interest, which eliminates much of the noise. Of course, this approach is of little use if the noise and the signal occupy the same bandwidth. If the unwanted noise signal has a near-zero mean value, then the signal-to-noise ratio (S/N) can be improved by averaging several blocks of data that come from the sensor. Usually, between 4 and 64 data blocks are taken.

Signal averaging is most effective when a deterministic signal is buried in a random signal. It can be applied to the raw time data or to the resultant spectrum of each block. It is a very effective way to clean up (smooth) plots. The improvement in S/N ratio is equal to the square root of the number of blocks of data used.

Random signals cannot be analyzed exactly (unless the sampling time stretches, from minus to plus infinity), unlike deterministic signals, where the sampling time can be confined to one cycle, because of the repeatability of the cycle. Finite sampling times applied to random signalswill introduce errors. If noise is present in the signal, then the quality of the result will depend on the averaging time, T_{av}, and the ideal filter bandwidth, Δf. It has been shown that if the noise in the signal has a Gaussian distribution, then the measurement uncertainty, σ, is (Ref 7):

$$\sigma = \frac{1}{(T_{av}\ \Delta f)^{0.5}} \qquad \textbf{(Eq 1)}$$

For example, if a random vibration is to be analyzed in 20 Hz bands, then the averaging time needed, if the measurement uncertainty is to be less than 5% of the mean squared signal, will be 20 s.

Exponential averaging is a continuous summation average in which most of the recent data are added while earlier data are removed. For example, ten exponential averages means starting with ten summation averages, removing the first, and adding the eleventh, and so on. Therefore, each new piece of data counts for $\frac{1}{10}$th of the average.

Peak averaging considers as many instantaneous spectra as are selected and saves only the highest amplitude at each frequency seen during the data gathering period.

Statistical Analysis Approach

Failure in moving surfaces that are in contact can be due to a number of causes related, primarily, to excessive wear. Pitting occurs at points of maximum Hertzian contact stress. A failure of this type depends on the number of stress cycles, and results in small surface fatigue cracks. Small pits are formed, usually 0.5 to 1.0 mm (20 to 40 mils) in diameter. Large areas of material removal are known as spalling.

Scuffing is related of the lubricating film and is caused by overheating, which could be due to friction and the sliding velocity between surfaces. This type of contact produces alternating welding and tearing, which removes metal rapidly. Once the condition begins, it is very difficult to reestablish a proper oil film. Severe surface welding is called scoring.

Plastic flow is due to cold working of the surfaces caused by high contact stresses, together with rolling and sliding actions. The surface deformation results from the yielding of the surface and subsurface material.

Abrasive wear, unlike the other types of surface damage, is not a local failure, but is likely to spread over large areas.

The amplitude distribution of a vibration signal picked up from surfaces moving relative to each other can be expressed in terms of a probability density function (PDF). This represents an estimate (probability) of the time the signal remains in a particular amplitude window. It has been well established in the literature that machined surfaces are neither perfectly flat nor smooth.

Experiments show (Fig. 2b) that the PDF closely approximates to a Gaussian distribution. As damage (wear) starts to occur, the PDF begins to deviate from this classic bell-shaped curve. Rather than examining the PDF in detail, Dyer and Stewart (Ref 8) decided to track the progress of this damage by examining the statistical moments of the data.

Any signal, particularly a random signal, can be described by its statistical moments. The first three moments are:

- Mean value, or average amplitude size
- Mean squared deviation, or average power in the signal
- Standard deviation, or the measure of how closely the data are clustered around the mean value

A general integral defining all the statistical moments (Ref 9, 10) can be expressed as:

$$M_n = \int_{-\infty}^{\infty} g(y)^n \, p(y) \mathrm{d}y \qquad \textbf{(Eq 2)}$$

where M_n is the nth moment, $n$equals 1, 2, 3, 4, . . ., $g(y)$ is the amplitude function, $p(y)$ is the probability density function, and y is amplitude in millimeters.

For a surface that is in good condition:

$$p(y) = \frac{1}{\sigma \sqrt{2\pi}} \exp \frac{[-(y - \bar{y})^2]}{2\sigma^2} \qquad \textbf{(Eq 3)}$$

Odd moments are related to information about the position of the peak density distribution in relation to the mean value, whereas even moments indicate the characteristics of the spread of the distribution. It has been well established mathematically (Ref 11) that if the fourth moment is normalized using the square of the second moment, then the Kurtosis coefficient takes on the unique value of 3.0, if the surfaces under consideration exhibit a Gaussian distribution of asperities. As the surfaces become damaged, the Gaussian indicator changes value, because the shape of the curve moves from the classic bell shape.

Volker and Martin (Ref 12) showed that for roller bearings, a damage map could be created by plotting the Kurtosis coefficient against acceleration level. It can be seen from Fig. 8 that the types of damage in progress can be identified. The damage map represents a plot of the energy present because of the damage (x axis) versus a measure of the impulsive nature of the damage and the number of defects (y axis).

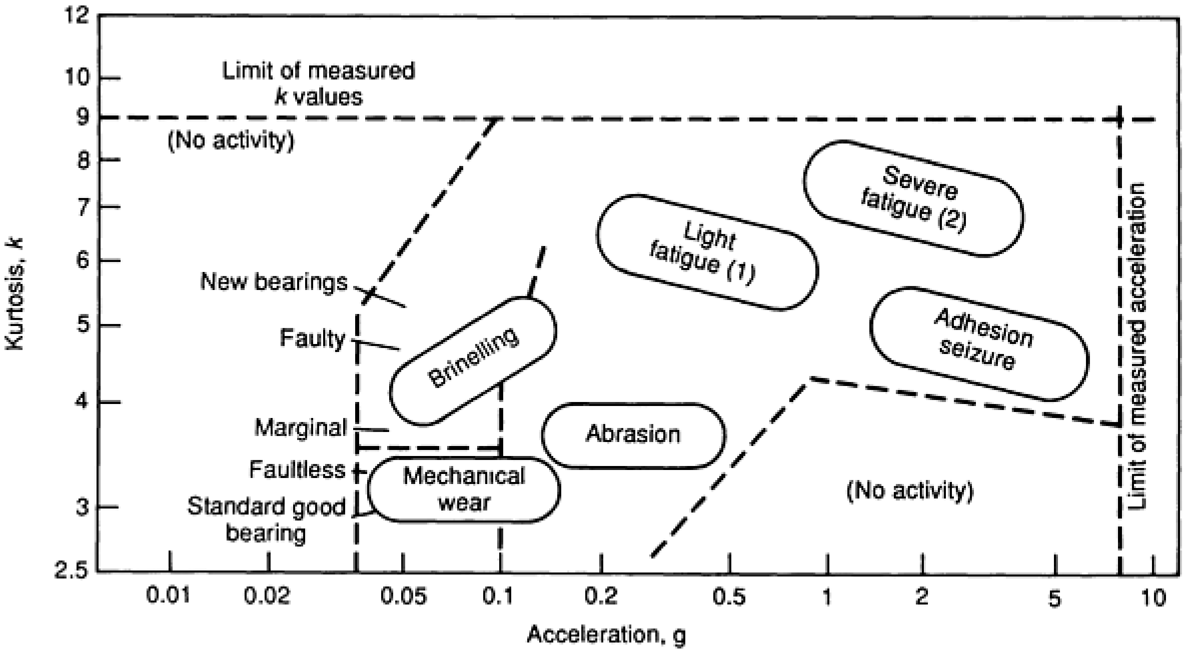

Fig. 8 Damage classification for roller bearings

Figure 9 shows the difference between dry and lubricated bearings using this approach. The accelerometer is placed on the bearing housing and the data is then filtered into five frequency bands on the graph.

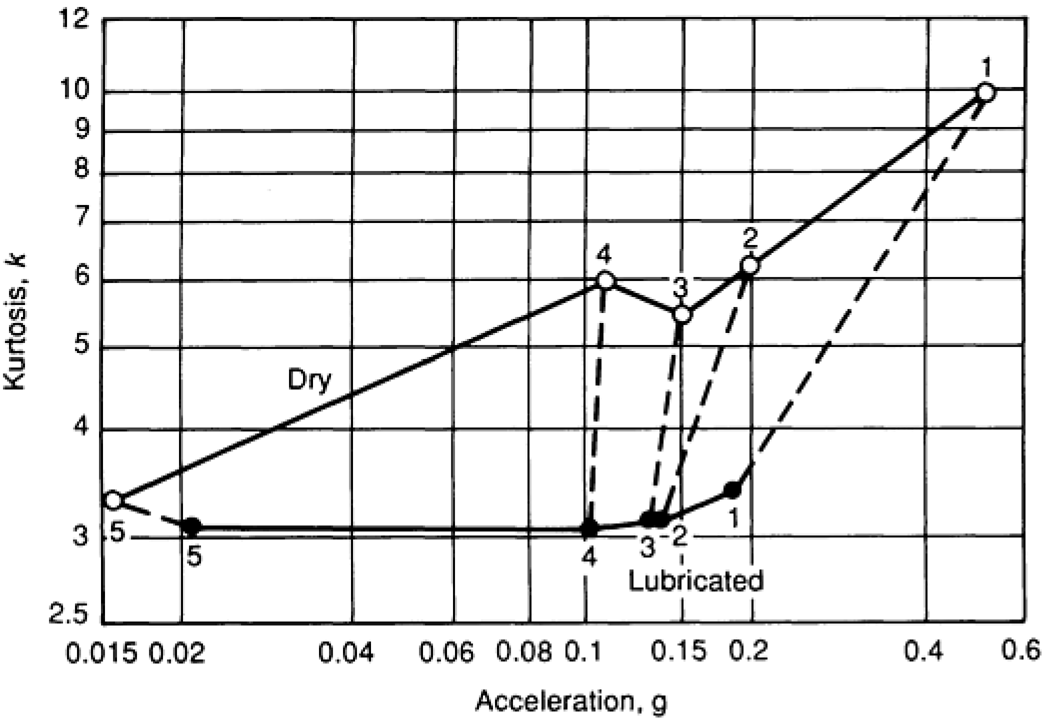

Fig. 9 Difference between dry and lubricating bearing. Points labeled 1 indicate frequency range from 2.5 to 5 kHz; points 2, 5 to 10 kHz; points 3, 10 to 20 kHz; points 4, 20 to 40 kHz; points 5, 40 to 80 kHz

Figure 10 shows the effect of adding silicon powder to the bearing lubrication in order to simulate abrasive damage. The particles used were size #230 SiC, applied in 0.2 mg doses over a period of 8 min.

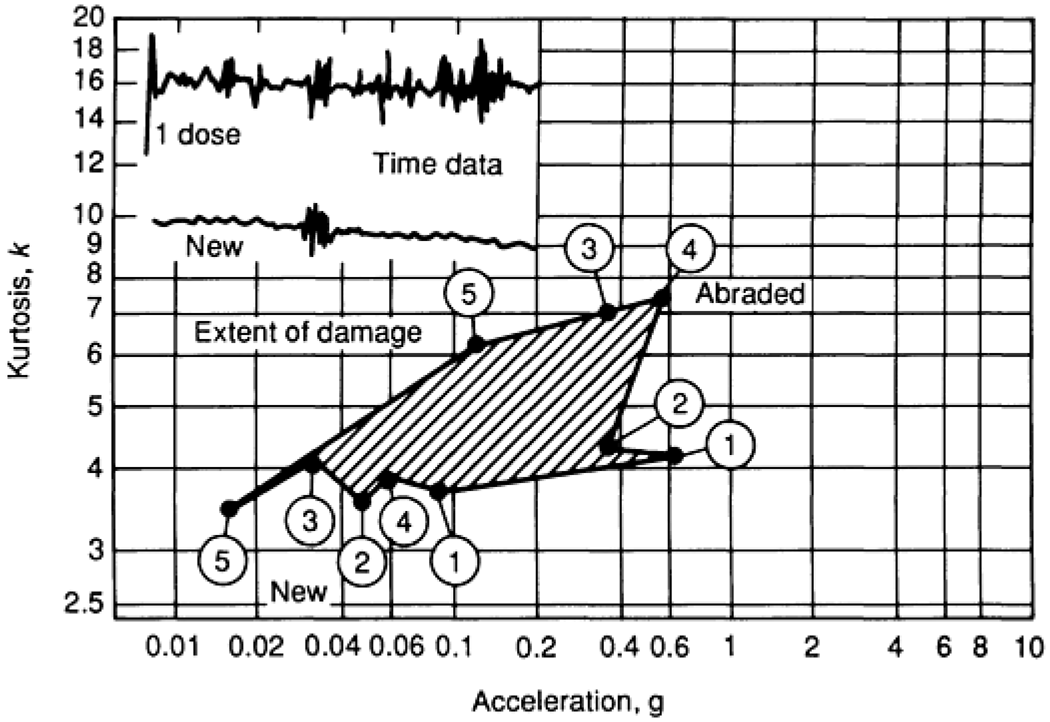

Fig. 10 Effect of adding abrasive powder

Relationship between Friction and Vibration

As mentioned previously, the amount of contact between any two surfaces, in the process of cold welding of the asperities, is a function of the load. In the case of two flat plates, Bowden and Tabor (Ref 13) generated the data shown in Table 1.

Table 1 Amount of contact between two flat plates

Load		True area of contact		Percentage of apparent area of contact[(a)]
N	**kgf**	**cm^2**	**10^{-5} in.^{2}**	
19.6	2	0.0002	3.1	0.0010
49	5	0.0005	7.8	0.0025
980	100	0.01	155	0.05
4900	500	0.05	775	0.25

(a) Nominal contact area, 20 cm^2 (3 in.^{2})

The general relationship between load and contact area can be expressed as:

$$A = \frac{F}{H} \quad \textbf{(Eq 4)}$$

where A is the true area of contact (cm^2), F is the applied load (N), and H is the indentation hardness (N/cm^2). The volume of material worn away when one of the plates slides over the other is proportional to the true area of contact, the total distance of sliding, and the nature of the materials.

$$V = kAl = \frac{kFl}{H} \quad \textbf{(Eq 5)}$$

where V is the volume of material removed (cm^3), l is the total distance traveled (cm), and k is the wear coefficient.

It has been found, in practice, that the wear coefficient, k, remains constant until the pressure between the plates exceeds a value greater than one-third of the hardness, H. Hence, the wear rate is reasonably linear. At pressures in excess of this, k begins to increase, and the wear rate rises rapidly and nonlinearly.

It is suggested that running parts, which are in motion relative to each other, need to be carried out with relatively light loads, until an indication of constant wear rate shows that the surfaces have settled in to each other. This happens when the asperities have been ground down and the effective pressure falls, allowing higher pressures to be applied. A typical value for k would be 26×10^4.

This "running in" effect illustrated in Fig. 11, which shows the results for a new bearing, just out of the box, and a repeat set of results after 60 minutes running. Although the vibration level does not give any significantly information, the Kurtosis values indicate that after 1 h, the results are closer to 3.0. This indicates a reduction in peakness in the data, that is, the asperity distribution is closer to Gaussian, after the honing period.

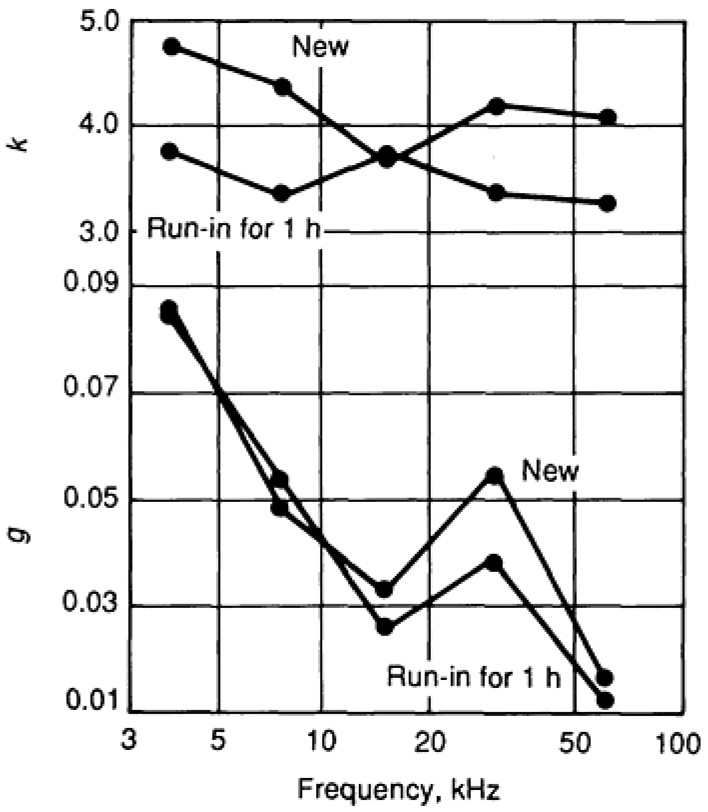

Fig. 11 Detecting the progress of "running in"

The interaction of surface asperities during sliding causes complex vibration patterns in both the normal and tangential directions. It has been suggested (Ref 14) that the asperities act as a system of microsprings, with appropriate stiffnesses in two directions. These normal and tangential contact springs are, of course, nonlinear with loading, because the geometry of the peaks changes, and more of them come into contact. For dry friction conditions, the asperities can be modeled as a random distribution of microaxially loaded bars that are set in free vibration by the sliding motion between the plates.

Calculations based on the above theory and experimental data indicate that the frequency of free vibration for metallic pairs experiencing asymmetrical deformation of asperities was found to be approximately in the range from 500 to 3000 Hz. The higher the relative velocity between the two surfaces, the more prominent is the normal component of impulses, because of collisions between the asperities, and the higher the amplitude of contact vibrations.

Lubricant Analysis

F.E. Lockwood, Pennzoil Products Company; R. Dalley, Predict Technologies

Introduction

LUBRICANT ANALYSIS PROGRAMS for predictive maintenance are now routinely practiced by a number of industries, including railway, aircraft, automotive and truck, chemical, refinery, and various others (Ref 1 2, 3, 4, 5, 6, 7, 8, 9, 10, 11). The physical appearance, viscosity, metals content, and other properties of oils sampled periodically from operating equipment are interpreted to provide an early warning of impending failure or to signal the need for oil changes and routine maintenance. Best known of such programs are the spectrometric oil analysis program (SOAP) and related programs practiced by the U.S. military services (Ref 12). Similar programs have also been developed for commercial aircraft, commercial truck and auto fleets, and industrial equipment such as compressors, gearboxes, and pumps. Continuous on-line oil monitoring may one day be standard practice.

Oil/wear particle analysis also is often a valuable failure analysis tool, although less has been published on this subject (Ref 13, 14). Failure analysis generally is practiced by mechanical engineers who primarily examine hardware. However, in the area of automotive lubricants, extensive use of oil/wear particle analysis is made in "post-mortem" failure investigations. This expertise is similarly useful in many other areas.

These two subjects, covering the details and references of applications of oil/wear particle analysis, are the focus of this article. The important oil analysis methods will be reviewed, and appropriate test programs for predictive maintenance and a methodology for failure analysis will be discussed.

Acknowledgements

Oil analysis cases and a number of helpful comments were provided by C.M. Comer, J.W. Fu, T.E. Rushing, and J. Torres of Pennzoil Products Company. Extensive information and figures were extracted from the *Wear Particle Atlas,* currently a publication of Predict Technologies.

Oil / Wear Particle Analysis Methods

Oil/wear particle analysis to determine lubricant condition includes both physical inspection and chemical examination of wear debris, contaminants, and reaction products from lubricants such as engine oils, hydraulic fluids, cutting fluids, greases, and synovial fluids from humans and animals (Ref 15). Because wear is an inevitable and anticipated consequence of surface contact between interacting machine parts such as shafts, bearings, gears, and bushings even in properly lubricated systems, oil/wear particle analysis can potentially be applied to all lubricated equipment. Equipment life expectancies, safety factors, performance ratings, and maintenance recommendations are predicated on normally occurring wear and lubricant service. Such factors as design complexity, unit size, intricacy of assembly configurations, and variations in operating conditions and environments can make maintenance or repair needs difficult to evaluate or detect without taking equipment out of service. Oil/wear particle analysis allows noninterruptive diagnostic determination of lubricant condition by determining the amount of wear and the lubricant reaction products. Based on this determination, equipment condition or impending failure can be predicted.

Sampling of Service Lubricants. Lubricant analysis begins with the sampling procedure, and the validity of a particular analysis depends on how well this procedure is carried out. The ideal sample is taken immediately downstream from the lubricated surfaces--for example, from a drain line off an individual bearing, prior to filtration, while the equipment is operating under usual conditions and temperatures. Care is taken to obtain a representative sample by discarding any volume that may have been stagnant in the drain line. The sample is captured in a clean nonmetallic container, sealed, and carefully labeled, including information about lubricant and equipment history. In practice, it is difficult to achieve this ideal. Samples often must be taken from sumps and recycle lines or large reservoirs. Deficiencies

in sampling points, however, are to some extent compensated for by consistent sampling at the same point under the same operating conditions (Ref 5).

Once in the laboratory, all samples should be brought to a uniform temperature and stirred condition before testing. This is particularly important when studying lubricant additive and wear metals, which may stratify in the lubricant under some conditions.

Sampling frequency is another key concern. This depends on the type of equipment, service conditions, and critical nature of service. Equipment maintenance records should suggest a proper sampling frequency. Otherwise, it is a good idea to sample frequently (for example, weekly) until a track record is built; then, if desirable, the rate of sampling can be lessened. Once a possible problem is detected, the sampling frequency must be increased until a positive determination is made on equipment condition and the action to be taken.

As general guidelines, aircraft should be inspected after every flight, while large industrial equipment with good filtration systems may require only monthly inspection. One rule of thumb is 25 to 40 h sampling frequency for gas turbines and 100 to 500 h for diesel engines. Recommended inspection guidelines for checking the condition of lubricants used in large industrial equipment are given in Table 1.

Table 1 Recommended lubricant inspection intervals for selected engines, drive systems, and power generating units

System	Recommended operating intervals between inspections, h
Aircraft gas turbine	50
Airborne hydraulic system	50
Aircraft derivative gas turbines	50
Diesel engine	200
Heavy transmission/gears	200
Surface hydraulic system	200
Heavy-duty gas turbine	200-500
Steam turbine	250-500
Large-bore reciprocating engine	250-500

Source: Ref 6

For each lubricant parameter that is measured, a control record is built that after a period of time will reveal normal operating ranges for a given type of equipment/lubricant. For parameters such as viscosity, direct comparison with lubricant and equipment manufacturer specifications also provides information on the acceptable operating range. In setting up a sampling and analysis program, it should be kept in mind that unless parameter operating guidelines are known beforehand, the program must provide enough information to set statistical guidelines for acceptable versus abnormal parameter limits.

Physical Inspection. A simple physical inspection, particularly in the case of failure analysis, can speed diagnosis of poor equipment operation and wear. Typical lubricant indicators that are often observed are listed in Table 2.

Table 2 Diagnostic guidelines for detecting and rectifying service lubricant deterioration

Lubricant appearance	Instrument verification of lubricant deterioration		Corrective action
	Test objective	**Detection method**	
Visibly thin or less viscous than fresh lubricant	Check for fuel dilution	Gas chromatography	Replace or vacuum strip lubricant contaminated with fuel
Visibly thick or more viscous than fresh lubricant; oxidized odor is detected and lubricant color is much darker than fresh lubricant (severe oxidation is evidence of excessive drain periods, abnormally hot running conditions, or exposure to abnormal types and levels of preoxidation)	Confirm lubricant oxidation level	Infrared spectroscopy	Replace lubricant, eliminate factors that accelerate oxidation
Milky lubricant (typically indicates formation of water emulsion)	Confirm presence of water	Infrared spectroscopy, Karl Fischer titration, hot-plate sputter test	Replace or vacuum strip lubricant, eliminate source of water if possible
Unusual precipitates or gel structures present in lubricant (due to contamination or presence of other lubricants)	Identify contaminants after filtration	Infrared spectroscopy	Replace lubricant, identify and eliminate source of contamination, evaluate and change lubricant formulation if necessary

Physical Testing. The most common physical tests run in conjunction with spectrometric and wear metal analysis programs are viscosity, total acid number (TAN), and determination of water content. ASTM methods are normally used for measuring viscosity (ASTM D 445) (Ref 16), TAN (ASTM D 974 or D 664) (Ref 17, 18), and low concentrations of water (Karl Fischer Titration) (ASTM D 1744) (Ref 19). The presence of glycol coolants can also be detected via ASTM method D 2982-85 (Ref 20). In cases where water is present at levels above 0.05 vol%, infrared spectroscopy is usually used. Although control limits for deviation of each of these parameters need to be set depending on the type of lubricant and equipment, viscosity variations of ±20%, TAN of greater than 3 mg/g, and water (in oil-based lubricants) in excess of 100 to 500 ppm are normally cause for action or at least further investigation. The presence of coolant is always a cause for concern, because it implies that coolant is leaking into the lubricant.

Spectrometric Metals Analysis. In the late 1940s, the railroad industry began testing lubricants for wear metals. With the advent of practical emission spectrometers, the SOAP methods were developed for military aircraft and then extended to gasoline- and diesel-powered military vehicles. Spectrometric methods include atomic absorption (AA), atomic emission spectroscopy (AES), inductively coupled plasma emission (ICPE) (Ref 21, 22), and x-ray fluorescence (XRF) (Ref 23). Of these methods, AES and ICPE, which rely on the detection of light emitted by the elements, are the most popular because of cost, speed, and other factors.

Unless special research measures are taken (Ref 24, 25, 26), spectrometric metals analysis determines the concentration of soluble metals and metal particles up to 10 μm in size. Therefore, it follows mild (benign sliding) rubbing wear and the early stages of fatigue quite well, because in these wear modes the predominant distribution of wear particles is within the detectable (<10 μm) range. However, in abnormal wear situations, such as severe sliding, rolling fatigue, cutting and abrasive wear, and scuffing wear, particles are generally larger than 10 μm. In such situations, which are typically of greater interest, ferrography (wear particle analysis) and particle counting are useful and, in some respects, superior monitoring techniques (Ref 3). Ferrography operates in the most useful particle size range, determining relative concentrations of midsize (<1 to 250 μm) particles; particles larger than 100 μm can be determined by particle analyzers. Combinations of these techniques are claimed to be the most effective (Ref 2), but spectrometric analysis has been most popular because of its relatively low cost. A further advantage is that a number of contract laboratories offer this type of analysis with very rapid turn-around time. In the near future, the particle size range of spectrometry may indeed be extended, making it more competitive with ferrography (Ref 27).

Spectrometric metals analysis has been successfully used to monitor aircraft engines. One correlation of maintenance findings to spectrometric analysis found a 70% prediction rate of malfunctions (Ref 28). On the other hand, the cost effectiveness of the technique is questionable, because overhauls may sometimes be undertaken sooner than necessary.

The application of spectrometry to gasoline and diesel engines has been somewhat more difficult because of greater complexity of contamination sources from fuel dilution and blow-by products from combustion gases, and the greater range of engine operating parameters. Test programs invariably include other physical and chemical tests to determine

viscosity change, water and fuel dilution, coolant contamination, and chemical changes in the engine oil. In general, such programs have been applied more successfully to rail and commercial diesel fleets or stationary diesels (Ref 29) than to spark-ignition engines, and the cost is more easily justified. Diesel engine bearing failures in military ground equipment have been predicted (Ref 12). Both abnormal bearing wear and piston/liner scuffing have been detected in advance in locomotive diesels (Ref 1) (see the section "Applications of Ferrography" in this article).

Iron, copper, lead, chromium, and aluminum are the principal component metals analyzed. Tin, silver, nickel, molybdenum, titanium, and vanadium are usually of lesser significance but are sometimes present, generally as alloying elements or coatings. The presence of silicon or the combination of silicon, aluminum, and titanium is often sought as evidence of dirt contamination. Contaminants from engine coolants include boron, potassium, and sodium. Lubricant additive elements analyzed are zinc, calcium, sodium, copper, magnesium, chlorine, phosphorus, antimony, molybdenum, sulfur, and boron. Because some of these elements fit into more than one category (for example, copper may be a wear metal and a lubricant additive metal), comparison with the baseline unused lubricant is desirable. Comparison allows easy identification of wear trends as well as changes in additive concentration between the used and new lubricant.

Table 3 summarizes several guidelines for recognizing normal versus abnormal operation. It must be emphasized, however, that trends should be established for the particular equipment under study, because material composition, operating conditions, lubricant, sump size, and absence or presence of filtration all determine "normal" levels of metals.

Table 3 Selected lubricant indicators and range of sensitivities required for indicator detection

Indicator	Indicates	Investigative level
Elements		
Iron	Wear	100% increase or change of 10-20 ppm[a]
Copper	Wear	100% increase
	Additive	100-200 ppm typical[b]
Aluminum	Wear	100% increase
	Additive	As specified
	Dirt	>25 ppm[c]
Chromium	Wear	100% increase
Molybdenum	Wear	100% increase
	Additive	100-200 ppm[d]
Lead	Wear	100% increase
	Fuel	100% increase
Tin	Wear	100% increase
Silver	Wear	100% increase
Nickel	Wear	100% increase
Vanadium	Wear	100% increase
Titanium	Wear	100% increase
	Dirt	>25 ppm
Silicon	Dirt	>25 ppm
	Additive	As specified
Sodium	Coolant	>30 ppm
	Additive	1000 ppm[d]
Boron	Coolant	>30 ppm
	Additive	1000 ppm[d]
Magnesium	Additive	500-1500 ppm[d]
Calcium	Additive	500-2000 ppm[d]
Zinc	Additive	1000 ppm[d]
Phosphorus	Additive	1000 ppm[d]
Barium	Additive	As specified
Antimony	Additive	As specified
Potassium	Coolant	>30 ppm
Sulfur	Additive	5000 ppm[d]
Chlorine	Contaminant	>20 ppm
	Additive	<200 ppm
Nitrogen	Additive	500-1500 ppm
	Fuel oxidant	2× normal
Compounds		
Water	Contamination	>100-500 ppm
Physical properties		

Viscosity	Oxidation or fuel oil	Change of ±20%
Total acid number (TAN)	Oxidation	>3 mg/g
Testing procedures		
IR ferrography	Wear[(e)]	±20% change in absorbance
	Dirt[(e)]	Increase of 50-100% in D_L (large particles)
Particle size analysis	Wear	100% increase in particle count or increase in number of large particles

(a) Wear metals should be investigated for cause when a sharp (>100%) increase occurs from baseline or a change of 10-20 ppm or more occurs.

(b) Typical levels are given for passenger car motor oils. Additive levels departing ±30% from norm should be investigated.

(c) Change from additive baseline is considered.

(d) Typical values.

(e) See Table 4 in this article.

Infrared (IR) spectroscopy is widely used to determine water and coolant contamination of the lubricant, as well as to identify (Ref 30) and monitor the depletion of additives and the buildup of oxidation products. The availability of Fourier transform infrared spectroscopy (FTIR) allows the detection of small changes in the IR spectrum of the used lubricant. A differential spectrum can be obtained by subtracting the spectrum of the new lubricant from that of the used lubricant to clearly reveal the areas of change. Table 4 indicates the IR absorbance wave numbers typically monitored.

Table 4 Infrared spectroscopy of lubricants

Contaminant or lubricant component	Adsorption, cm^{-1}	Type of vibration	Interferences
Water	3300-3500, 1600	O−H stretch	Glycol, oxidants
Fuel	500-1000, 1600	C−H out of plane deformations of aromatics	Unsaturation in lubricants
Oxidized lubricant	1700-1750, 1100-1200	C=O stretch	Viscosity index improvers
	1630, 1270	N=O stretch (oxidized from blow-by)	Alkenes
Glycol coolant	1040, 3300-3500	C=O stretch	Oxidation
	1080, 3300-3500	C−O stretch	Antioxidant
ZDDP	950-1050	P−O−C asymmetric stretch	Aromatics
Sulfonate detergent	1100-1200	SO_3 asymmetric	Oxidation
Pour-point depressant (polymethacrylate)	1732		
		C=O stretch	Oxidation
Dispersant:		O O	
Succinimide	1707	‖ ‖	
Mannich base	1650	C−N−C	Oxidation
Viscosity index improver:			
Polymethacrylate	1732	 −O−R	
Styrene-isoprene	700	C=O	
		 −R	Oxidation, Fuel

Contaminants such as water and glycol can be picked up in infrared by detection of the -OH stretch for water and the -C-O stretch for glycol. Degradation due to oxidation is detected as the carbonyl, -C=O, stretch from the formation of organic acids and conjugated carbonyls. Lubricant oxidation will also result in the depletion of antioxidant additives in the lubricant, usually zinc dialkyldithiophosphate (ZDDP) or phenolic compounds. The ZDDP concentration can be monitored via the P-O-C stretch; however, the phenolic antioxidants are usually not present in great enough concentrations to be easily differentiated from other compoundsadsorbing at the same wavelength. Several other additives can usually be detected, including detergents, dispersants, and occasionally polymethacrylate pour-point depressants, depending on concentration.

Infrared equipment manufacturers are quite familiar with lubricant analysis and can provide assistance in setting up analysis methods. Some IR manufacturers have designed equipment with oil analysis especially in mind. In addition, lubricant analysis by infrared is widely available at contract laboratories.

Particle counting, which involves monitoring the number of particles of a given size range per fluid volume, has been used as a primary monitoring tool in combination with other analytical methods. Both particle counting and direct-reading ferrography detect the onset of severe wear as a rapid increase in the amount and size of particles. Particle counting detects all particles, whereas ferrography screens primarily for ferrous wear particles.

Typical reporting formats require that the number of particles per milliliter of fluid volume be broken down into the following particle size categories based on the method used (Ref 31):

Particle size, μm	
ISO method	**OSU method**
>5	>10
>10	>20
>15	>30
>25	>40
>50	. . .

Particle-detection equipment is either of the light-interruption type or the laser-scanning type. Problems with this method include the difficulty of obtaining consistent samples and incorrect counts caused by artifacts such as air bubbles. A more laborious, but acceptable, alternative to particle counting is collecting the particles onto a filter (sediment testing) and then counting and sizing them under a microscope (Ref 11, 31, 32).

Particle counting is widely used to monitor hydraulic systems, where wear particles larger than 10 μm (beyond normal spectrometric limits) are of primary interest (Ref 11). Many manufactures publish recommended particle-count levels (Ref 31). Particle counting is more suitable when fatigue mechanisms are a primary means of failure or when contaminant particles cause abrasion. Fatigue of subsurface origin occurs in full-fluid-film conditions, leading to larger initial debris distribution, which may proceed rapidly. This scenario, where λ(the ratio of oil film thickness to surface roughness) exceeds approximately 1, is amendable to monitoring by particle count or magnetic plug detection (Ref 33).

Magnetic plug/chip detection (MCD) is a variation of the filter/counting method of particle counting. A magnetic stub is introduced into the oil flow in a piece of machinery to continuously collect ferrous material. The debris typically is viewed microscopically. This collection method favors large debris and is therefore suitable for systems that run in the full-fluid-film condition (for example, many hydraulic systems).

Ferrography. First adopted by the U.S. military, ferrography is now also used by heavy-equipment manufacturers, oil companies (Ref 5, 34), and other industries for wear particle analysis and predictive maintenance. The technology, developed by Westcott and Seifert (Ref 35, 36, 37) in the early 1970s, is used either as the primary analytical method or in conjunction with spectrometric analysis (Ref 2) and has been shown to give earlier prediction (Ref 5) and greater diagnostic information than spectrometric analysis alone. However, ferrography is comparatively expensive--on the order of $25 per routine sample if performed in house versus less than $10 per sample for spectrometric analysis (1990 prices). It is not particularly useful when applied to equipment where the samples must be taken from extremely large sumps (large steam and power generation systems, for example).

Ferrography is unique in that it allows potential determination of the amount and type of wear as well as the source of wear. Ongoing advances in foregoing instrumentation have enabled the broader study and classification of wear particles produced by many different metals and substances, both magnetic and nonmagnetic.

A ferrographic analysis of wear particles begins with the magnetic separation of machine wear debris from the lubricating or hydraulic media in which it is suspended. To establish accurate baselines for oil condition, regular samples are taken from carefully selected locations with the machine system, preferably during normal operation, as described in the discussion of sampling earlier in this article. In ferrographic examination, two types of ferrographs may be used. The direct-reading (DR) ferrograph uses optical density to quantitatively measure the concentration of wear particles in a

lubricating oil or hydraulic fluid. The particles are subjected to a powerful magnetic-gradient field and are separated in descending order of size (Fig. 1). Particles 5 μm and larger are confined to the entry end of the deposition field. The particle sizes become progressively smaller along the deposition path. Light attenuation at two locations along the path--at the entry deposit, D_L (large particles), and a point several millimeters farther down the tube, D_S (smaller particles)--is used to quantify the relative concentration of "direct large" (D_L) to "direct small" (D_S) particles. Values of wear particle concentration (WPC) and the percent of large particles (PLP) are thereby derived, establishing machine wear baselines and trends in wear condition.

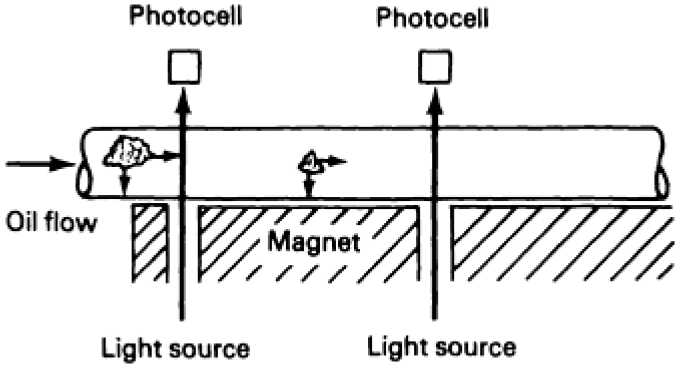

Fig. 1 Diagram of DR ferrograph deposit areas

Machines starting service go through a wearing-in process, during which the quantity of large particles quickly increases and then settles to an equilibrium concentration (Ref 38) during normal running conditions. A key concept of ferrography is that machines wearing in an abnormal mode will produce unusually large amounts of particles and a particle distribution with proportionally more large particles; that is, both WPC and PLP will show a significant increase above the baseline established after wearing-in (Fig. 2). The different regimes of wear, from mild to severe, a characterized by different size particles, the most severe being associated with particles larger than 1 mm (Ref 39).

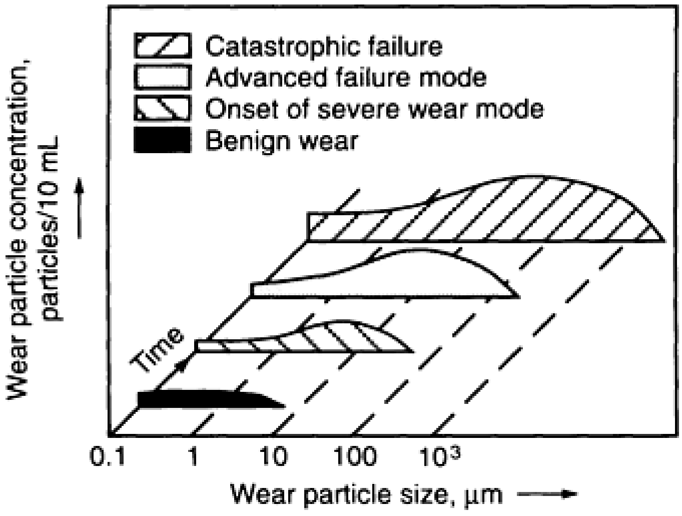

Fig. 2 Typical progression of severe wear

When subsequent DR ferrographs indicate an abnormal trend in wear, analytical ferrographic techniques can be utilized to study the wear pattern to specifically identify the nature of potential machine problems. In analytical ferrography, ferrograms (slides upon which wear particles have been deposited) are prepared and examined under a bichromatic microscope for measurement and identification.

Preparation of the sample entails (1) dilution of used fluid (lubricant, hydraulic fluid, or aqueous solution) with a wash solution to improve particle precipitation and adhesion and (2) flow of the prepared sample down and inclined slide, passing across the magnetic field. Wear particles arrange themselves along the slide, with the largest particles deposited first (Fig. 3). Ferrous particles line up on strings that follow the magnetic-field lines of the instrument. Nonferrous particles and contaminants travel downfield in a random distribution pattern not orientated by the magnetic field. This long deposition pattern spreads the wear particles out, providing good resolution of large and small particles--an important factor in diagnosing wear problems.

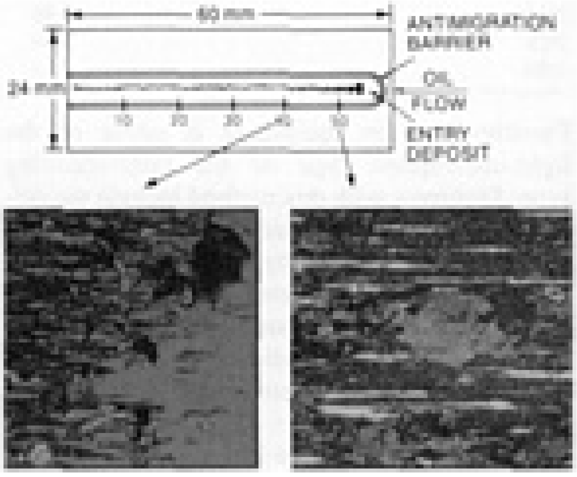

Fig. 3 Typical analytical ferrogram deposit patterns

The resulting ferrograph is examined using a three-power bichromatic microscope with cameras. Under magnification of 100×, 500×, and 800×, the microscope utilizes both transmitted and reflected light sources together with red, green, and polarizing filters to distinguish the size, composition, shape, and texture of both metallic and nonmetallic wear particles. The wear particles are classified to determine the type of wear and its source.

Types of Wear Particles

Ferrography is used to differentiate abnormal wear conditions from the normal rubbing wear that occurs during stable machine operation and from break-in wear that occurs during start-up of equipment. During break-in of a wear surface, the rougher surface irregularities are smoothed by grinding contact of the two surfaces so that the surfaces conform or "mate," effectively forming a smoother contact region. During this time, some large particles will break off the surfaces; however, in metals the majority of the particles formed result from exfoliation of the ductile, mechanically worked layer that is created at the metal surface. The slow process of forming and rubbing off of this shear mixed layer results in many small, normal rubbing-wear particles. When this layer is removed too rapidly (by abrasion, for example) or when other undesirable processes take place (fatigue, for example), new types or unusual amounts of wear particles are detected by ferrography.

The various types of wear particles are illustrated in Fig. 4. These particles are described in considerable detail in Ref 39, 40, and 41.

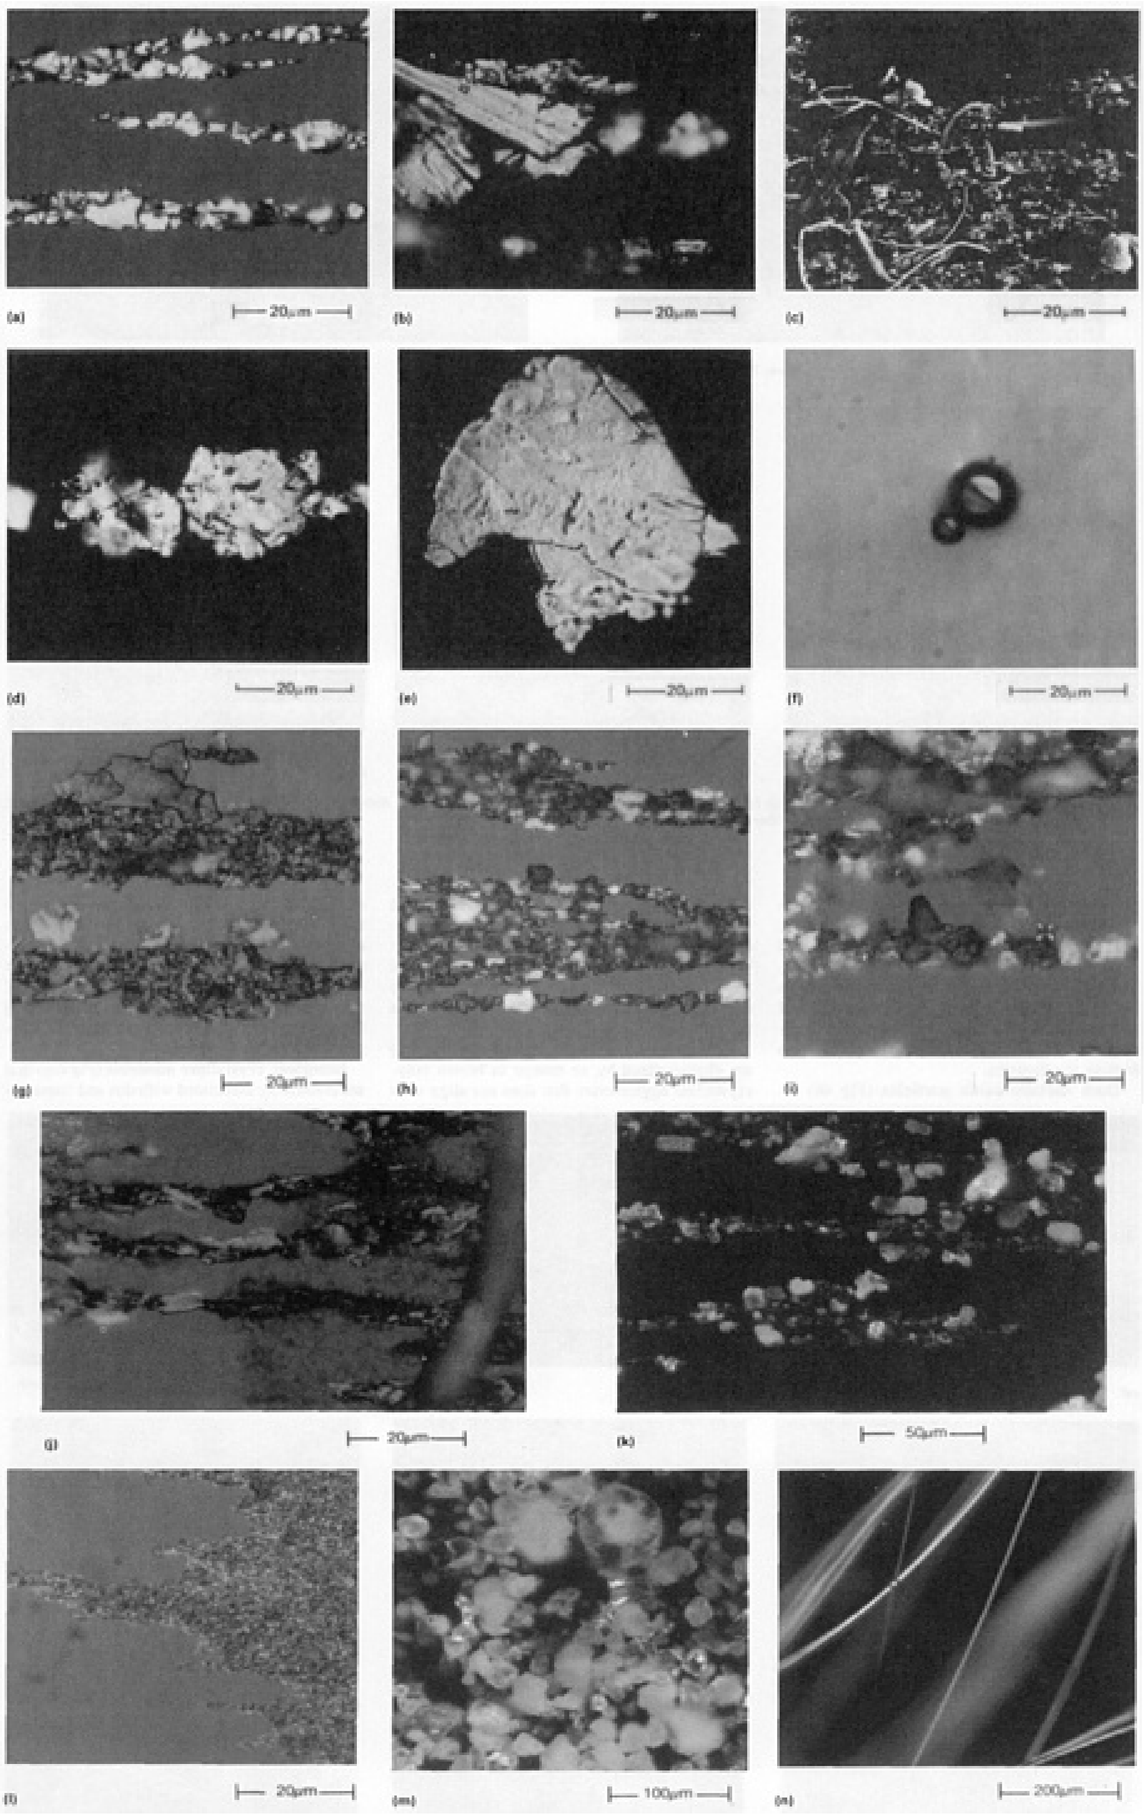

Fig. 4 Various types of wear particles. (a) Normal rubbing wear particles. (b) Sliding wear particles. (c) Cutting wear particles. (d) Fatigue particles. (e) Laminar particles. (f) Spheres. (g) Red oxide sliding wear particles. (h)

Dark metallo-oxide particles. (i) Black oxide particles. (a-i) 1000 ×. (j) Friction polymer. 1000×. (k) Red iron oxide particles. 400×. (l) Corrosive wear particles. 1000×. (m) Inorganic crystalline debris (road dust). 200×. (n) Glass fibers. 100×

Rubbing wear particles consist of flat platelets (Fig. 4a), generally 5 μm or smaller, although they may range up to 15 μm before their wear effect is considered to be severe. There should be little or no visible texturing of the surface, and the thickness should be 1 μm or less. A special case of normal rubbing wear is break-in wear, which is characterized by long, flat particles generated as machining marks are rubbed off by sliding surfaces. Abrasive contaminants can also dramatically increase the amount of rubbing wear, occasionally to the point of causing failure.

Sliding wear particles (Fig. 4b) are identified by parallel striations on their surfaces. They are generally larger than 15 μm, with the length-to-thickness ratio falling between 5 and 30. Severe sliding wear particles sometimes show evidence of temper colors, which may change the appearance of the particle after heat treatment.

Cutting wear particles (Fig. 4c) may resemble wire, drill turnings, whittling chips, or gouged-out curls. They may be caused by penetration of a soft surface by a hard, sharp edge, perhaps resulting from fracture of another component, or by cutting by abrasive particles embedded in an opposing soft surface.

Fatigue spalls and chunks (Fig. 4d) are removed from the metal surface as a pit or crack opens up. They are generally larger than 5 μm, with a length-to-thickness ratio of less than 5. There is generally some surface texture, and particles appear rough and shaped like chunks of coal, rather than flat. Spalls are similar in appearance to chunks, but are thinner. Small spalls are distinguished from normal rubbing wear by slightly greater thickness and surface texture. It is often necessary to examine very small particles at magnification of 800× to clarify these characteristics.

Laminar Particles. When a particle of any severe wear type passes between the surfaces of rolling elements, the effect is similar to that of a rolling pin on pie dough. The particle is flattened out, the edges may split, and there are often holes in the center. Particles such as this are called laminar particles (Fig. 4e). The length-to-thickness ratio is generally greater than 30. Although laminar particles can be very small, in a practical sense only the larger particles will be rolled out. Laminar particles larger than 15 to 20 μm are indicative of the formation of other severe wear particles. The presence of laminar particles in addition to spheres is indicative of rolling-bearing fatigue microcracks.

Spheres (Fig. 4f) are caused by wear, fatigue, or contamination. Their formation as a wear phenomenon is generally associated with rolling elements. Spheres formed by wear mechanisms are generally less than 5 μm in diameter, with very smooth surfaces. Such spheres are often a precursor of fatigue spalling. If the diameter exceeds 5 μm, or if the surfaces appear rough or oxidized, the spheres were probably caused by cavitation or contamination. Source of contamination include grinding and welding. Spheres in this size range can also be formed during lubricant oxidation, but can be distinguished by identifying their chemical composition, which will typically involve metallic lubricant additives.

Red oxide sliding wear particles (Fig. 4g) resemble severe sliding wear particles, except that they are usually gray in color and, when viewed in white transmitted light only, appear translucent and reddish brown. They are formed in conditions of inadequate lubrication and are, in effect, severe sliding wear particles that have oxidized, the oxide being Fe_2O_3. Particles of this type that are thick and rounded (with a thickness ratio similar to chunks) may originate from fretting mechanisms.

Dark metallo-oxide particles (Fig. 4h) resemble red oxide sliding wear particles, except that they contain a core of free metal and thus are not translucent. They also often show flecks of free metal on their surfaces. These particles are caused by heat and lubricant starvation, and indicate more severe wear. Large, partially oxidized particles indicate catastrophic surface failure.

Black oxide particles (Fig. 4i) are dark gray to black in color and resemble pebbles in shape. The oxide in this case is Fe_3O_4. Such particles result from a more severe condition than red oxide particles, in that a proportionally greater amount of iron is consumed in the oxidation process because of inadequate lubrication.

Friction polymer (Fig. 4j) is a material that forms when a lubricant is under stress; the resulting polymeric material is insoluble in the solvents used in ferrography. Depending on the wear mechanisms within the equipment, there may or may not be metal particles trapped within the polymer.

Red iron oxide (Fe_2O_3) particles (Fig. 4k) are characterized by an orange to brown polycrystalline agglomerate that does not align with the magnetic field on the ferrogram. They typically result from the presence of water in the oil. Their color may best be evaluated under reflected polarized light. Particles that change from yellowish orange to a more reddish brown after heat treatment are hydrated iron oxide and probably originate from rust. Particles that are reddish brown before heat treating may be rust that has been exposed to a drying mechanism such as heat, or they may originate from fretting or other corrosion/oxidation mechanisms.

Corrosive wear particles (Fig. 4l) result from attack on the surfaces of a machine and its wear particles by acids and other corrosive agents. They are submicron-size particles of free metal, oxides, and other metal compounds and are so small that they generally do not form a deposit along the ferrogram. However, in the eddy currents at the exit from the ferrogram, and under the influence of the magnetic flux at the end of the magnetic field, a deposit of this material will form. The size of this deposit can warm of chemical attack on the equipment.

Inorganic crystalline minerals (Fig. 4m) that are commonly associated with dirt and construction materials will depolarize light that has passed through a polarizer. This phenomenon is called birefringence. Materials that are birefringent usually show some degree of internal order, or crystallinity. The birefringence of inorganic materials usually is not influenced by heating to the temperatures used for analyzing a ferrogram. Some minerals are not birefringent and thus must be classified under the "Other particles" category below.

Organic crystalline materials that are birefringent include certain plastics, wood, Teflon, insect parts, and cotton. These materials will generally char or lose birefringence upon heating to 345 °C (650 °F).

Other particles that may appear in ferrogram as contamination include glass, amorphous blobs, paper dust, paint, varnish, glue, and so on. Other particles that may appear as part of a lubricated system that do not fall into any of the specific classification given here include molybdenum disulfide, graphite, and seal materials.

Fibers (Fig. 4n) include any particles that are fibrous, even if they fit into categories such as organic crystalline. Typical fibers include hair, cotton (from rags), wood, glass, minerals (rock wool), nylon (from brushes, and cellulose (from filters).

Alloy Identification: Heat Treatment of Slides. For the purposes of alloy identification ferrography, direct chemical analysis by techniques such as AES or ESCA (electron spectroscopy for chemical analysis) can be used, but are rarely available. Heat treatment of the particles on the ferrogram slide is a quick, inexpensive method of identification. Heating the particles at 340 °C (640 °F) for 90 s yields oxide film thicknesses that are in the range of the wavelengths of visible light. Reflection of light off the metal surface underlying the oxide layer produces interference effects, resulting in coloring of the particles. Different classes of alloys exhibit predictable colors. Therefore, the prior heat history of a particle may sometimes be apparent as temper colors or variations in the color of the heat-treated surface. Table 5 provides a guide to alloy identification based on heat treatment at 340 °C (640 °F) for 90 s.

Table 5 Application of ferrography to identify ferrous and nonferrous alloy wear particles

Heat treated at 340 °C (640 °F) for 90 s

Wear particle		Identifying color
Material	**Composition or property**	
Low-alloy steels	<1% C	Turns blue under heat treatment; degree of color saturation varies, depending on residual oil on the particles and variations between alloys
Medium-alloy steels	Generally cast iron or case-hardened low-alloy steel with <3.5% C, without other alloying elements	Turns a straw color under heat treatment
High-alloy steels [a]	. . .	Under heat treatment, no significant change in color is observed. Weakly affected by the magnetic field of the ferrograph, and thus shows a more random distribution across the ferrogram than other ferrous alloys
Copper alloys	. . .	Show few variations under heat treatment. Brass generally shows no change from its characteristic yellow color, or a slight deepening of the color toward gold. Aluminum bronze may show a mottled appearance with varying intensities of yellow, white, and blue.

		Copper alloys are not affected by magnetic fields and will be randomly distributed on the ferrogram.
Aluminum	. . .	Alloys do not show color change under heat treatment. Aluminum can be confused with high-alloy steel; less dense than steel, particles will tend to appear farther down the ferrogram for a given size distribution than steel. Has a more whitish cast than does stainless steel. Other chemical tests can be performed.
Tin/lead alloys	. . .	Dull or grayish cast before heat treatment. Heating metals the alloy and facilitates oxidation of the entire particle, most often resulting in a whitish residue at the site of the original particle.
Other alloys	. . .	See table of tests for white nonferrous alloys in Ref 42.
Molybdenum disulfide	Commonly used as an EP additive in greases and may be found in other lubricants. Diamagnetic, which causes MoS_2 particles to collect near the nonwetting barrier or, if large enough, to distribute evenly over the slide	Particles are bluish gray, are unaffected by heat treatment, and have a layered, somewhat crystalline, appearance.

(a) Includes all stainless steels

Applications of Ferrography

This section examines specific concerns regarding wear particles and examples of the application of ferrography to various types of equipment.

Gear Boxes. Monitoring of gear boxes and detection of gear wear within motors (Ref 3) and other industrial equipment constitute a broad area of ferrography application. In gear wear, combined rolling and sliding occur, leading to variations in characteristic particles, depending on relative rolling and sliding velocities. A gear pair fails only when teeth break, preventing transmission of power, or when noise and vibration become unacceptable. Therefore, ferrographic observation of gear wear must be placed in the context of the entire affected operating system when deciding upon the need for immediate maintenance.

The most common problem observed is fatigue at the pitch line (Fig. 5a and b), where rolling occurs. Pits form in the pitch-line area either initially (arrested pitting) or continuously, resulting in eventual tooth damage. The formation of a large number of pits may result in a step at the pitch line. Another type of fatigue process is the exfoliation of the skin on hardened gears, which occurs on nitrided, carburized, and other hardened materials.

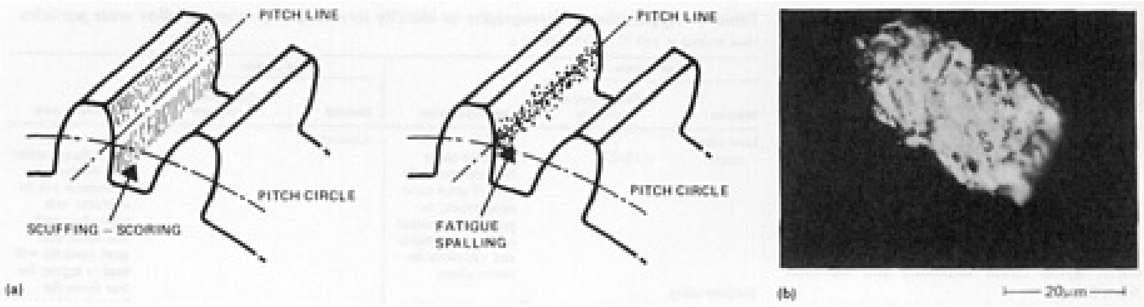

Fig. 5 (a) Gear failure. (b) Chunky fatigue particle from gear pitch line. 1000×

In the sliding portion of the gear (Fig. 5a), scuffing or scoring may occur, resulting in sliding wear particles with striated surfaces. These conditions, detectable by ferrography, indicate the need for correction, often by use of a more viscous lubricant or one with a more active extreme-pressure (EP) additive in order to prevent severe scuffing and total failure. Other modes of gear wear include overload wear and abrasion by contaminants.

To handle the problem of elastohydrodynamic (EHD) lubrication effects, the designer needs to consider three regimes of lubrication (Ref 43):

- *Regime I:* no appreciable EHD oil film (boundary)

- *Regime II:* partial EHD oil film (mixed)
- *Regime III:* full EHD oil film (full film)

Figure 6 shows idealized gear system operating regimes as a function of speed and load. To the left of the overload wear curve, where heavy loads are carried at low speed, wear occurs because the EHD oil film becomes discontinuous. At higher speeds, the allowable load increases because the EHD oil film is partial (due to partial metal-to-metal contact) or full (thick enough to prevent metal-to-metal contact). Above the fatigue spalling line, wear is governed by the strength of the gear material. It is not that the lubricant is inadequate, but rather that the load is transmitted through the oil film. If the load is excessive, fatigue particles from the gear pitch line will be generated. If the load is greater still, a tooth may break. Choice of lubricant has little effect in this case, because this event is governed primarily by material selection and load. If speed is increased, the wear regime will be to the right of the scoring or scuffing line.

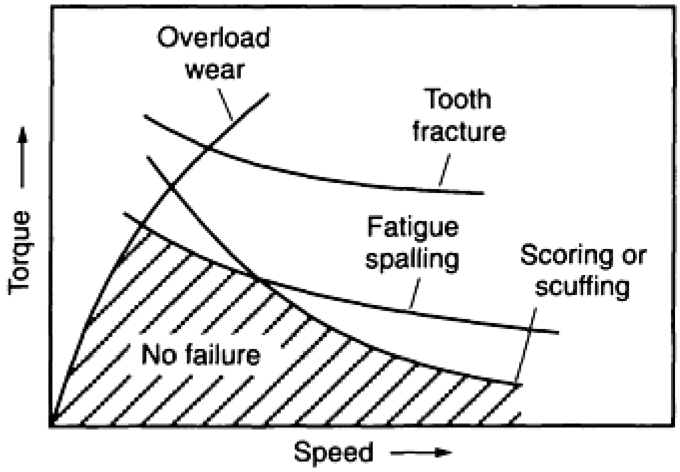

Fig. 6 Gear system operating regimes

Fatigue particles from a gear pitch line have much in common with rolling-element bearing fatigue particles. They generally have a smooth surface and are often irregularly shaped. A high ratio of large particle to small particles is found by direct-reading ferrography, which is again similar to rolling-element bearing fatigue (Fig. 4d). Depending on the gear design, the particles may have a major dimension-to-thickness ratio between 4:1 and 10:1. Chunkier particles (Fig. 5b) result from tensile stresses on the gear surface, causing the fatigue cracks to propagate deeper into the gear tooth prior to spalling.

Scuffing of gears is caused by a load and/or speed that is too high. Excessive heat generation breaks down the lubricant film and causes adhesion of the mating gear teeth. Roughening of the wear surfaces ensues, with subsequent increase in wear rate. The regions of the gear teeth affected are between the pitch line and both the gear root and tip.

Once initiated, scuffing usually affects each tooth on a gear, resulting in a large volume of wear debris. Since there is a large variation in both sliding and rolling velocities at the wear contacts, corresponding variations in the characteristic of the particles are generated. The ratio of large to small particles in a scuffing situation is low. All the particles tend to have a rough surface and a jagged circumference. Even the small particles may be distinguished from rubbing wear by these characteristics. Some of the large particles have striations on their surfaces, indicating a sliding contact. Because of the thermal nature of scuffing, quantities of oxide are usually present, and some of the particles may show evidence of partial oxidation--that is, tan or blue temper colors. The degree of oxidation depends on the lubricant and the severity of scuffing.

The ratio of large to small particles depends on how far the surface stress limit is exceeded. The higher the stress level, the higher the ratio becomes. If the stress level rises slowly, a significant increase in the quantity of rubbing wear prior to the development of any large severe wear particles may be noticeable.

Severe sliding wear particles are 15 μm in size or larger. Some of these particles have surface striations as a result of sliding. They frequently have straight edges, and their major dimension-to-thickness ratio is approximately 10:1. As the wear becomes more severe, the striations and straight edges on particles become more prominent and many large particles showing striation marks are present.

Diesel Engines. Ferrography for diesel engines has been used in conjunction with other test methods (usually spectrometric analysis) with superior results (Ref 44). As in other oil-lubricated equipment, wear is indicated by increasing amounts of particles and by changes in particle size distribution, composition, and morphology. The effects of engine operating conditions on the wear of cylinder liners, piston rings, and crankshaft main bearings have been successfully observed via ferrography (Ref 44).

For diesel engines, heat treatment of analytical ferrographs distinguishes between, for example, low-alloy steel (crankshafts) and cast iron (piston rings and cylinder liners), depending, of course, on the specific engine metallurgy. Although ferrous particles are primarily analyzed, other particles such as lead may be partially retained and have been used to follow main bearing wear (Ref 44).

Normal ferrograms from diesel engines generally show only small rubbing wear particles and very few large metal particles. A light deposit of corrosive wear particles at the ferrogram exit is typical. Diesels are exposed to acid conditions caused primarily by sulfur-containing fuels. In the United States this is becoming less of a problem, because the sulfur content of diesel fuel is being reduced by environmental regulation. Common wear problems in diesel are bore polishing, in which the cylinder wall is polished in spots to a mirror finish, and ring wear. Both of these problems are associated with piston deposits to some degree, depending on the engine. This wear mechanism results in an increase in wear debris that is detectable by both ferrography and spectrometry, since the number of small particles increases. Another problem--cylinder wall scuffing or scoring--tends to occur in engines with tight crownland clearances. This problem can also be detected by ferrography as the presence of an increased number of large particles with striations, typical in sliding wear. Similarly, ferrography has been used to detect scuffing in a diesel valve train system where sliding was taking place (Ref 45).

Aircraft Gas Turbine Engines. Aircraft and aircraft-derivative jet engines are subject to various failure mechanisms. Some of these failure modes proceed very rapidly, whereas others can be detected hundreds of operating hours before a shutdown condition is reached. Most failures of gas turbines occur in the gas path. Gas-path failures frequently, but not always, cause an increase in wear particle size and concentration in the oil system, probably due to the transmittal of imbalance forces to turbine bearings and other oil-wetted parts. The resulting bearing or gear wear is then detected by ferrographic observation.

Determining the exact source of a wear problem can be difficult in gas turbines because of the complexity of the oil-wetted path. Typically, several cavities, housing, or gears will be force lubricated through individual return lines connected to a tank from which the oil is pumped, then passed through a filter and heat exchanger, and the cycle is repeated. Magnetic chip detectors or magnetic plugs are often installed in the return lines from the various engine parts. These can help to pinpoint the source of generation in cases where particle metallurgy, as determined by heat-treating ferrograms, is similar for various engine parts. However, chip detectors will not give a warning until the wear situation is so severe that extremely large particles are being generated. By this time, the opportunity for predictive maintenance may be lost. Other analytical techniques, such as spectometric oil analysis or vibration analysis, may help to pinpoint the part(s) in distress; however, in most cases the engine will have to be inspected by borescope or, more likely, by disassembly. In this instance, the oil analysis must be confident that a problem exists.

Nevertheless, the colds of determining a failure before it is critical improve if ferrography and spectrometric analysis are combined as screening tools and backed up by analytical ferrography or microscopic examination of wear debris (Ref 3). Continued analysis of existing gas turbine monitoring programs and improvements in such programs are needed to ultimately determine their cost effectiveness.

Gasoline Engines. In general, ferrography seems to be used far less for gasoline engines than for diesels. However, Fiat has adopted ferrography for the development of new engine components and prototypes, thereby significantly reducing test time and avoiding catastrophic failures (Ref 9). During engine testing, the oil was monitored by ferrography and spectrometry every 20 h. Ring and liner wear was detected, as well as the effect of such test variables as blow-by. Ferrography was found to be far superior to spectrometry in this application.

Hydraulic Systems. Problems in hydraulic systems are most often caused by contamination (Ref 11) or fatigue wear. Because most of the contaminant and fatigue wear particles are larger than 10 μm, the analysis program should begin with a particle-monitoring test--either particle counting. DR ferrography, or sediment testing. In addition, most programs include viscosity, water, and spectrometric metals analysis.

The particularly deleterious nature of particles in the 10 to 40 μm size range has been pointed out by Leugner (Ref 32). Particles of this size are not detected spectrometrically, yet they often escape filtration and circulate with the lubricant, acting as abrasives. Upon determination that a system contaminant problem exists, improved filtration is often part of the solution (Ref 5, 32).

Ferrography has been used extensively by the Fluid Power Research Center to measure the quantity and to identify the type of wear debris in hydraulic system components as well as in complete systems. This work has resulted in an improved hydraulic pump contaminant sensitivity test.

Among other findings, the work demonstrated that for linear mechanisms more wear occurs for dust with a maximum particle size near the spool clearance dimension than for much coarser or much finer dust at the same concentration. This is attributed to the wedging action of critical-size particles that are close to the clearance dimensions. The Fluid Power Research Center also performed ferrographic analysis over substantial portions of the operating life for the following systems: (1) two complete vehicle hydraulic systems (agricultural tractors), (2) a vehicle hydraulic steering system, (3) a vehicle transmission lubrication system, and (4) an auxiliary hydraulic system on an agricultural tractor. Ferrogram readings as well as particle analysis data are presented in Ref 46.

Compressors. Gas compressors of the reciprocal, rotary, or centrifugal type are often candidates for lubricant monitoring programs in industrial plants. Depending on the type of compressor, cylinder wear, rolling-element bearing water, or gearbox wear may be detected by ferrographic analysis. Lubricant viscosity, contamination by water, and chemical composition should also be monitored in many cases, because deleterious effects caused by contact with the gas being compressed are not unusual.

Grease. In order to apply the techniques of ferrography to grease-lubricated bearings, a solvent system must be used that dissolves the grease sample to produce a fluid of suitable viscosity for ferrogram preparation. The ingredients used in grease formulations are diverse, including a wide variety of soaps or thickeners and solid particles such as molybdenum disulfide. However, a mixture of toluol/hexane--an aromatic; aliphatic, essentially nonpolar blend of solvents--has been found to be a good general solvent. Sampling greases is difficult. Typically, only the grease in the immediate vicinity of the wear contact is being worked and thus contains the wear particles to be observed. This grease can normally be sampled only by complete teardown of the bearing. Nevertheless, such analysis can be useful, particularly for failure analysis. Infrared spectroscopy and physical observation often also provide evidence as to the mechanism of grease deterioration.

Case Histories

In practice, equipment is often complex and different types of wear particles are found together.

Gearbox Wear. In a case where severe sliding and overload occurred because of lubricant deficiency in a process industry reduction gearbox, examination of the ferrogram at low magnification showed an obvious abnormal wear mode ongoing because of the many large metal particles present (Fig. 7a).

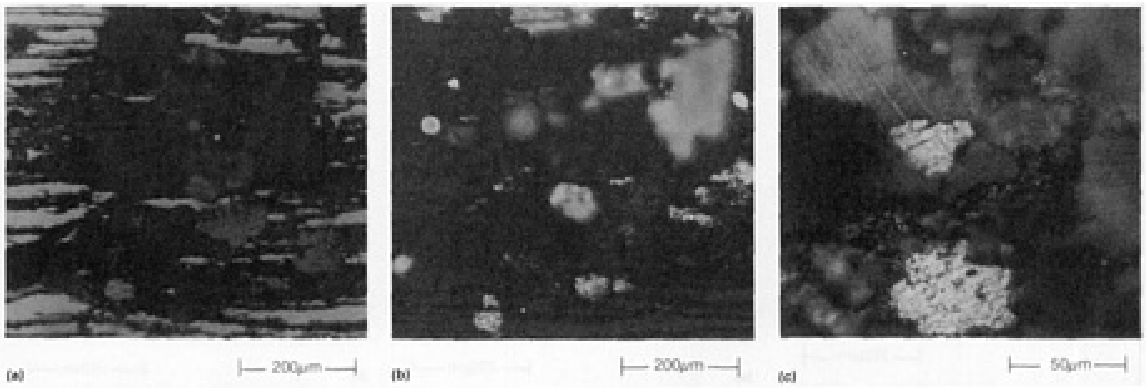

Fig. 7 Gearbox wear. (a) Wear particles resulting from gear overload. 100×. (b) Red oxide particles. Polarized reflected light. 100×. (c) Temper-colored particles. 400×

In this sample, however, may of the severe wear particles showed striation marks, indicating that sliding was involved during their generation. Also, the relatively huge size of some of these particles was indicative of a severe sliding regime. Present, although not as plentiful as the sliding wear particles, were large free metal platelets with smooth surfaces and irregular edges, characteristics typical of rolling-element bearing fatigue or gear-touch pitch-line fatigue.

Therefore, the wear particles appeared to be generated at the pitch as well as at the tips and roots of the gear teeth. Present to a lesser extent were large cutting wear particles and some copper alloy particles. Figure 7(b) shows the entry deposit in polarized reflected light, which emphasizes the presence of large, flat, red oxide agglomerates that may be described as scale; the significance of these particles is relation to the wear situation was not ascertained. Examination of the ferrogram at a magnification of 1000× shows that the free metal wear particles are virtually free of oxidation, such as temper coloring; it can be safely assumed that the abnormal wear was not due to speed-induced scuffing or scoring, as represented on the right side of Fig. 6.

Actual inspection of the same gearbox revealed that the gear teeth were heavily worn--especially at the tips, where the case had been worn away. This fact explains the presence of both steel and cast iron particles in this sample. In the manufacture of gears for industrial applications, a steel gear often is case hardened by heating in a carbon atmosphere so that carbon will diffuse into the outer layers of the gear. Subsequent quenching and tempering of the gear harden the outer case, but leave the steel core soft. This results in a hard, wear-resistant surface with a tough, shock-resistant core to prevent tooth breakage. Examination of a heat-treated ferrogram from such a gear shows the particles to range from blue to straw color, depending on their carbon content. In Fig. 7(c), both straw and blue temper-colored particles are present. The low-alloy steel particles (blue, shown as darker particles) are consistent with the finding that the case had worn away at the tips of the teeth, exposing softer steel. The steel particles show striation marks, indicating a sliding contact.

The problem was solved by using a gearbox oil with EP additive, which arrested the excessive wear. EP additives moved the overload wear curve in Fig. 6 to the left so that, for this case, an operating regime formerly, outside the no-failure envelope was now within it.

Water in the Oil in a Reduction Gearbox. Figure 8 shows the entry in polarized reflected light of a ferrogram prepared from an oil sample from a reduction gearbox used to drive an agitator in a pharmaceutical manufacturing plant. The agitator motor and gearbox were roof mounted, with the impeller driveshaft extending down from the ceiling to the mixing tank inside the plant. In this case, water had entered the gearbox, which was splash lubricated, causing an abnormally high wear rate. Many red oxides, characteristic of water attack, were present. Practically no free metal wear particles were found in this sample, probably the result of oxidative attack caused by the water during the two-week storage time prior to preparation of the ferrogram.

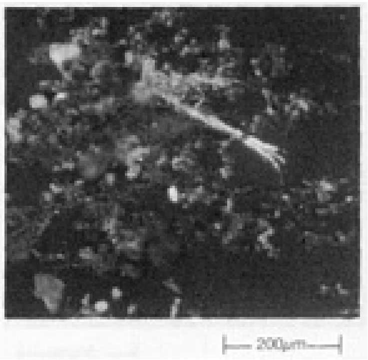

Fig. 8 Particles in oil from reduction gearbox. Red oxides are due to water in oil. 100×

The sample yielded DR ferrograph readings of D_L = 40.6 and D_S = 2.6, giving an unusually high ratio of large to small particles. This size distribution differs drastically from the nearly equal ratio of large to small particles found, for example, in the corrosive wear in a diesel engine. The water compromised the load-carrying capacity of the lubricant, causing a severe wear mode.

As previously discussed, water in oil, at least in concentrations above a few tenths of a percent, can be easily detected by various methods other than ferrography.

Abrasive Wear. Figure 9 is the entry view in which a baseline of wear was established by taking one sample from each of several machines. This ferrogram, from a single machine, shows heavy strings of ferrous wear particles, as well as many large nonmetallic crystalline particles. Compared with a baseline sample, this ferrogram deposit is extremely heavy. Closer examination of Fig. 9 shows that large cutting wear particles dominate the ferrogram. Because there are many nonmetallic crystalline particles, the assumption was made that the cutting wear was caused by abrasive contamination. It was recommended that the oil and oil filter be changed or that a filter bypass rig be used and that the machine be examined for possible means of ingression of contaminants. Another sample from the same machine was submitted a month later, and wear levels had returned to baseline.

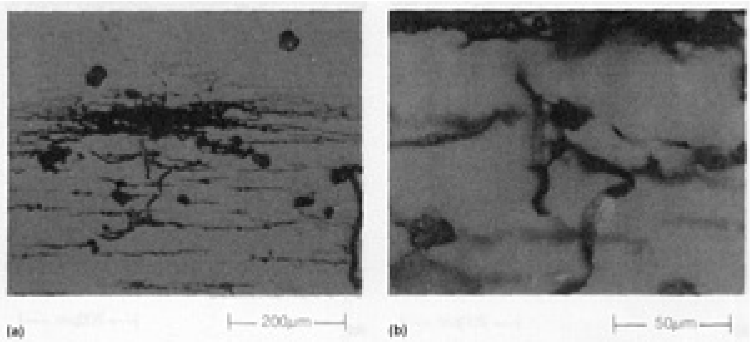

Fig. 9 (a) Entry view of a ferrogram showing a baseline of wear. 100×. (b) Cutting wear caused by abrasion. 400×

A different abrasive wear problem occurred in a refinery moist solvent pump (P-975). The first three samples (10/20/86, 11/15/86, and 11/13/86) from the bearing box of the pump gave DR results that indicated that normal wear conditions existed in the system (Fig. 10). Optical and scanning electron microscopy (SEM) examination of the particles showed dirt particles and a small amount of normal wear debris. At this point, the ferrographic analysis of this machine was no different from that of other unfiltered machines.

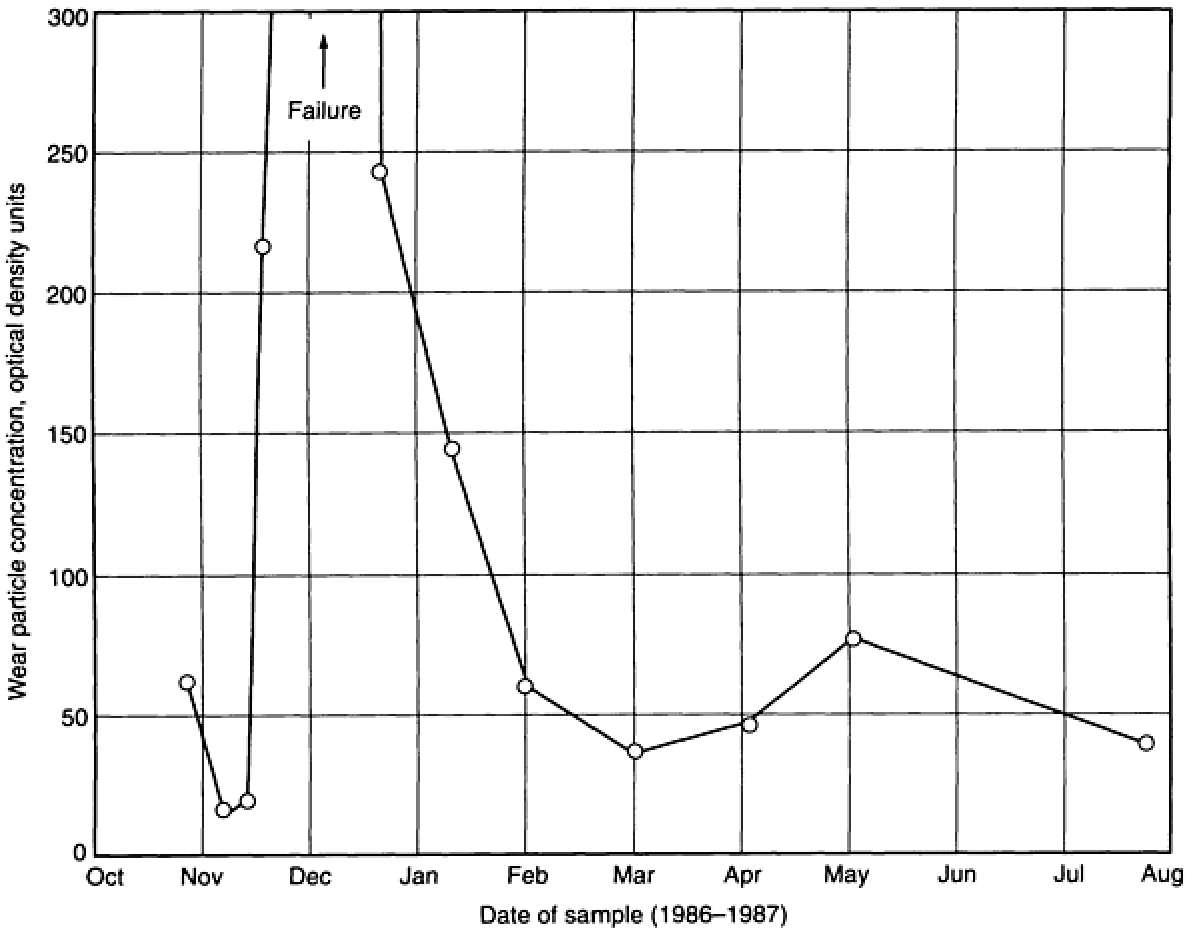

Fig. 10 Wear particle concentration changes in a P-975 moist solvent pump tested over an 11-month period

The fourth sample (11/18/86) gave a 10-fold increase in the large particles (D_L) and a 70-fold increase in severity index, from 105 to 7412. SEM analysis of the particles showed dirt particles and a substantial increase in the wear debris in the form of flakes. Energy-dispersive spectroscopy (EDX) analysis of the flakes indicated that they were steel and babbitt-bearing flakes. X-ray spectrometry of the same samples showed a significant increase in iron, from 35 to 78 ppm (Fig. 11). The combination of ferrography, x-ray spectrometry, and microscopic analysis clearly indicated greatly accelerated rubbing wear caused by dirt contamination. Nevertheless, no action was taken.

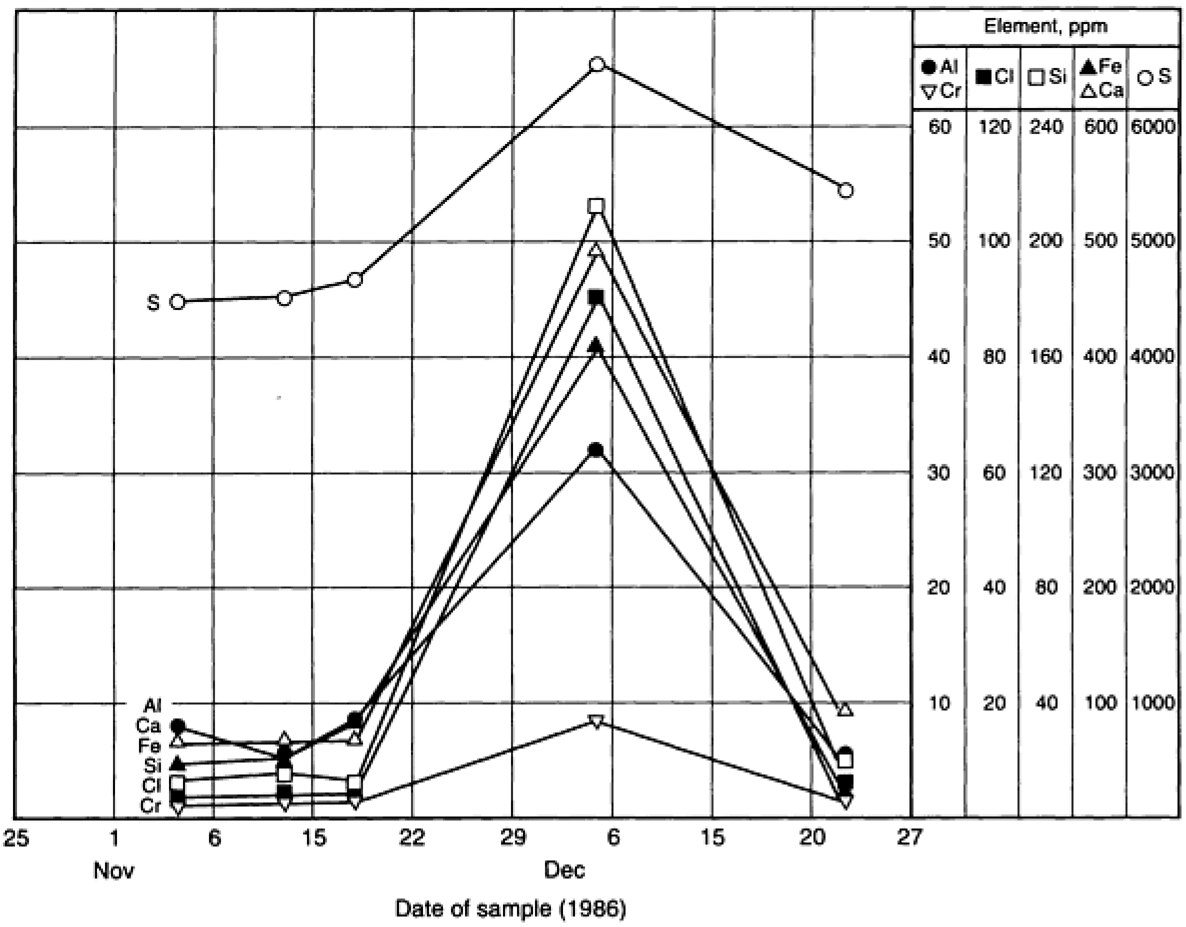

Fig. 11 Spectographic analysis of metals in lubricant samples from a P-975 moist solvent pump before and after failure

On December 5, 1986, a few hours after the fifth sample was drawn, the machine overheated and was shut down before catastrophic failure occurred. The severity index (SI) for this sample was more than 146,000. The 12/5/86 sample was composed of wear debris and lubricant thickened by prolonged heating caused by friction during the abnormal wear mode. The oil was so thick that 10× dilution was necessary before the individual particle could be observed under the microscope. When the equipment was disabled for repairs, maintenance personnel found severe wear on the ball bearings and damage to the race and cage. Subsequently, the damage was repaired, and the pump was cleaned and returned to service.

The 12/22/86 sample showed a substantial decrease in the WPC and SI. SEM analysis showed several strings of wear particles, which were identified as steel and leftover wear debris from the earlier failure. The strings of wear particles were probably break-in wear particles.

The 1/12/87 sample continued to show the break-in wear particles and further reduction in WPC. The February sample showed a return to normal baseline WPC and SI values.

Cast Iron Wear in a Diesel Engine. Figure 12(a) shows the entry deposit (400×) of a ferrogram prepared from a medium-speed marine diesel engine oil sample. The photograph was taken after heat treatment of the ferrogram to 330 °C (625 °F) to distinguish between steel and cast iron. Notice that the particles display the light temper color of cast iron where they do not appear black from oxide formation or from their tortuous shape. The fact that they were heavily oxidized and showed some spots of temper coloring even before heat treatment indicates a high-temperature wear mode, probably caused by inadequate lubrication. Also, the number and size of the particles (many may be classified as severe wear particles) were much greater than normal, implying an abnormal wear mode.

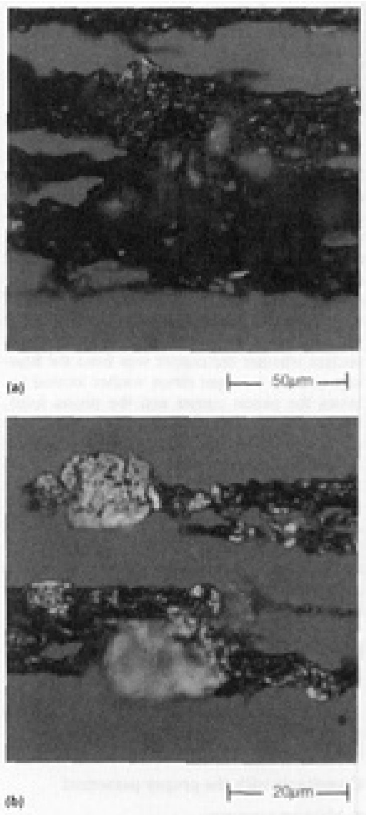

Fig. 12 Entry deposit of a ferrogram from a medium-speed marine diesel engine oil sample. 400 ×. (b) Oxidized cast iron particles with torn shapes. 1000×

Figure 12(b) shows two cast iron severe wear particles at a magnification of 1000×. Even the smaller particles are abnormal in that they are oxidized and have twisted, torn shapes with greater height than in usual for normal rubbing wear platelets. Some weeks after this sample was taken, one of the cylinders froze due to plugging of its oil line.

Corrosive Wear. As previously mentioned, sulfur-containing diesel fuel is corrosive. Alkaline chemical additives are put into diesel engine lubrication oil to neutralize fuel-derived acids as well as to neutralize organic acids, which can form as oil oxidation products. As acid is neutralized, the alkaline additive is consumed. When it is depleted, the engine is exposed to aggressive chemical attack. The result is severe wear, mostly to the piston rings and cylinder liners, although lead in bearings may also be attacked.

Analytically, corrosive wear is readily detected by a low total base number combined with a high wear metals concentration as reported by an emission spectrometer. Total base number (ASTM D 2896) is a measure of the neutralizing capacity of an oil and relates to the amount of alkaline additive in the oil. Corrosive wear can be effectively controlled if the total base number is not allowed to fall below a value of 1.

Corrosive wear is readily detected by ferrography (Fig. 4e), although other oil analysis techniques are also effective. Corrosive wear is indicated by the DR ferrograph by concentration readings that are much higher than the baseline, perhaps 100 times higher. The ratio of large to small particles may nevertheless be very close to 1 because of the absence of many large particles.

Nonferrous Metal Wear in a Marine Engine. An oil sample taken from a 12-cylinder General Motors series 645 engine used for marine propulsion showed a dramatic increase in wear particle concentration compared with a sample taken 2 weeks previously. The DR results were as follows:

Date	Large particles, D_L	Small particles, D_S
July 3, 1980	1.4	1.5
July 7, 1980	39.2	36.2

A ferrogram prepared from the second sample indicated that a piston/cylinder failure was imminent, based on the presence of many severe wear particles as well as many normal rubbing wear particles. These particles were predominantly cast iron, as determined by heat treatment of the ferrogram. Also of concern was the presence of many large, heat-affected copper alloy wear particles. Figure 13 shows one of these particles. At the time of the analysis, it was unclear whether the copper was from the bearings or from a copper thrust washer located between the piston carrier and the piston itself. Eventually, the ship entered a shipyard because of noise in the engine. Two cylinder heads were removed, and signs of excessive wear and scoring of the piston skirt and cylinder liners were observed. Piston thrust washers cannot be visually observed without piston disassembly, but readings can be taken to check clearance to ascertain wear. The copper particles were from a copper thrust that was greatly diminished in size and that showed signs of excessive heat.

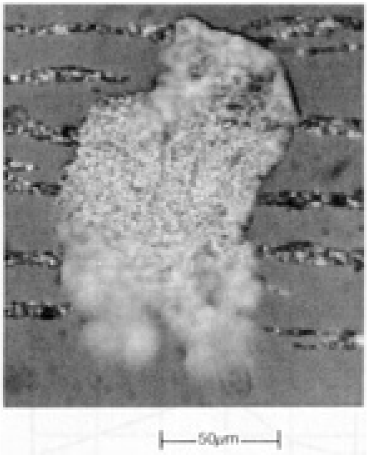

Fig. 13 Copper particles from a piston thrust washer in a marine engine. 400×

Preventive Maintenance Programs

The following recommendations are offered as guidelines for establishing a condition-monitoring program:

Coordinate with the proper personnel

- Machine operators
- Machine maintenance personnel
- Machine service personnel
- Management

Establish personnel involvement

- Document the role of each person
- Use their knowledge to improve the program
- Establish a chain of authority
- Educate all personnel involved

Establish a database before program start-up

- Machine specifications
- Fluid system schematics and specifications
- Operator, service, and repair manuals
- Lubricant type
- Filter specifications
- Wear components, especially material survey data
- Prior service and maintenance reports to identify problem

Establish sampling and sample handling procedures

- Design and document sampling methods, such as in-live valve, modified drain plug, suction tube, and so on
- Ensure cleanliness of sample containers; run some blank ferrograms with filtered oil
- Take sample from system while it is operating, if possible
- Take sample at the same location and machine operating conditions each time
- Coordinate sampling with operator or maintenance personnel
- Provide sampling kits
- Document handling or shipping

Database after start-up

- Program normally should be quantitative;plot DR graphs for each machine
- Initially generate ferrograms for all samples to establish machine signature
- Document all ferrograms with ferrogram analysis sheets
- Store oil sample and ferrograms for possible retrospective analysis

Program administration

- Communications; ensure that results and recommendations reach the appropriate personnel
- Ensure that the role of the analyst within the organization is understood
- Document all substantive work
- Establishment contacts with equipment manufacturer personnel
- Be aware of events in plant and equipment operation that could affect readings temporarily--equipment washing, shutdowns, and so on

Failure Analysis Programs

It is not always understood that post-mortem lubricant screening can significantly speed failure analysis. Difficulty may often arise in obtaining a sample of the lubricant associated with the failure and especially in obtaining a sample of the same lubricant in new condition. The latter is a worthwhile exercise in order to rule out (1) use of the wrong lubricant in the application and (2) unacceptable contamination in the new lubricant. Infrared spectroscopic examination is usually sufficient to rule out these possibilities. Metals analysis often is used to obtain additive metals concentrations and to detect the presence of dirt (Table 3).

The used lubricant should be examined for clues to the cause of machine failure (Ref 41), which commonly include:

- Misalignment or misassembly
- Overheating
- Lack of lubricant, lubricant starvation, inadequate oil changes

- Abrasive or corrosive contamination

Depending on the degree of lubricant or grease decomposition that has occurred, the sample may need to be diluted or filtered. Nevertheless, it is often possible to determine by spectrometric metals and IR analysis the presence of foreign abrasives, corrosive contaminants, water, or fuel. Overheating of the lubricant or old age is readily detected as lubricant oxidation or thermal decomposition via IR analysis. These clues can often be coupled with the results of ferrographic analysis; for example, overheating will result in oxide formation visible as temper colors (black and blue in steel wear debris), whereas predominantly red oxides may confirm rusting caused by water contamination (Ref 47).

Ferrography may also be useful in confirming the type of wear debris. However, it is always preferable to have a preestablished history rather than to draw conclusions from a single sample. In the final failure stages, cutting wear may occur due to roughening and fractured elements (Ref 47). In constructing a story, care must be taken to differentiate changes that caused a problem from those that resulted from the problem.

As an example of a lubricant failure analysis, the used oil from a van was analyzed to determine the cause of severe thickening noted in drawn oil. As shown in the IR spectra (Fig. 14), the used oil contained water but no antifreeze and was very oxidized. Metals analysis, also given in Fig. 14, showed increased additive concentrations, indicating that the oil had been overheated. A high silicon level signified poor air cleaner maintenance and possible engine wear. The overall picture suggested that the engine oil and air cleaner had not been maintained properly, resulting in low oil volumes, oil over-heating, and probably engine wear.

Motor-Current Signature Analysis

D.M. Eissenberg and H.D. Haynes, Oak Ridge National Laboratory

Introduction

FRICTION-GENERATED WEAR is a major cause of degradation of mechanical equipment. Wear can result from the normal operation of the equipment, or it can be accelerated because of operation under unanticipated severe conditions, or it can result from other degradations of the equipment that exacerbate the wear. The diagnosis and correction of wear, particularly accelerated wear, before it causes equipment failure can lead to a significant reduction in overall maintenance costs. Depending on the application, the detection and trend tracking of wear can also improve safety and reliability, as well as reduce unscheduled outages.

The key to successful early diagnosis and correction of wear in various types of equipment is the availability of cost-effective nonintrusive techniques for sensing, monitoring, and diagnosing either the causes or the extent of the wear. This article describes a new diagnostic monitoring technique, motor-current signature analysis (MCSA), which provides early diagnostic capabilities for detecting wear for the subset of mechanical equipment that is driven by electric motors.

The MCSA technique was developed by Oak Ridge National Laboratory (ORNL) to provide an improved means of determining the condition of motor-operated valves (MOVs) widely used as isolation or control valves in nuclear power plant safety systems (Ref 1). MCSA has been successfully tested on MOVs in nuclear power plants and has been demonstrated at the Electric Power Research Institute (EPRI) Monitoring and Diagnostic Center. Experience with the application of MCSA to motor-operated valves has shown that the technique detects MOV wear as well as other types of degradation.

Described below are the principles and equipment associated with MCSA, followed by specific examples of its application to the measurement of friction and wear of motor-operated valves.

Acknowledgement

The research described in this article was sponsored by the Nuclear Regulatory Commission Nuclear Plant Research Program and by the Oak Ridge National Laboratory Advanced Diagnostic Engineering Research and Development Center. Oak Ridge National Laboratory is operated by Martin Marietta Energy Systems, Inc. under contract DE-AC05-84OR21400 with the U.S. Department of Energy.

Operating Principles

The technical basis of MCSA is the observation that an electric motor driving a mechanical load acts not only as a transducer, in the sense of converting electric power to mechanical power, but also in the reverse sense, as a permanently available and easily accessible transducer that converts the mechanical load features of the driven device into an electrical signature. It is noted that for most types of electric motors, the relationship between current and output load is not linear, and is dependent on the supply voltage. However, that relationship is a characteristic of the motor, and characteristic curves can be obtained from the manufacturer for each motor over a range of input voltages.

The electric-current signature can be decomposed into two elements:

- The mean value of the current supplied to the motor and its (gradual) change with time. In the case of ac-powered motors, the mean value is the average root-mean-square (RMS) value
- The instantaneous fluctuations in the motor current. The amplitudes of the fluctuations are in general small, when compared to the mean value of the current

Both types of motor-current information can be useful, although in different ways, in diagnosing friction and wear. The mean value of the electric current provides a direct measure of the mean value of the total mechanical load of the driven device, and thus is a measure of the friction load within the device. In addition, gradual changes in the mean value of the motor current may reflect changes in the coefficient of friction that are due, for example, to the roughening of surfaces in sliding contact within the driven device.

Instantaneous motor-current fluctuations appear superimposed on the mean current. They can be either periodic or nonperiodic. In each case, the characteristics of the motor-current noise reflect the fluctuations in the mechanical load that the motor is driving. Nonperiodic load fluctuations (transients) occur, for example, during start-up of the motor-driven device, as well as when the device is subjected to rapid changes in load. In the case of MOVs, this occurs during valve seating or unseating.

Periodic fluctuations occur when there are rotating elements in the driven equipment. Gears, bearings, pistons, multivane impellers, and rotating seals are all sources of periodic load fluctuations.

Motor-current signatures are analyzed in both the time domain and the frequency domain using commercially available equipment, including PC-based programs. The time domain provides is optimum approach for detecting and monitoring both the mean value and the transients. The time of occurrence and the shape of the transient both provide useful information. The frequency-domain signatures are used to analyze periodic fluctuations. The frequency of rotation of each rotating element of the load usually can be readily identified, and the harmonics associated with that frequency are used to determine the extent of service wear of that rotating element.

MCSA Equipment

The application of motor-current signature analysis involves three types of equipment: signal acquisition and recording, signal processing, and signal analysis. Signal acquisition is accomplished using conventional nonintrusive electric-current sensors. These include a current transformer (split jaw or permanently installed coil) for ac-powered motor-driven equipment and a Hall-effect probe for dc-powered motor-driven equipment. It is usually necessary to place the current-measuring equipment on only one of the power leads. The current sensor can be placed anywhere along the power leads, from the motor itself to the motor control center or other circuit branch point or power transformer. The resulting current signal is amplified prior to further processing. The amplifier must be one that does not introduce significant signal distortion over its expected dynamic range.

For ac-powered motor-driven equipment, it is generally necessary to demodulate and filter the signal. This is because the 60-Hz frequency component and its harmonics will tend to make further analysis more difficult, particularly when signals close to 60 Hz or its harmonics are present.

The demodulation can be performed using several techniques. One that has been found effective is RMS-to-dc conversion. Generally, a low-pass filter is used after the RMS-to-dc conversion, although in some special cases a notch filter and band-pass filter have been found useful. A functional block diagram of a motor-current signal conditioning circuit is shown in Fig. 1.

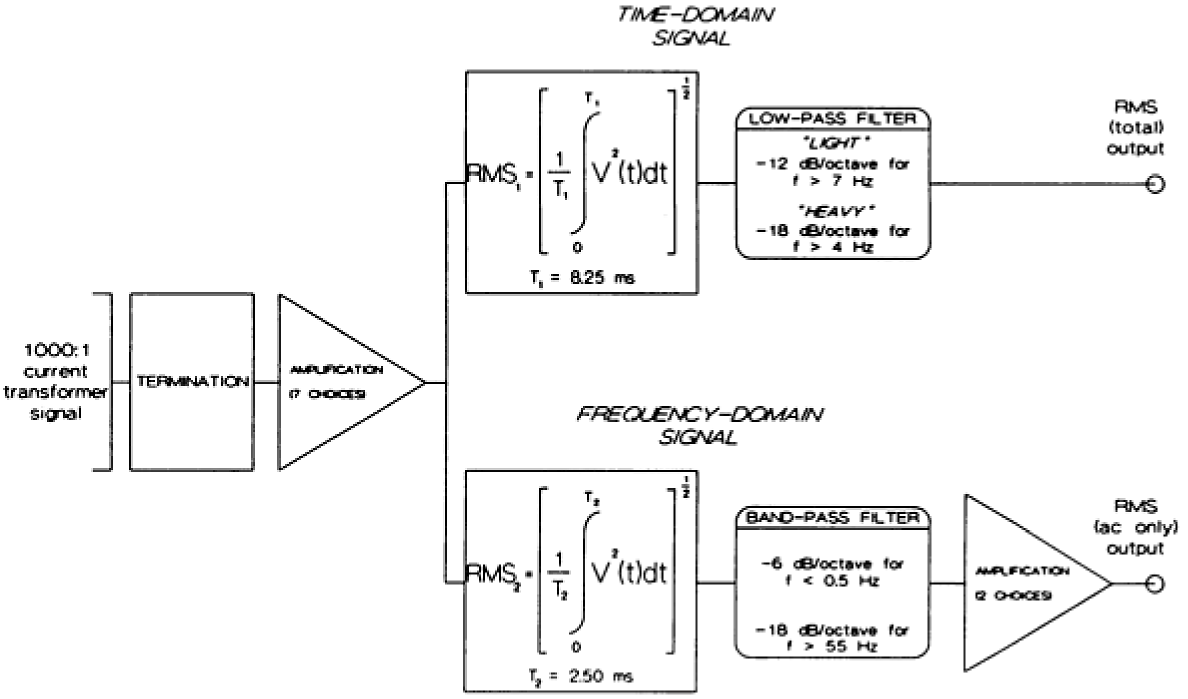

Fig. 1 Functional block diagram of a motor-current signal conditioning circuit used for ac-driven motor applications

Two separate output signals are developed from the amplified, demodulated, and filtered signal: one is optimized for time-domain analysis and the other is optimized for frequency-domain analysis. The signal conditioned for time-domain analysis is digitized, and the signature is displayed on a digital oscilloscope. The signal that is optimized for frequency-domain analysis is digitized and fed to a fast Fourier transform (FFT) analyzer for display of the frequency-domain signature (Fig. 2). Instead of using separate instruments, it is convenient to use a commercially available computer program that combines both oscilloscope and FFT display functions using a personal computer.

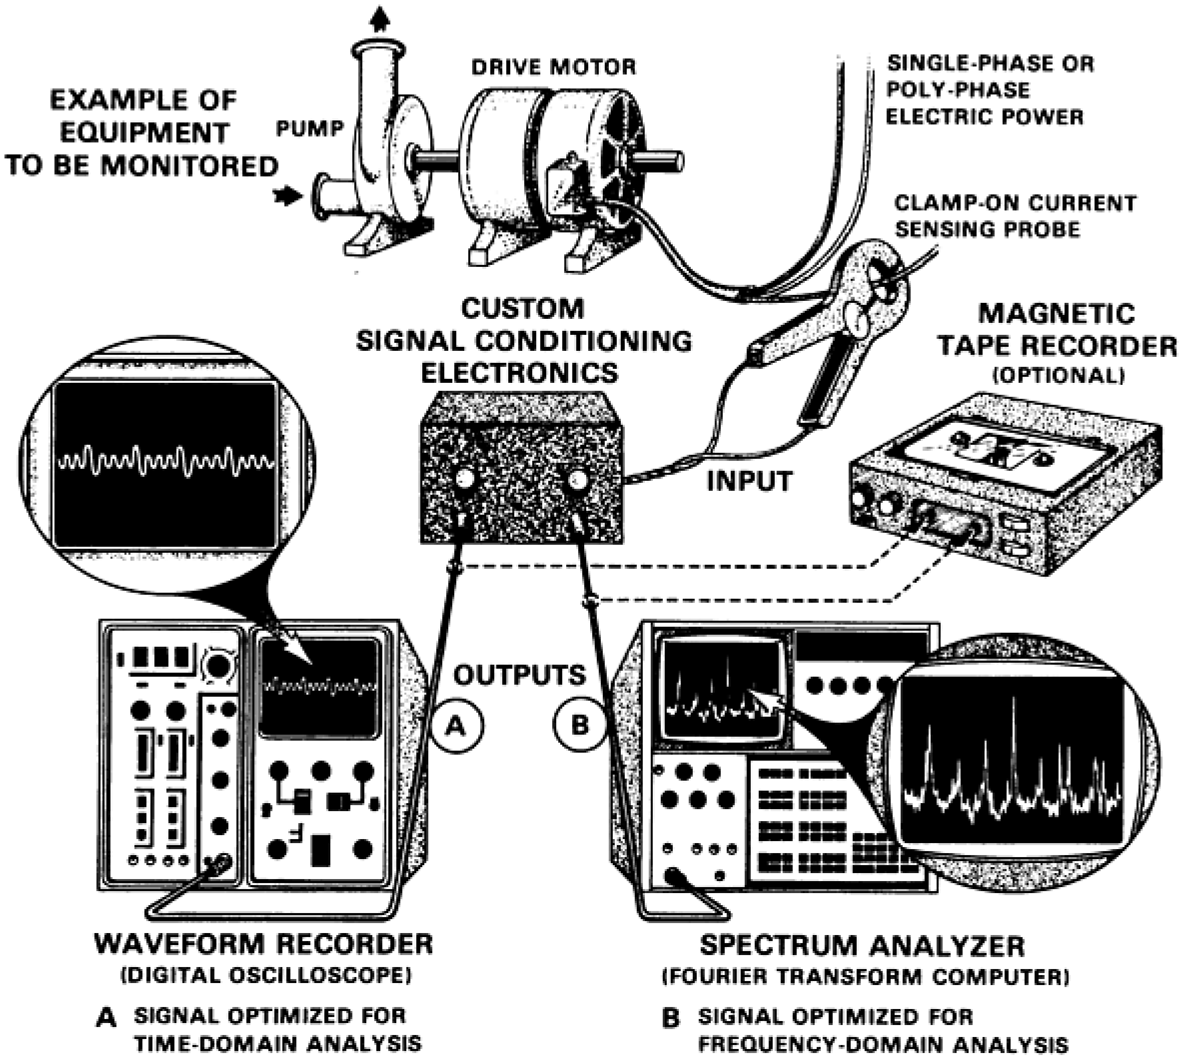

Fig. 2 Motor-current signature analysis (MCSA) method

Application to Motor-Operated Valves

ORNL has carried out extensive laboratory and field investigations to evaluate the capability of MCSA for determining the operational readiness of MOVs used in the safety systems of nuclear power plants. Operational readiness is the ability to function under all anticipated operating conditions, including those associated with accident mitigation and recovery. Readiness is affected by many factors, including improper installation, improper setup, and the presence of defects (degradations) that result from operations under the extreme conditions that occur during or following an accident. Investigations show that MCSA can provide useful wear information, as illustrated by the examples below.

Stem-Nut Wear. During a disassembly inspection, the stem nut from a motor-operated 150 mm (6 in.) globe valve was discovered to have suffered extensive thread damage (Fig. 3). Investigations revealed that the root cause of this damage was a lower grease seal spring that had become loose during an earlier, improperly completed installation of the drive sleeve and had entered the stem-nut thread region. During subsequent valve actuations, the spring had become wedged between the stem nut and the stem, causing the accelerated wear of the stem nut.

Fig. 3 Valve stem nut showing wear of threads

The damage affected the motor-current signatures. In the time-domain signature, there was an increase in the time interval between the motor start-up and the initial stem movement (pickup time), which reflected the increase in clearance between the stem nut and the stem threads.

A precise measurement of the pickup time was made for signatures obtained from the 45 valve cycles during which stem-nut damage occurred and also after a new stem nut was installed. A plot of the pickup time for open-to-close valve strokes obtained during the 45-cycle sequence is shown in Fig. 4. The relationship between increases in this time and increases in stem clearance was calculated based on the known stem speed, 1.7 mm/s (67 mils/s). Thus, the approximately 0.2 s increase in time differential corresponds to an increased clearance of 330 m (13 mils) that was due to the accelerated wear.

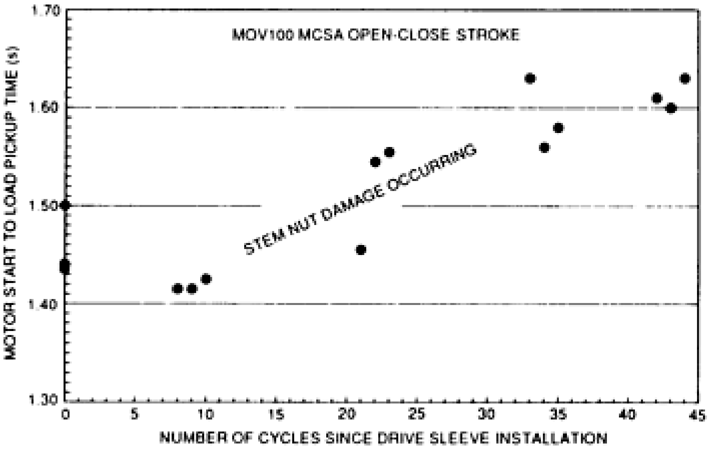

Fig. 4 Influence of valve stem nut wear on load pickup time for 150 mm (6 in.) motor-operated globe valve

A review of historical data for that valve revealed a longer-term trend in the pickup time that had preceded the incident cited above. This is shown in Fig. 5, which includes data collected over the last 650 valve cycles. It is seen that even without the accelerated wear resulting from the broken spring, there had been a gradual trend of increasing clearance. Also shown is the pickup time that resulted after installation of the new stem nut. The results are consistent with the conclusion that the pickup time as measured by the motor-current signature is a precise measure of stem-nut wear.

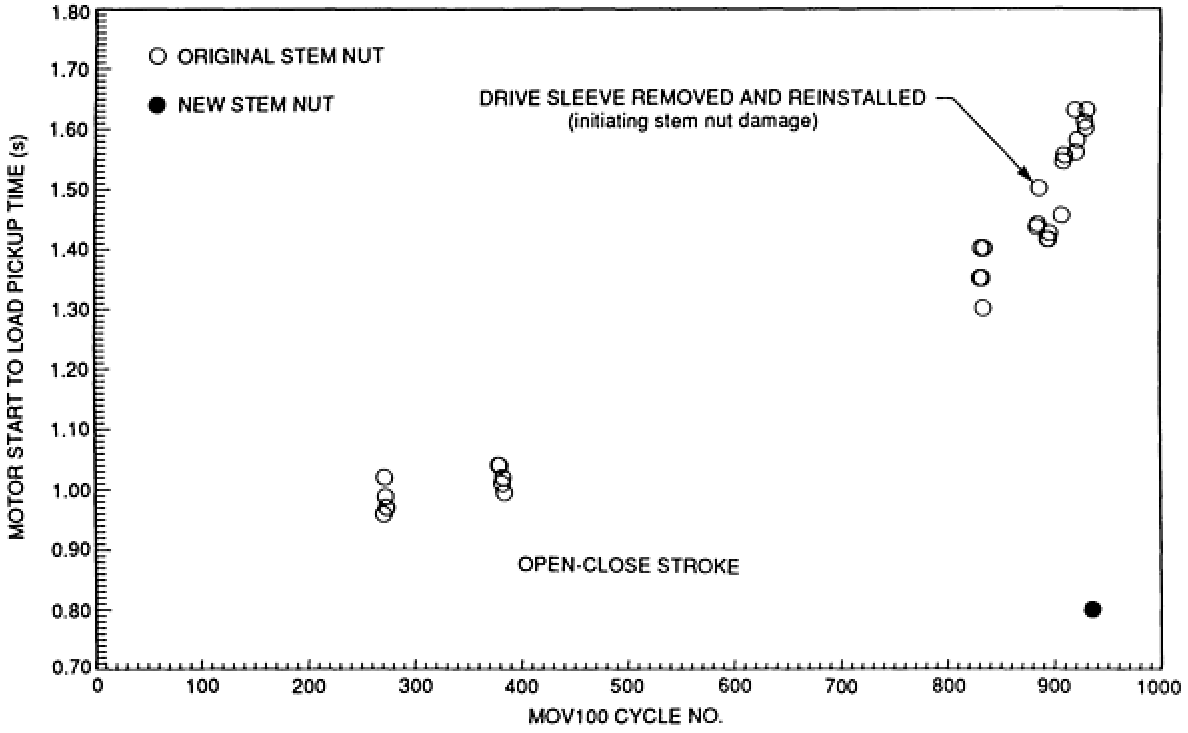

Fig. 5 Historical measurements of load pickup time for 150 mm (6 in.) motor-operated globe valve

An examination of the frequency-domain signatures of the valve motor current during mid-stroke provided additional evidence that accelerated stem-nut wear was occurring. Figure 6 presents two 10- to 20-Hz spectra of motor current. One was acquired before the improper drive sleeve installation and one soon after the drive sleeve was installed. Sidebands, located around the worm-gear tooth-meshing frequency at spacings equal to the stem-nut rotation frequency, approximately doubled in average amplitude soon after the drive sleeve was installed, during the time when stem-nut damage most likely occurred.

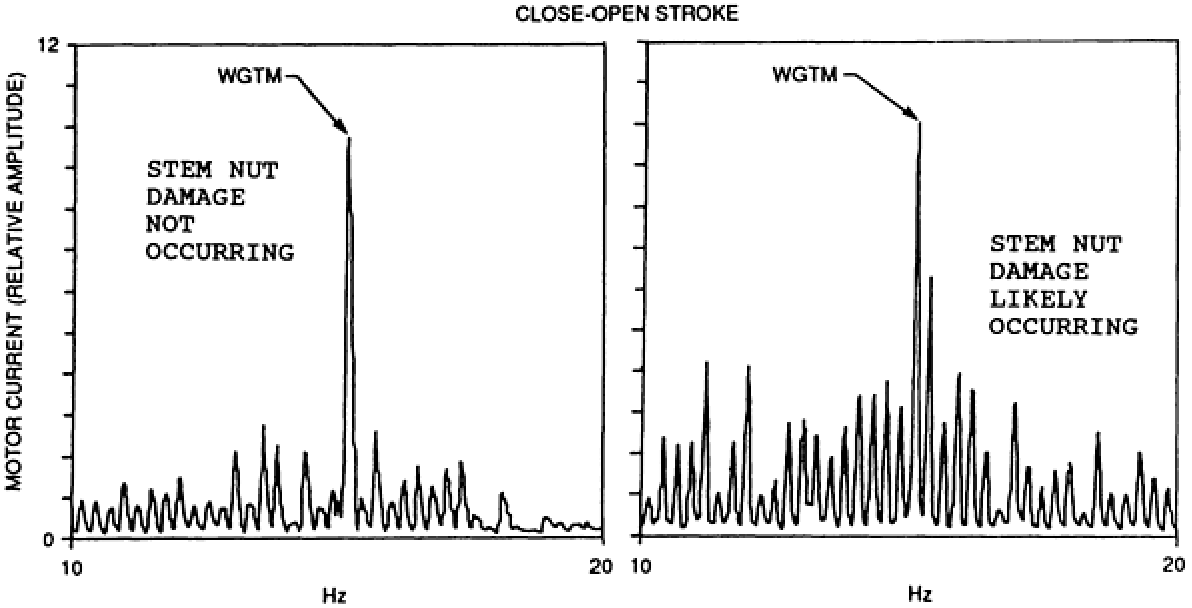

Fig. 6 Influence of valve stem-nut damage on frequency spectrum of demodulated motor-current signals from

150 mm (6 in.) motor-operated globe valve

These sidebands were observed to return to normal amplitude levels by the end of the 45 cycles. This suggested that the sidebands reflected a dynamic occurrence (stem-nut galling in progress), rather than a residual condition (after stem-nut damage had occurred). The diagnostic information acquired from this method thus complemented the differential time measurement described previously as an indicator of residual stem-nut wear.

Degraded Worm and Worm-Gear Lubrication. The worm and worm gear of a motor operator are normally lubricated with grease in order to reduce friction and wear. In one instance, a valve was actuated inadvertently without sufficient lubrication in this area. This occurred because the valve was used for training and was frequently being assembled and disassembled. Motor-current signatures were obtained during valve actuation with no lubrication under two conditions of load: the as-found condition when the valve packing was loose, and the condition after the packing was tightened. The results (Fig. 7) indicate a normal signature for the loose packing, but a high motor-load condition when the packing was tightened moderately. Because the high loads occurred in the drive train between the motor and the torque switch, the normal torque switch cutout of the motor did not occur and the motor stalled. When the worm and worm gear were lubricated, actuations with both loose and tight packing yielded normal motor-current signatures, as shown in Fig. 7.

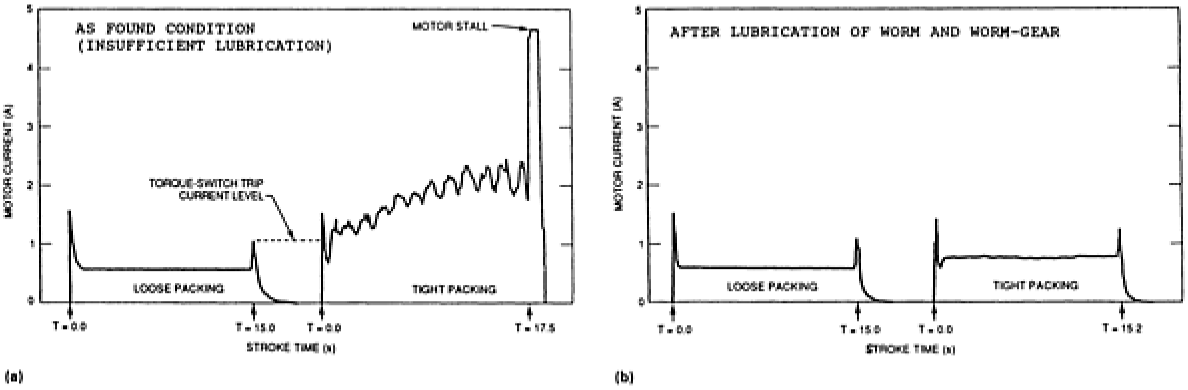

Fig. 7 Open-to-close stroke actuations of a 75 mm (3 in.) motor-operated valve before and after lubricating the worm and worm gear. (a) As-found condition (insufficient lubrication). (b) After lubrication of worm and worm gear

Gear-Tooth Wear. The detection of gear-tooth wear is illustrated by the time-domain plots of Fig. 8. The uppermost plot shows a 10 s midstroke portion of the motor-current signature at the start of the test, that is, the baseline condition with no gear-tooth wear. The ordinate scale has been expanded and offset from zero to show clearly the cyclic variations in motor current that result from motor slip and the engagement of individual teeth of the MOV worm gear with the worm (which occurs with each revolution of the worm, that is, each 65.16 ms for this particular motor operation).

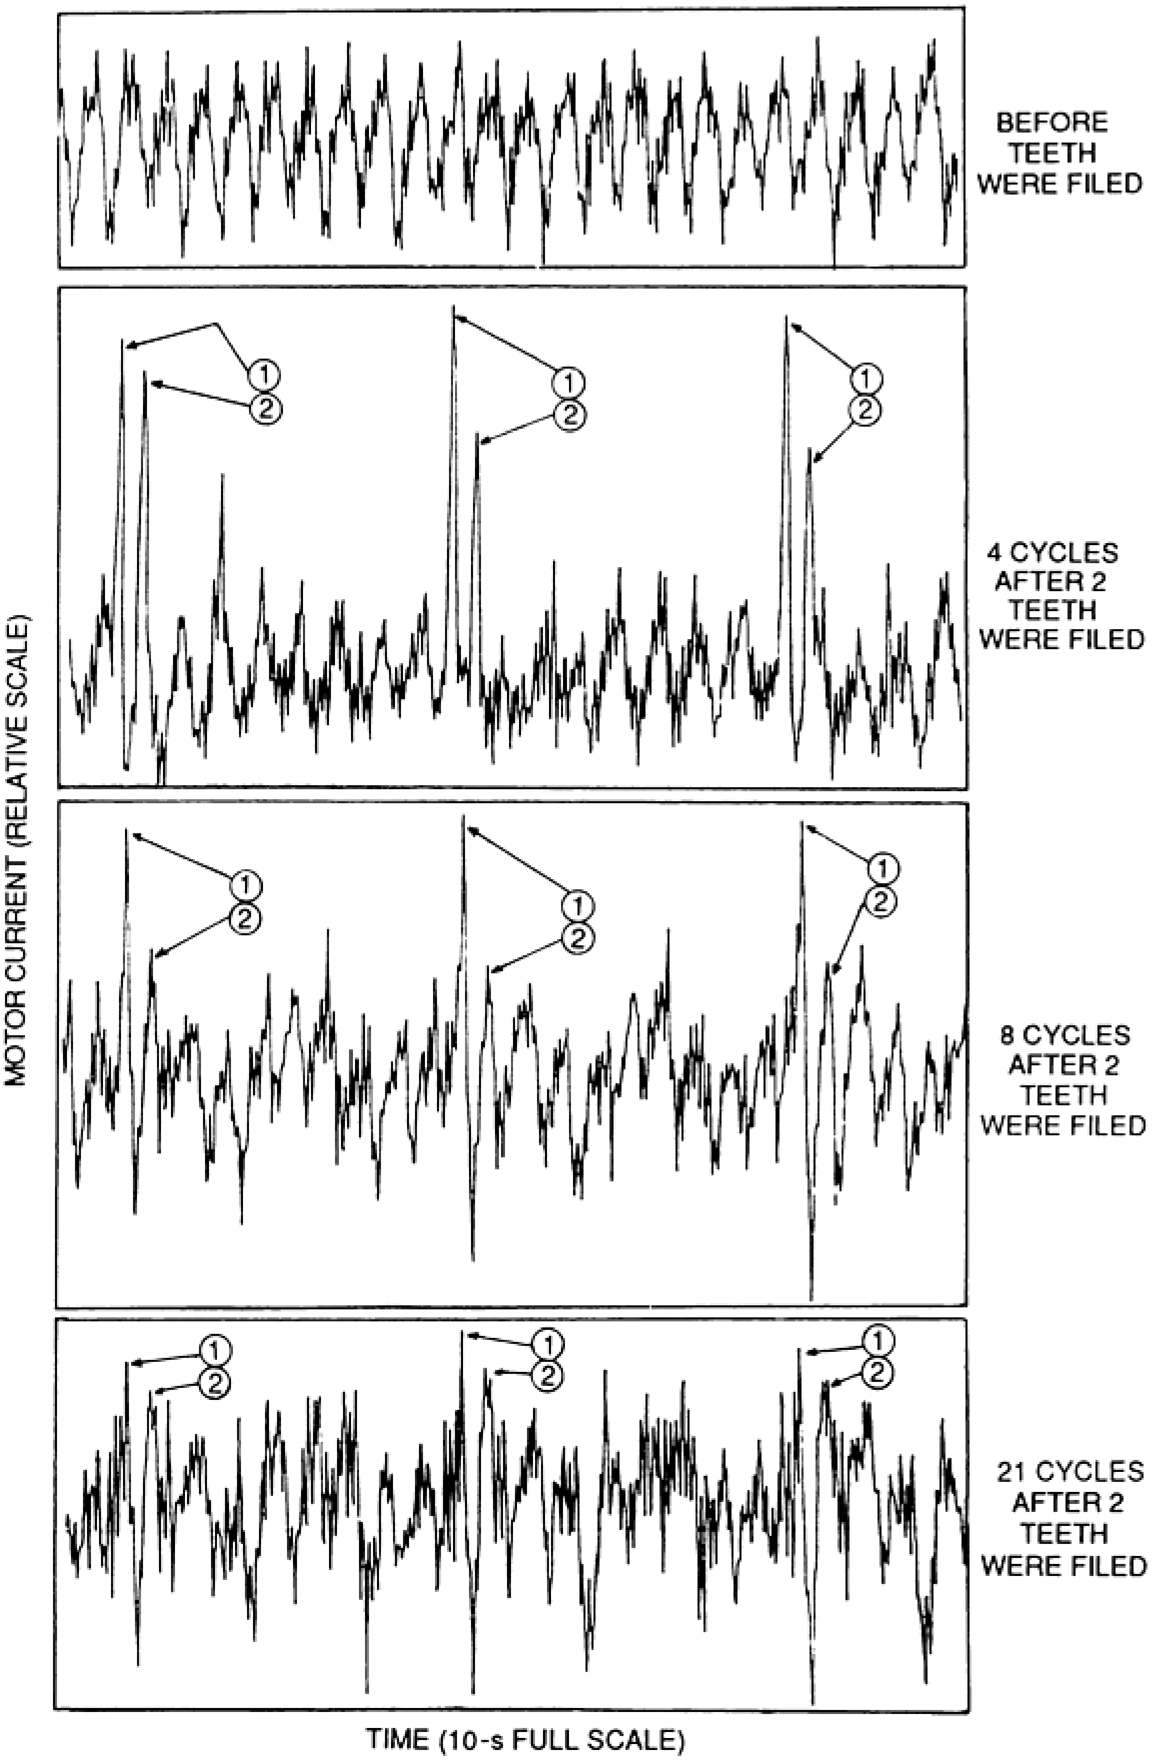

Fig. 8 Impact of worm-gear tooth wear on motor-current signatures; frequency, 2,33 Hz; time period, 0.429 s

For the purpose of demonstrating the capability of the motor-current signature to detect this type of wear, the worm gear was removed from the operator and the contact surfaces of two non-adjacent teeth were filed to both remove metal and roughen the surfaces. Approximately 165 m (6.5 mils) were removed from one tooth and 125 m (5.0 mils) from the other, later-engaging tooth. (In each case, the material was removed symmetrically from both sides of the tooth and from across the entire tooth width, in order to maintain tooth surface angles.)

After reinstallation of the defective gear, the operator was actuated repeatedly, giving the results shown in the lower three traces of Fig. 8. The presence of two strong peaks corresponds to the successive meshing of the two altered gear teeth with the worm. Note that the more heavily filed tooth gave the larger transient and that the pair of peaks recur each 3.7 s, which is the time required for one complete revolution of the worm gear. The peaks became less pronounced as the operator was stroked repeatedly, presumably the result of gradual "wearing in" of the implanted defects.

Stem Taper Effect on Packing Friction. When the motor-current signature of a 150 mm (6 in.) globe valve was first examined, the current level decreased during the open-to-close valve stroke and increased in a symmetrical fashion during the close-to-open stroke, as shown by Fig. 9. Because of the symmetrical and smooth nature of this reproducible motor-current signature feature, the current level behavior was assumed to be an indication of a valve stem anomaly. A close inspection of the valve stem after disassembly provided the reason for this signature characteristic. It was found that the diameter of the stem varied within the region that was in contact with the stem packing during valve actuations, as indicated by Fig. 10.

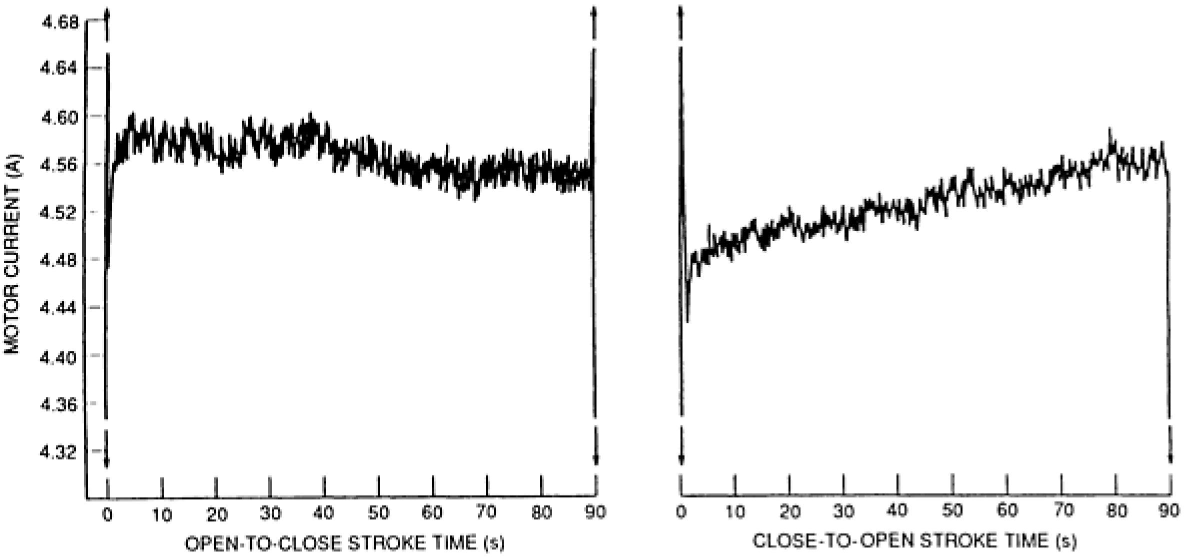

Fig. 9 Motor-current signatures for 150 mm (6 in.) globe valve showing influence of valve stem taper

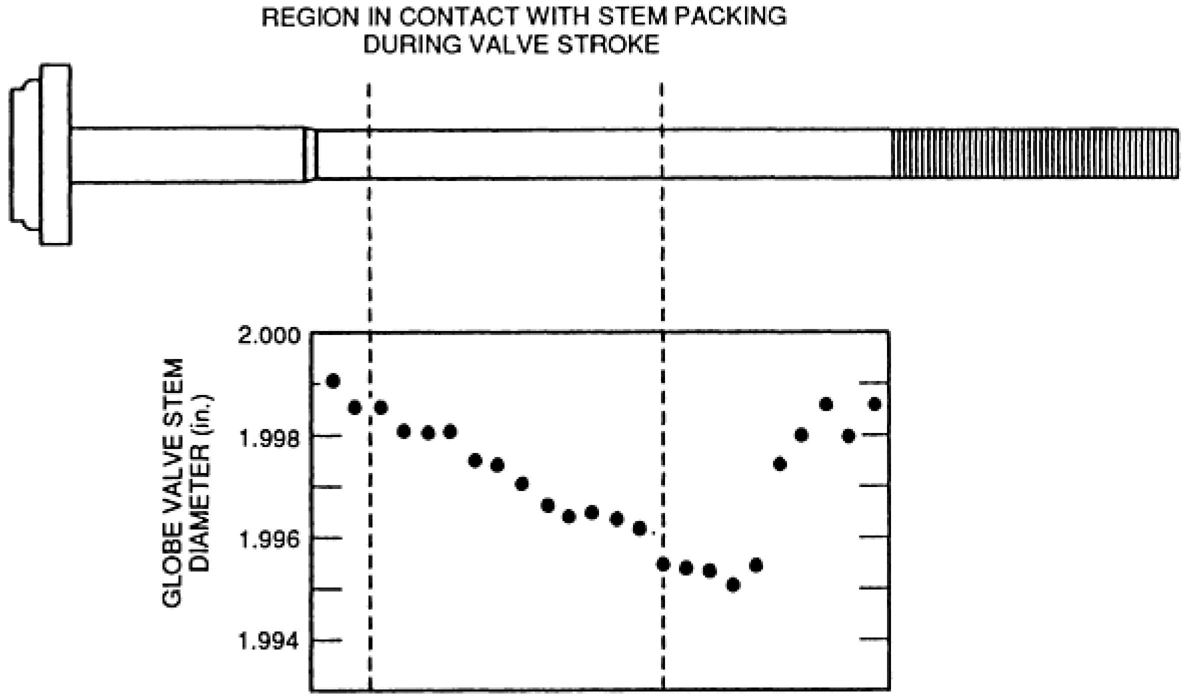

Fig. 10 Tapered valve stem of 150 mm (6 in.) globe valve illustrated in Fig. 9

As the valve was actuated in the open-to-close direction, the average stem diameter within the packing gland decreased. This reduced the packing friction load and therefore reduced the load driven by the motor. Conversely, during the close-to-open stroke, the average stem diameter within the packing gland increased, and the loads driven by the motor increased during the valve stroke. The current rise during the close-to-open stroke was greater than the decrease in the aforementioned open-to-close stroke. This may have reflected a relaxation of the packing load in the interval following completion of the close-to-open stroke.

Gate-Valve Unseating. Wedge-gate valves are seated by the wedging action of the tapered disk as it is forced between two tapered seat rings. Both the seating and the unseating transients can be seen in motor-current signatures. A typical normal unseating transient appears in Fig. 11(a).

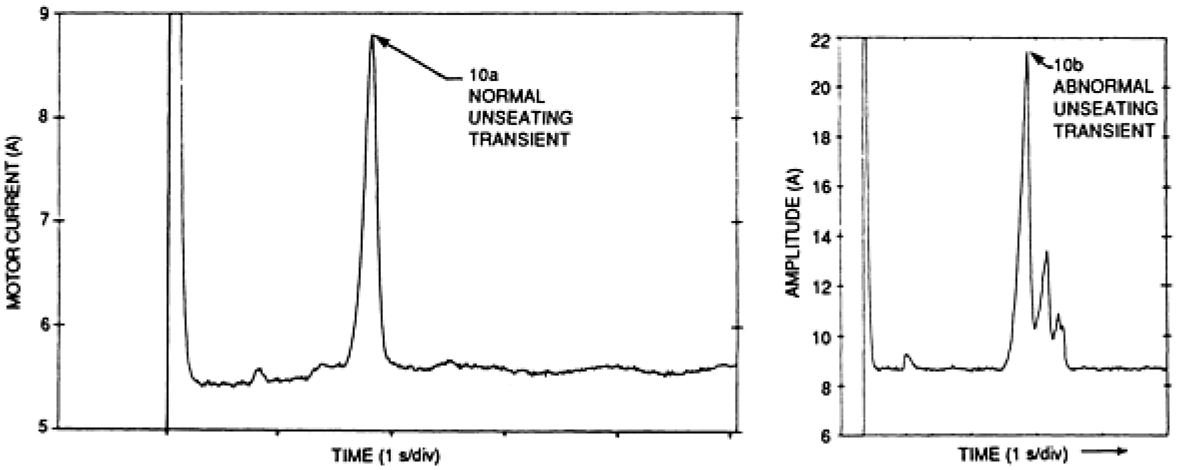

Fig. 11 Normal and abnormal unseating transients observed on two different motor-operated gate valves

In tests carried out at a nuclear power plant, the unseating transient of one of the valves appeared as shown in Fig. 11(b). It appears that a stick-slip condition occurred in the unwedging of that valve. Because of operating conditions, it was not possible to disassemble the valve to determine the cause of this behavior.

Actuation of Wedge-Gate Valves under Differential Pressure. When a wedge-gate valve is opened with a pressure drop across the gate or when the valve is closed while there is a flow of water through the valve such that a pressure drop builds up as the valve is closed, there is a frictional load between the gate and stationary seat or guide surface that is proportional to the pressure drop across the sliding gate. For some valves, this can result in excessive wear, including galling of the affected surfaces and an inability of the motor operator to open or to fully close the valve.

Motor-current signatures were obtained during actuations of a motor-operated gate valve with and without differential pressure. Shown in Fig. 12(a) and 12(b) are time-domain motor-current signatures obtained while the motor-operated gate valve was closed under two different conditions. In Fig. 12(a), the valve was closed while nonflowing internal fluid was at a temperature of 275 °C (530 °F) and a pressure of 7 MPa (1 ksi). The pressure drop across the gate during closure was zero. In Fig. 12(b), the motor-current signature is shown when the same valve was closed at the same fluid temperature, but with flow through the valve such that, at closure, there was a pressure drop across the gate of 7 MPa (1 ksi).

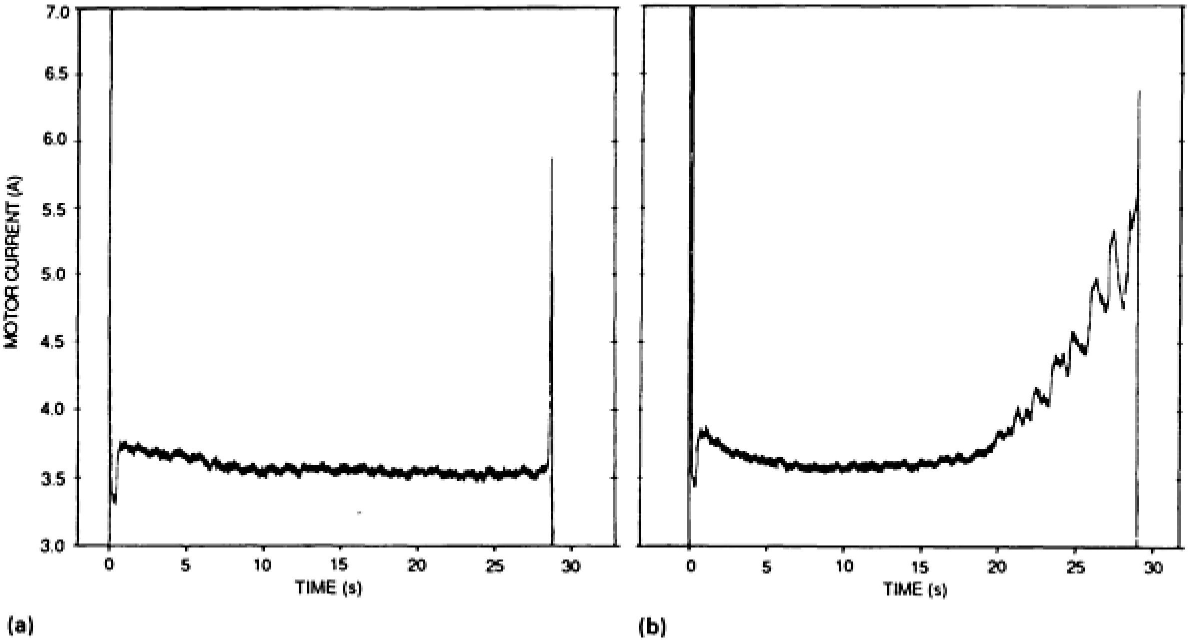

Fig. 12 Open-to-close stroke motor-current signatures for a gate valve. (a) Before blowdown. (b) During high-flow (blowdown) test

The following observations were noted. In Fig. 12(a), there was a virtually constant motor current during the stroke. In Fig. 12(b), the mean value of motor current increased sharply during the latter portion of the stroke as the gate blocked the flow, as would be expected as a result of the increased friction load between the gate and seat surfaces. In addition, there was a periodic variation in the motor current (also picked up by a direct-reading strain gage) that was due to rubbing of the lower edge of the gate against the lower edge of the seat. In some wedge-gate valves, the clearance between the gate and guide surfaces is such that the gate can tilt and rub the seat as noted above. Subsequent disassembly and inspection of the rubbing surfaces confirmed that excessive wear had occurred.

Future Trends

The above-cited and other data support the conclusion that MCSA is a useful tool for monitoring the mechanical and electrical condition of MOVs, particularly in relation of their operational readiness. Experience with motor-driven machinery other than MOVs, though limited, strongly suggests that MCSA is equally applicable to monitoring present conditions and to diagnosing impending trouble in a wide variety of consumer and industrial equipment. MCSA has a number of inherent strengths, the most notable being that it:

- Provides nonintrusive monitoring capability at a location remote from the equipment
- Provides degradation and diagnostic information comparable to conventional instrumentation (accelerometers, for example) but without the attendant disadvantages of added sensors and signal cables
- Offers high sensitivity to a variety of mechanical disorders affecting operational readiness
- Offers means for separating one form of disorder from another (selectivity)
- Can be performed rapidly and as frequently as desired by relatively unskilled personnel using portable, inexpensive equipment
- Is equally applicable to high-powered and fractional horsepower machines, driven by either ac or dc motors

Radionuclide Methods

Charles C. Blatchley, Spire Corporation

Introduction

GAMMA-EMITTING RADIONUCLIDES have been widely used for over 40 years to measure wear in engines, high-temperature environments, and lubrication testing. Their unique ability to provide on-line *in-situ* readings, both effectively and in real time, has made approaches based on them valuable for many engineering problems in either system design or lubricant evaluation. Extreme precision also makes these methods ideal for basic tribological research, particularly for relating surface loss, which is a critical effect of mechanical interactions, to other tribological aspects, such as friction.

Radionuclides Applied to Tribology

As material loss occurs, gamma-emitting material is removed, along with the original surface material. A gamma detector measures either the decrease in intensity from the activated part (marker approach) or the increase in debris collected in a filter or trap (tracer approach).

Tracers. First applications of radionuclides in wear testing used reactor-generated wear debris tracers as a diagnostic tool in 1949 (Ref 1). Tracer use became common in diesel engine testing through the 1960s, particularly in locomotives (Ref 2, 3, 4, 5, 6, 7, 8, 9). They are still often applied to engines, either where shielding prevents the effective use of other approaches or where timing of wear onset is more important than quantity removed.

Markers. Surface layer activation (SLA) by accelerator bombardment, rather than neutron irradiation, allows the creation of shallow surface markers that can be monitored remotely for decreases in activity. Although any activated material can be used for tracing (debris activity increases), direct monitoring of a marker allows much greater precision,

particularly if the marker is sufficiently shallow. Marker monitoring requires much less total activity, which simplifies handling, disposal, and licensing requirements.

Consequently, this mode has dominated radionuclide wear measurements since the early 1970s, when several groups working with diesel engines independently developed SLA marker-based techniques (Ref 10, 11, 12, 13, 14). The first application of the marker approach in the United States was to measure missile nose cone ablation for the U.S. Air Force (Ref 15). A comparison of marker and tracer configurations is shown in Fig. 1. Both tracers and markers require corrections for natural radioactive decay, and possibly for background "noise."

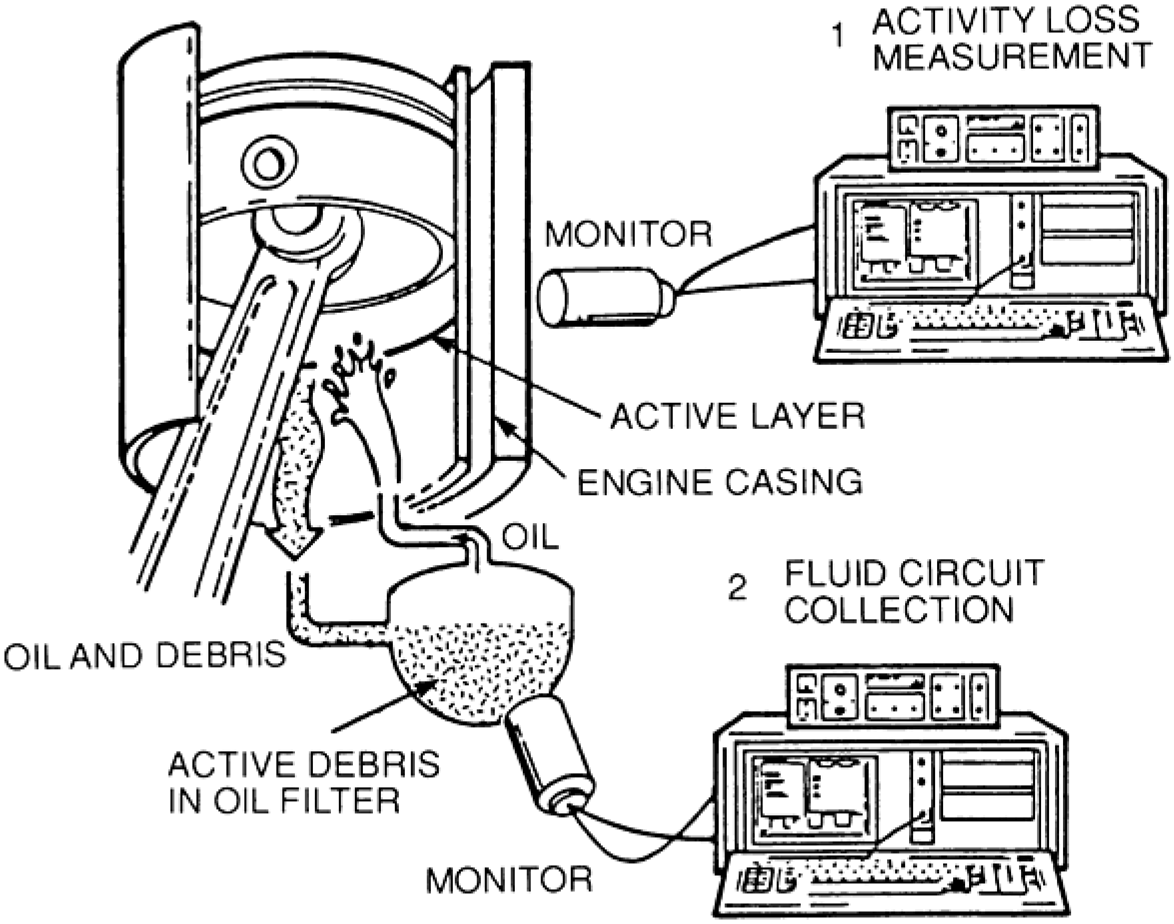

Fig. 1 Tracer and marker schemes commonly used for radionuclide wear measurements

In marker monitoring, a part or sample to be monitored is first exposed to a high-energy particle beam, which transforms atoms in a layer near the surface to specific radionuclides, about 1 atom per billion. Because total beam fluence is small, material properties do not change, and activity produced does not present any handling hazard.

Gamma Detectors. Both tracers and markers depend on gamma radiometry to deduce material amounts from detected gamma interactions. For marker monitoring, a gamma-ray detector is installed near the wearing part, typically a sodium iodide scintillator type (thallium-activated), shown in Fig. 2, to allow room-temperature spectroscopy. For tracers, a similar type of detector can be placed either at an oil filter or sump or simply near the recirculated oil line. Details of detector operation and optimizing performance are presented later in this article.

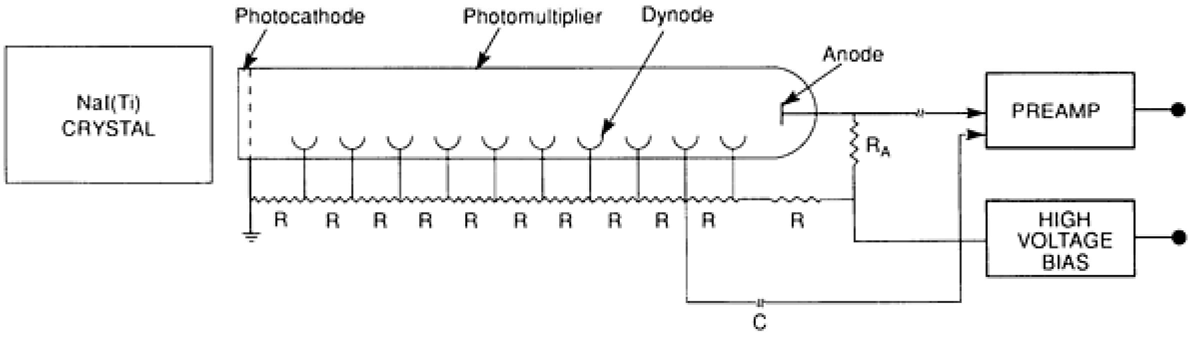

Fig. 2 Gamma-ray spectrometry based on sodium iodide scintillator that converts energy from gamma ray into visible light pulse

Activation Methods. The most commonly used methods for creating radionuclide tracers and markers (Fig. 3) are based on inducing nuclear reactions in the test piece itself. Either neutrons or energetic ions are allowed to interact, at the subatomic level, with a fraction of host matrix material. Lighter particles, such as electrons, photons, or mesons, are too unlikely to interact to be practical, and their range is too great to create a shallow layer.

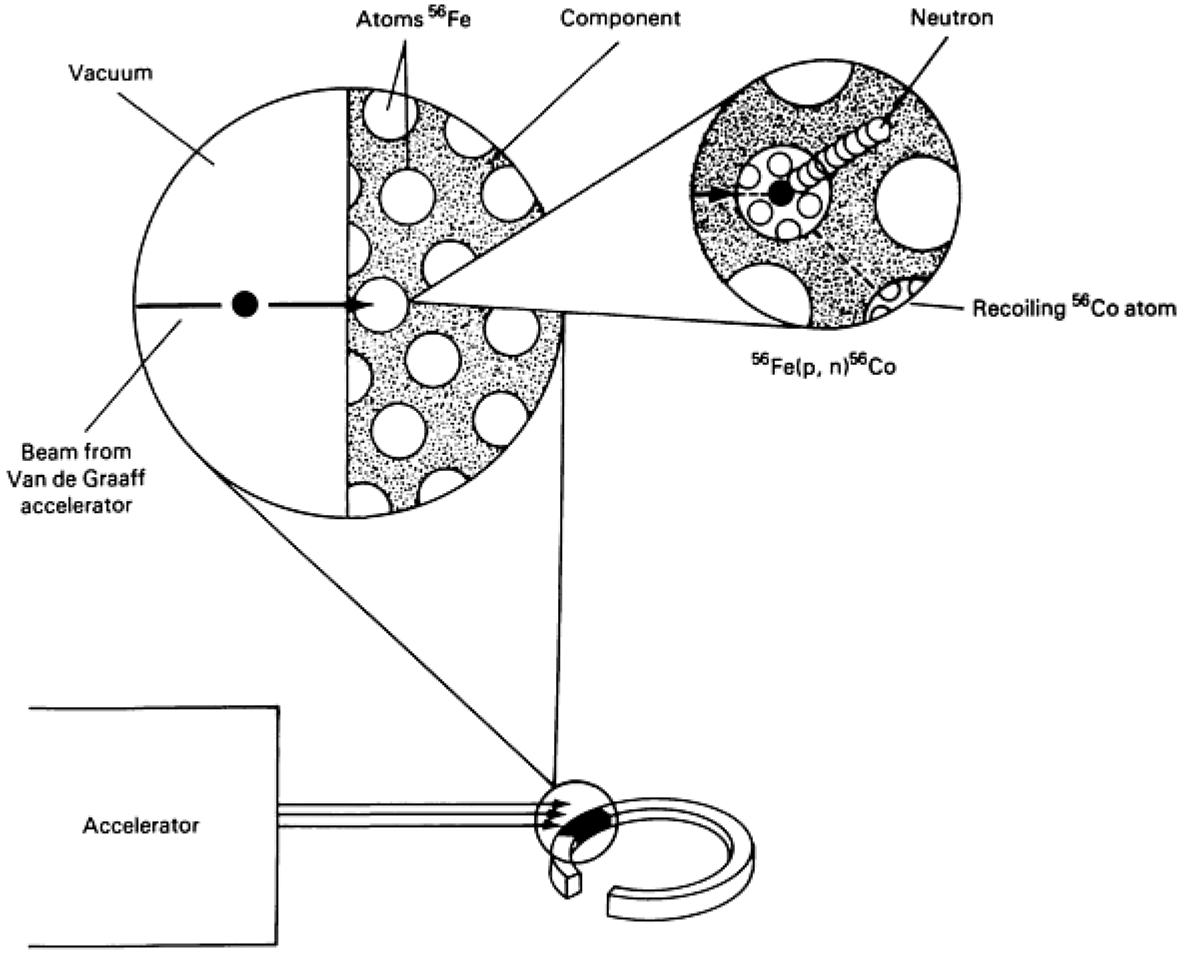

Fig. 3 Methods for creating radionuclides

The advantage of such in-place generation, compared to plating, coating, or implanting methods, is that the basic material properties of the host material are not changed. This allows valid comparisons between materials or coatings.

When the host material is too difficult to activate directly, either mechanical implanting or electrochemical plating can be selected for limited requirements, such as system characterization or lubricant evaluation. However, even for these restricted test objectives, care must be taken to minimize impact on the wear properties of the material itself, which could invalidate test indications. Radionuclides in the implants also typically come from either neutron or particle activation.

Thermal Neutrons. As previously mentioned, the first radionuclides in engine tests were produced by neutron activation. This is most commonly achieved by simply exposing the monitored part to thermal neutrons from a nuclear reactor core. Neutron activation can also be performed on-site using a portable neutron source, but these are rarely intense enough to create a usable activation. Care must be taken to avoid activating other materials in the vicinity. Small accelerators configured to produce neutrons can be used, but these are not portable, and they require substantial shielding when operating.

The main advantage of neutron activation is its relatively lower cost per microcurie of activity. However, there are many nuclides that can only be produced by accelerator reactions. For some materials, only accelerator-produced nuclides are suitable for monitoring, because of half-life or gamma energy. Conversely, nuclides produced by neutron absorption can also be generated by accelerated deuteron (H-2) bombardment.

Neutron activation has several major disadvantages for SLA purposes, compared to ion beams. Most notably, activity is necessarily distributed through the bulk material. This results in neutron activation being restricted almost exclusively to tracer-type monitoring. It is sometimes possible to partly shield or mask the activated component, but a shallow surface layer is not feasible unless the material to be activated is already in a thin coating.

Even with a thin coating, if the target constituent is not also present in the substrate to thoroughly confound the desired surface layer, then neutrons tend to activate other elements as well. Sometimes trace constituents can activate so much more readily than the one desired for monitoring that they create special handling problems. Consequently, neutron activation is difficult to configure without dealing with large amounts of unwanted activity, in addition to the relatively large amount required for tracer monitoring.

Energetic Ions. Modern particle accelerators can avoid these problems by carefully selecting the species and energy of the incident beam to stay below the reaction threshold for unwanted reactions. Often, depth of a single useful nuclide can be manipulated over a broad range without producing other gamma emitters, except for short-lived nuclides that will not interfere. Any allowed reaction only continues until the beam is below its unique threshold energy, which restricts activity to a shallow layer extending either several μm or sometimes up to several hundred μm from the surface.

This simple fact alone typically reduces the amount of activity needed by a factor of thousands in the ratio of the activated volume to the bulk volume. Switching from tracer to marker configurations can reduce the activity requirement further, depending on the attenuation involved. Thus, although cost per microcurie is much lower for neutron reactions, cost per monitored component is comparable for many materials.

Accelerator beams are typically narrow (pencil-sized) and easily restricted to small zones that are to be monitored using masks or collimation. Mask thickness only has to be great enough to exhaust the activation depth, although it is more common to completely absorb the beam range. To treat target areas larger than the beam spot (for example, the circumference of a piston ring), components can be either moved in the beam or rotated.

Among various types of ion accelerators, two are most commonly used for SLA (cyclotrons and tandem Van de Graaffs), because both operate in the energy range just above the threshold for common reactions. Cyclotrons typically reach energies well above this range, as well. Reaching the lower ranges that are best for SLA is difficult for many.

Even higher-energy machines, such as the synchrotron at Brookhaven National Laboratory, have been used to make centimeter-depth activations, but the need for this type of monitoring is relatively rare. High energy can also increase radiation damage and produce many unwanted nuclides through multiple-nucleon knock-out reactions. However, it can be advantageously used for recoil implantation, a process discussed in the next section.

For reactions involving low cross sections in durable materials, cyclotrons often have a cost advantage over less-energetic Van de Graaff accelerators, because they can generate large beam currents to shorten operating time and use extra beam energy to bring the beam out of vacuum. This keeps the irradiated sample from overheating in the higher beam current, and the convenience of bombardment without breaking vacuum is attractive. However, these advantages are obtained at the expense of degraded definition and spread in energy through straggling and beam dispersion.

Tandem Van de Graaff accelerators can also be configured to bring the beam out of vacuum, but, for most materials, this is not necessary (nor desirable) to create an economical bombardment. The advantage of lower beam currents delivered in vacuum is that the undegraded beam energy can be precisely reproduced with very little spread. This eliminates the need to calibrate the activity versus depth profile for each bombardment, the common practice with cyclotrons. In addition, many materials are sensitive to high currents and the resulting intense local heating, even with cooling at atmospheric pressure. Many materials that are too sensitive for any direct bombardment can still be activated using yet another activation technique, recoil implantation.

Recoil implantation can be used with both Van de Graaff and cyclotron accelerators to create ultrashallow activated layers (Ref 16, 17). In this process, a target foil is bombarded, instead of the part to be monitored, which is placed downstream of the foil (Fig. 4). Reaction products in the foil recoil with enough energy to escape and be implanted downstream. The result is a layer of activity without exposing the part directly to the beam.

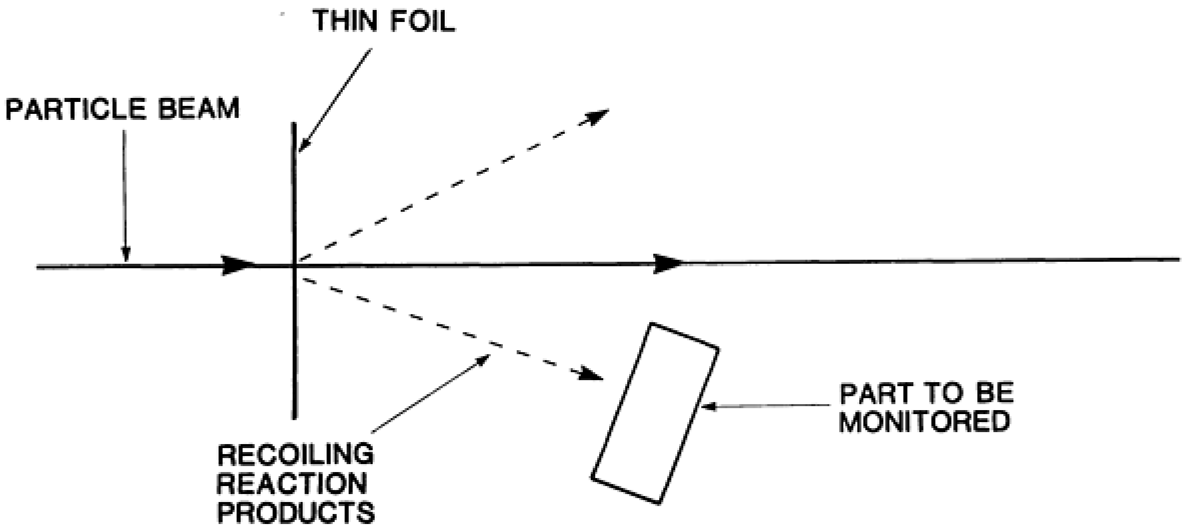

Fig. 4 Recoil implantation configuration

This is ideal for delicate materials, such as polymers, which would degrade from radiation damage, because of the direct beam. It is also an excellent approach for materials with low melting points. For shallow activation depths, this procedure is still usually performed in vacuum, because air or even helium would limit the range of large ions.

With the beam energies attainable in a tandem Van de Graaff accelerator, recoil-implant profile depths are typically under 1 μm (40 μin.). Such ultrashallow profiles are desirable in many precision measurements, such as magnetic recording media, or for detecting fretting damage.

Higher energies from cyclotrons and heavier projectiles allow reactions in which the beam ions fragment into lighter species. For example, the National Superconducting Cyclotron Laboratory at Michigan State University has created deeply implanted Be-7 profiles by nitrogen bombardment, in which the N-14 nucleus fragments into two Be-7 recoil atoms (Ref 18). The variety of reactions and depths available allows the activation of materials that are otherwise difficult to treat. However, high cost prevents deep recoil implantation from replacing direct bombardment in most materials.

Advantages of Surface Layer Activation. The extreme precision possible with SLA is its greatest single advantage, particularly for markers. It can greatly shorten test periods required to create measurable wear damage or reveal minute effects that are only accessible to its submicron resolution capability. With engine testing, the savings in fuel alone usually more than justifies the use of SLA techniques. Even in situations where other variables might interfere, such as temperature or pressure fluctuations, resolution of each increment of wear is still so fine that wear rates (relative measurements) are still more accurate than readings obtained by more conventional means.

In addition, both marker and tracer readings are made noninvasively, without interfering with any aspect of system operation. Readings are made *in situ,* without opening the system and possibly changing clearances, valve seating, or

vibration resonances. This is particularly important for lubricated systems, such as engines, which experience break-in wear whenever the system is opened.

Although static off-line readings are possible (and recommended for confirmation), SLA is typically configured to produce on-line monitoring in near real-time. This allows rapid feedback for either evaluating test conditions or preventing damage. Lubricants or other conditions can be modified on-the-fly, allowing the engineer to intelligently change test protocols, as needed, to investigate new phenomena.

The nature of the activation process makes SLA ideal for inaccessible locations, hostile environments, and parts with difficult shapes. Gamma-ray emission is not affected by environmental factors, and the signal is transmitted to a detector outside the system without wires, fiber optics, or connections of any kind.

Virtually any industrial metal and most other materials (ceramics, alloys, and many polymers) can be activated for wear monitoring. Nature was particularly generous with ferrous alloys, because four different nuclides can be generated from iron alone.

Simultaneous readings from several locations are possible through either one of two possible methods. Gamma-energy resolution, in which two distinct nuclides are used and monitored by one detector, is one method. Off-line analysis distinguishes gamma rays from each nuclide by their characteristic energies. This is ideal for simultaneously monitoring mating surfaces or for multiple tracers.

In the second approach (only possible with the marker method), several detectors are each collimated and shielded to view a single activated zone. Either multiple analysis systems are used to allow concurrent readings, or fewer devices are rotated between detectors for sequential readings. A switching system can be used to effect rapid changes.

Considerations in Planning SLA Testing

Choosing SLA for monitoring surface loss should be based on several key requirements. First, either marker or tracer methods are only valid for situations in which wear debris is actively removed from the measurement area. This can occur either through normal operation, or mating surfaces can be separated to determine whether material has transferred from one face to another.

Requirements for debris removal can be stretched somewhat, either by artificially interrupting a test to remove debris (for example, in fretting tests) or collimating the detector so that it only views the activated area, rather than an immediately adjacent zone. This approach has been used in sealed bearings, for example, but it is much more difficult than normal flowing configurations.

In addition, tracers require that wear debris be collected from the working fluid. For marker monitoring, the debris can be completely lost or exhausted, for example, from a gas turbine engine. In some systems, such as engines with recirculating lubricant, both methods are feasible and can be used simultaneously.

Other critical planning questions involve whether the material is suitable for activation at the required depth, whether a reliable monitoring configuration is possible, and whether the test information generated will, in fact, adequately answer the desired experimental questions. These issues are addressed in the section "Details for Executing SLA Measurements," which provides both a basis for evaluating SLA for a particular application and detailed procedures for conducting SLA monitoring.

Depth of the activated marker is an important parameter in the trade-off between measurement precision and test duration. It is controlled by beam energy and angle of incidence, once the reaction and, therefore, beam species, are selected. In general, limits to precision for individual wear increments are proportional to the total depth, usually by about 1%. Thus, a depth no greater than 100 μm (4 mils) is required for precision finer than 1 μm (40 μin.).

On the other hand, surface loss can only be monitored for as long as the marker persists. Thus, duration of a test is limited in proportion to marker depth, and a compromise must be made in test planning between precision and duration requirements. Sometimes, cost can play a role in making this compromise, because beam-time costs tend to increase as depth decreases.

Depths that are easily accessible to SLA range from 15 μm (0.6 mil) to hundreds of μm, depending on beam energy, which is often limited by the type of accelerator. Activation depths outside this range are certainly feasible, but they require alternate techniques, such as recoil implantation, or larger machines, which are either expensive or rarely accessible.

Typical Applications

One of the earliest applications of accelerator activation was associated with machine tooling, particularly drill bits (Ref 19, 20, 21). Parallel developments in measuring ablative wear in cannons occurred in this same period (Ref 22, 23, 24), as well as refinements in calibration and detector configuration for tracers in engines (Ref 25, 26, 27). Since these early tests, many successful applications have been made in industrial fields, including nuclear and fossil power generation, chemical processing, piping, medicine (prosthetic bone replacement), and aerospace propulsion, and research has been conducted in the fields of metallurgy, corrosion, and tribology (Ref 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54).

SLA markers are currently applied to a variety of industrial wear problems (including diesel engine parts such as bearings, piston rings, valves) and occasional large-scale (centimeter) erosion problems, such as in pipelines, reactor or furnace walls, boiler tubes, and other heavy industry components. Extreme precision of this technique is ideal for evaluating minute differences in wear rates, such as those produced by variations in critical operating conditions. Typical system parameters that can be correlated with these changes in wear rate include temperature, vibration, load (Ref 55), and, particularly, type of lubricant or lubricant conditions (Ref 56, 57). Coatings or surface treatments with very similar performance capabilities can also be rapidly compared (Ref 58).

For diagnostic condition monitoring, the convenience of on-line readings is frequently more significant than accuracy. Consequently, tracers are often used in industrial systems where debris can be caught in a filter for later examination in the laboratory. Of course, the tracer approach is only suitable for systems with an enclosed working fluid, such as diesel engines or steam turbines, and therefore could not be considered for gas turbine or jet propulsion applications, except possibly in bearings or a drive train. Tracers have been applied, with minimal success, to wear in magnetic disk drives (Ref 59). Ultrashallow markers have also been used for magnetic recording media (Ref 60).

Even in systems with a captured fluid, tracer monitoring can be less preferable, because it includes stochastic effects of mixing, settling, and chemical interactions, which can either delay or distort readings. In contrast, the only requirement for the marker approach is that debris be thoroughly removed from the immediate vicinity of the wearing surface so that it no longer contributes to the detected signal. Other considerations include whether the detector can withstand installation near the activated component (if not, tracers must be used), rapidity of measurements needed, and whether the user is willing to work with the higher levels of activity needed for tracers.

Laboratory Wear Characterization. Probably one of the most representative and consistently used applications of SLA is in lubricant testing. A good example is a continuing evaluation of additives for motor oil conducted at the Exxon Research and Engineering Company (Ref 56), based on the activation of overhead cam lobes in a four-cylinder 2.3 L engine. In tests lasting several hours, repeated marker readings track lubricated wear. An example plot of readings produced in this type of test is shown in Fig. 5. Note that there is some scatter in the data, which emphasizes that gamma-ray counting is an inherently statistical type of measurement. However, with a series of readings such as these, it is easy to determine the slope, or wear rate, for each operating condition.

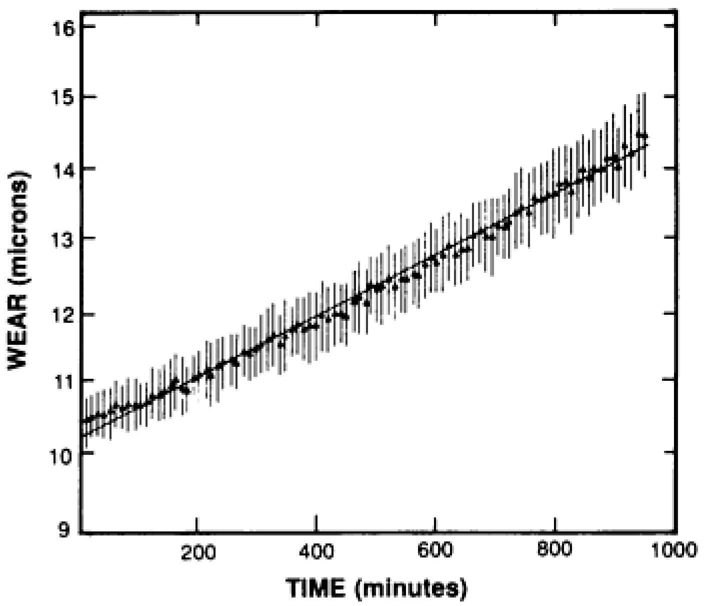

Fig. 5 Typical wear history. Source: Ref 56

Diagnostic Condition Monitoring. Field tests in which SLA was used to monitor heavy industrial systems have been effective, most frequently in fossil-fuel power plant components. For example, a configuration for monitoring a steam turbine stop/bypass valve at a power-generating station was recently tested by the Electric Power Research Institute (Ref 26). At the Stuart plant of Dayton Power and Light, the stop-valve bypass carries the entire steam flow to the turbine during start-ups. Oxide and magnetite exfoliation in upstream pipes and boiler tubes cause serious erosion of the valve, necessitating its annual replacement long before it is fully expended, which makes this valve an excellent candidate for monitoring.

Two activated valve disks were installed side-by-side on the same turbine inlet and monitored during a series of start-up cycles. One had a skirt made of conventional Stellite, and the other had a Stellite skirt with a boron diffusion treatment to increase erosion resistance. Scintillation counters monitored the activated regions of the valve disks through the valve body, approximately 300 mm (12 in.) of steel, plus insulation. Results are shown in Fig. 6.

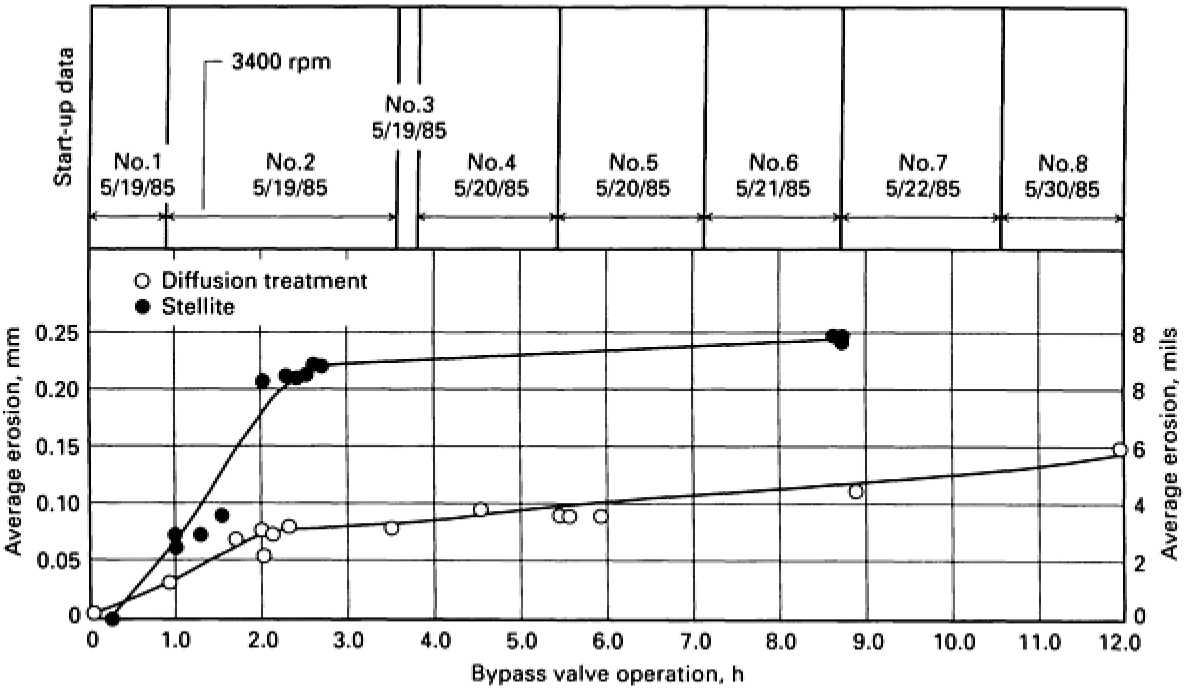

Fig. 6 Erosion of valve disks, which indicates ability of SLA to measure lower initial wear rate and eventual disappearance of boron diffusion coating

This test demonstrated that erosion resistance of the diffusion-treated valve was superior to that of the untreated valve during the first two start-up cycles. However, because the treated layer had eroded away by the end of the second start-up, the subsequent erosion rates of the two disks were essentially the same. Real-time monitoring provided a rapid and accurate comparison of the performance of the valve disks.

Tracer Monitoring. In heavy industry applications, measuring activity that accumulates in erosion debris is preferable to monitoring the part itself. For example, at another station (Ref 26), SLA tracers have been used to monitor high-pressure turbine blade erosion, because the thick casing makes direct measurement of blade activity impractical. Researchers sampled debris from the condensate water using a conventional felt bag filter, which was examined by gamma spectrometry at a laboratory away from the power plant. Multiple isotopes were used to independently detect erosion at different locations.

Engine testing has been the most common application for radionuclide tracers, as it is for markers. Tracers can have an economic benefit, in that they can achieve a degree of accuracy, even when based on less-costly activations in a nuclear reactor. However, because reactor activation is a bulk process, the entire component is uniformly affected, with the result that much more activity is needed than that amount required for the same accuracy with a thin layer. Often, the costs of handling, storage, and disposal after the test can outweigh the savings in the activation cost. Consequently, most tracer work today relies on cyclotron bombardment.

Tracers are still commonly used in U.S.-based companies (Ref 47), as well as in many other countries, as evidenced in recent literature from Germany (Ref 61, 62, 63, 64, 65), the United Kingdom (Ref 66, 67), Japan (Ref 68), France (Ref 69), India (Ref 70), Poland (Ref 71), and Ireland (Ref 72). A good example is a recent series of tests described in Ref 73, which includes a description of calibrations and procedures for measurements based on reactor activation. Such neutron activations can still be used to advantage in calibrating a cyclotron-based measurement, because it is easier to uniformly activate a powder using the reactor approach, than to polish a cyclotron-bombarded solid and collect the residue. However, a correction for detector efficiency can be required if the reactor-produced nuclide emits a different energy gamma ray from the cyclotron product.

Aerospace. In gas turbine engines, blades are often shrouded at their tips for aerodynamic control and structural support. A short segment of the shroud is attached to each blade, and these segments are separated by a small gap (Fig. 7). Clearances in these gaps are observed to grow during engine operation, either because of wear or deformation of the

shroud segments. Enlarged clearances allow increased vibrational amplitudes that lead to fatigue and eventual blade failure. Consequently, gaps are regularly inspected to ensure that total clearance remains within specified limits.

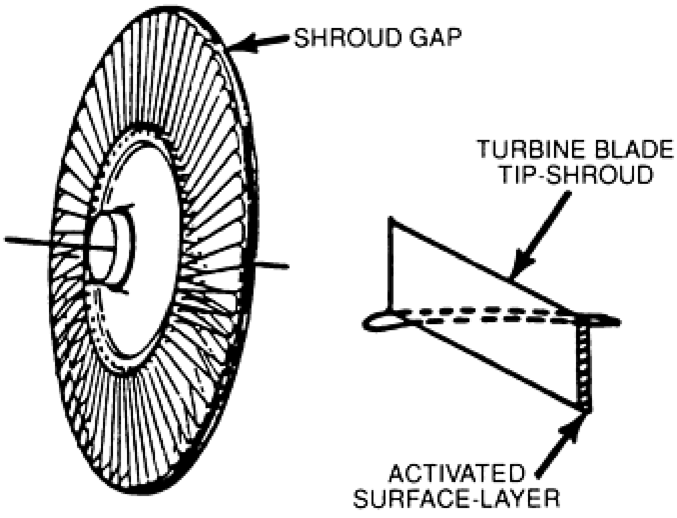

Fig. 7 Common arrangement of turbine engine blade shroud gaps. Source: Ref 55

Because inspection and repair are expensive processes, causes of gap growth and possible prevention were investigated using SLA markers (Ref 55). Two distinct nuclides, ^{60}Co and ^{54}Mn, were used to separately monitor gaps that were initially smaller or larger, respectively, than average. Two different turbine wheel configurations were tested, one "tight" with a total shroud gap of 0.41 mm (16 mils), and one "loose" with a total gap of 2.95 mm (116 mils).

On-line readings were able to characterize wear rates as a function of engine speed. These were found to be significant only at the highest speeds, 92 to 96%. A number of other significant results were produced. First, although the gap size increase was greater for the tight wheel, SLA indicated much greater wear for the loose wheel. This suggests that most of the initial increase in gap size for a new wheel is due to other processes, such as plastic deformation or turning of the blades, and not wear. Off-line readings for individual blades indicated that wear was a function of total gap size for the wheel, but was independent of individual gaps.

Another important indication from the SLA readings was the presence of a previously undetected vibrational mode. This was evident in anomalous increases in detected counting rate at a certain engine speed and believed to be related to opening and closing of shroud gaps during torsional motion. The motion was later linked to a resonance that could be suppressed by design changes.

Details for Executing SLA Measurements

Activation Fundamentals. Critical properties of gamma-emitting radionuclides, which determine their suitability for wear monitoring, are their decay half-line and gamma-ray energy, which must be sufficiently energetic to penetrate surrounding material and allow detection from the outside. Rate of decay must be sufficiently slow to allow a reliable signal to persist throughout the planned measurement interval. For quick tests, half-lives of a few days are sufficient. For long-term monitoring, reliable measurements can typically be made for up to six half-lives.

By carefully choosing the species of incident particle, bean energy, and angle of incidence, a suitable radionuclide can be produced in a controlled pattern. Lists of nuclides, their radiations, and reactions producing them are available in several well-known tables (Ref 74, 75). Some of the more commonly used species are summarized in Table 1. The reactions most commonly used to produce these are (p, n), (d, alpha), and (alpha, d), because these have low thresholds and large cross sections. In this nomenclature, the first symbol in the parentheses is the incident beam species, and the second is the reaction product. Letters stand for proton, neutron, deuteron, and alpha particle, respectively.

Table 1 Some useful SLA radionuclides from common metals and their production methods

Material	Accelerator beam	Major half-life radionuclide ($T_{1/2}$)
Cr	Alpha	^{54}Mn 300d
Cr	Protons	^{52}Mn 5.6d
Cu	Protons	^{65}Zn 244d
Fe	Alpha	^{58}Co 71d
Fe	Protons	^{56}Co 78d
Fe	Deuterons	^{54}Mn 300d
Ni	Deuterons	^{60}Co 5Y
Ti	Deuterons	^{46}Sc 84d
Ti	Protons	^{48}V 16d

Maximum depth of activity can be estimated by integrating the basic Bethe formula for ion stopping power (Ref 76). Low-energy corrections for recombination, adiabatic interactions, and (Sternheimer) density effects can be safely neglected, because interest is limited to range above the reaction threshold, which is typically at a relatively high energy level of several MeV.

An alternate approach is to look up ranges in available range tables (Ref 77). The range below the reaction threshold is subtracted from the range at incident energy to produce the depth of activity generated. Energy loss or range calculations can even be used to predict the activity versus depth calibration, if reaction cross sections are known at all involved energies. Cross sections are particularly important near the reaction threshold.

One problem with these calculations and range table estimates is that wear measurements are rarely performed in pure elements, and calculations are sensitive to average atomic number and density. Because exact composition and density of industrial metals can vary substantially, calculated profile calibrations are not reliable, even if reaction cross sections are available. Consequently, a laboratory calibration procedure should be completed for each combination of material and beam conditions.

Laboratory Marker Calibrations. To convert the decrease in marker intensity to a precise measurement of wear, the relation between the amount of material removed and the fraction of radiation intensity that remains must be known. This activity-versus-depth profile is typically determined in a series of calibration measurements by activating an identical part or sample and then carefully simulating wear by controlled polishing in the laboratory.

Care must be taken in mounting the specimen in a jig to ensure uniform surface removal from the activated area. Additionally, the grit size andtype of polishing fluid, if any, should be selected to match the wear or erosion process being simulated. Once begun, it is more important to maintain surface roughness than to actually match the surface finish on a worn part. Changing grit size or polishing conditions can cause an anomalous jump in the calibration curve.

Activity remaining is measured on an optical bench using a reproducible geometry for each increment of material and a technique appropriate to the depth involved. For deep profiles (more than 50 μm, or 2 mils), a precision micrometer is sufficiently accurate. A deep profile can also be evaluated by exposing a stack of foils made from the same material as the wearing part and then detecting the activity in each foil.

For shallower activation depths, an actual part can be exposed and then polished to simulate wear. To produce the necessary measurement resolution, either an electronic diamond-stylus profilometer or optical technique is required. For ultrashallow activations, both uniformity of surface removal and measurement of wear depth can become problems that require special care.

For profiles under 1 μm (40 μin.) deep, a diamond-tipped indenter (for example, in a microhardness testing system), is best. This approach is also useful in somewhat deeper profiles as a check against other measurement methods. Because the microscopic indentation is typically exhausted after 1 to 2 μm (40 or 80 μin.), several overlapped indents must be made to span the entire depth. Typical calibration microindents are shown in Fig. 8.

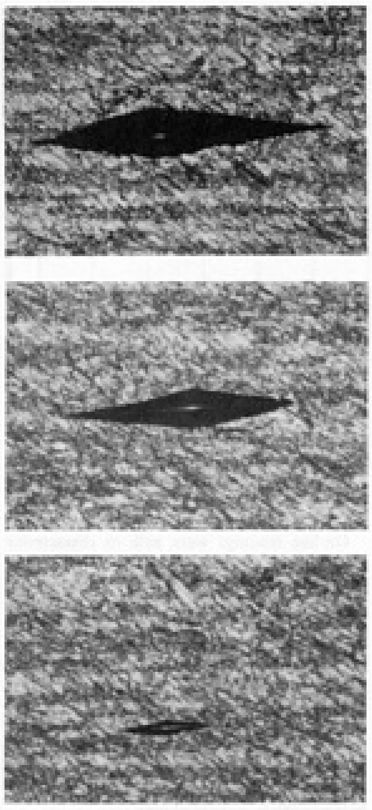

Fig. 8 Diamond-shaped (Knoop tip) indents before and after polishing. Longest indent is about 31 μm (1.2 mils) long and 1 μm (40 μin.) deep.

Once the distribution of activity remaining as a function of depth removed is known, the original part can be installed for actual wear monitoring or testing. A representative calibration curve is shown in Fig. 9.

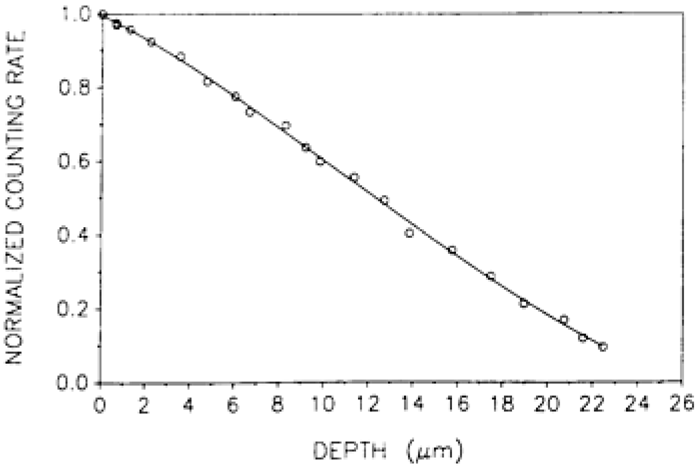

Fig. 9 Typical activity versus depth profile calibration curve. Linearity implies relatively uniform concentration of activity.

Tracer Calibrations. Tracer monitoring also requires calibrations, but not of activity versus depth, which is usually assumed to be uniform. Instead, a correlation between total activity, distributed in an unfiltered operating test system, and

detected counting rate must be made. If the detector is stationed at a filter, then activity in the filter must be correlated with detected counting rate.

Both filtered and unfiltered calibrations can be achieved by adding a known amount of activated debris (or simulated wear debris) to the lubricant or filter. A good check on this type of calibration is to add activated material in small increments to confirm a linear relation between counting rate and total added activity. Linear regression analysis on incremental readings also smooths out small measurement errors from each sample. An example of this type of calibration for a small bearing test rig, rather than a full engine, is shown in Fig. 10.

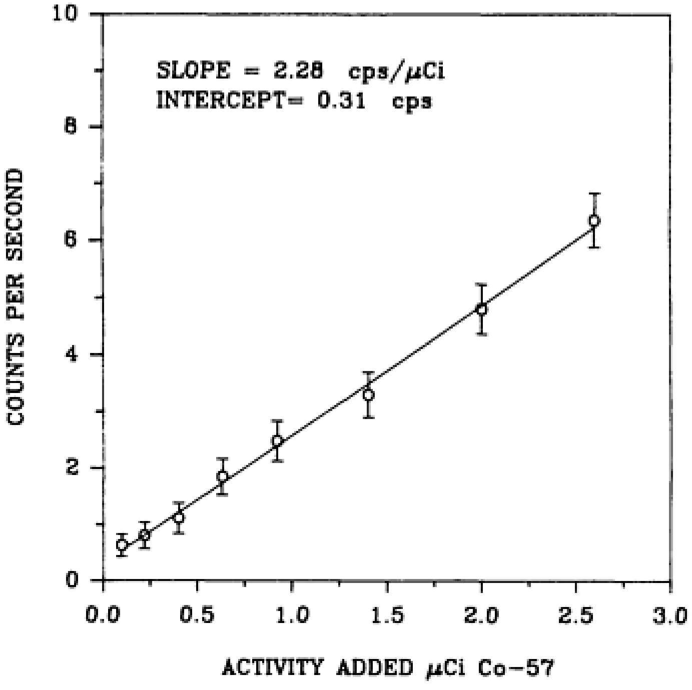

Fig. 10 Counting rate measured by a 50 × 50 mm (2 × 2 in.) detector as a function of activity dispersed in a lubricated bearing test rig with circulated oil

Attenuation and Detection of Gamma Rays. Interactions of gamma rays with matter critically determine SLA performance, both by creating scintillator responses and by attenuation of signal. The same mechanisms are responsible for both detection and attenuation: primarily Compton scattering, but also photoelectric absorption and electron-positron pair production.

Only a few nuclides with gamma energies that are sufficient to produce positrons also have long enough half-lives to be suitable for SLA monitoring. Photoelectric absorption is only prominent for low energies or very high atomic numbers. Consequently, interactions essential for both detection and attenuation are dominated by Compton scattering in most SLA configurations.

It is often useful, in planning an SLA measurement, to estimate the detected counting rate based on distance from source to detector, source strength, gamma energy, thickness of attenuator, and size of the detector scintillator. This estimate is important for optimizing the signal from a monitored component and minimizing interference from background nuclides. Choice of nuclide, source strength, and detector size may all need revision if the counting rate is too low or too high.

Measured intensity from a point source (small compared to the distance, *r*, to the detector) is proportional to $1/r^2$. This means they should generally be as close as practical to ensure a strong signal. Signal strengths for a 76 × 76 mm (3 × 3 in.) detector can be more than adequate several feet away from quite modest sources, but when attenuation is added, the detector may require closer positioning to avoid signal-to-noise problems in brief readings.

The $1/r^2$ dependence occurs because the detected signal is proportional to the effective solid angle (surface area subtended on a sphere of unit radius) intercepted by the cross-sectional area of the detector. However, this is exactly $1/r^2$ only when

detector and source are both small, compared to the distance. In fact, sensitivity to changes in range is enhanced for detectors that are moderately large, compared to *r*. The size of this increase can be $1/r^3$ or better over a selected range. In contrast, at extremely close range, measured intensity becomes insensitive to changes in *r*.

Attenuation in intervening material in many systems has a stronger effect on detected signal than range. Intensity falls exponentially on passage through matter with a strong dependency on energy, density, and atomic number (*Z*). Because attenuation depends on different processes, effects of atomic number vary with gamma-ray energy. Also, at low energies where the dependence is approximately Z^3, discontinuities occur because of x-ray shells.

The complexity of these dependencies is concealed in the relatively simple attenuation formula:

$$I = I_0 \, e^{-\mu \rho x} \qquad \textbf{(Eq 1)}$$

where I is the detected radiation flux, I_0 is the source flux, μ is the mass attenuation coefficient, ρ is the mass density, and x is the linear range through the material in question. The mass attenuation coefficient, μ, can be represented as a sum of attenuation coefficients for each of the separate interaction processes:

$$\mu_{(\text{total})} = \mu_{(\text{photo})} + \mu_{(\text{Compton})} + \mu_{(\text{pair})} \qquad \textbf{(Eq 2)}$$

As previously discussed, Rayleigh and other very low energy photon interactions are negligible above a few keV. Therefore, the corresponding additional terms are missing. Because $\mu_{(\text{total})}$ contains the complicated dependencies on materials, values are most easily obtained from readily available tables (Ref 78, 79, 80). Representative plots for steel and the detector material are provided in Ref 81.

Presence of mass density, ρ, in the exponent implies that the denser the material, the more rapidly the signal is attenuated. Consequently, the detector should be positioned to avoid intervening materials, particularly dense or large atomic number materials, which can block the signal or create a shadow effect.

Partial shadowing can be especially troublesome if the source moves at all with respect to the shadowing object during measurements. Materials such as steel or, especially, lead and tungsten can also be used to collimate or shield sources for storage and shipment.

In addition to solid angle effects, the issue of appropriate detector size is complicated for high-energy gamma rays by thickness of the scintillator, which can greatly affect efficiency. Lower-energy interactions are unaffected by extra scintillator material if they are certain to occur near the front surface.

Detector Configuration. Following calibration, the activated part can be installed with a gamma-ray detector nearby. Sodium iodide scintillator (activated by thallium) is usually preferred, because of its relatively high detection efficiency and stability in light output when operating at room temperature. Even large crystals are relatively inexpensive, which is important for working with small or heavily attenuated sources with penetrating hard gamma rays.

Energy resolution in NaI(T1) is at least a factor of two better than similar materials, such as plastics or bismuth germanate. Most SLA applications are in low-background environments and involve only one or two nuclides. Consequently, high-resolution provided by cryogenic semiconductor detectors (Ge or GeLi) is not needed. Bismuth germanate does have advantages, when cold, in detection efficiency (particularly important for high-energy gamma rays) and resistance to thermal shock.

Alkali halide scintillator detectors were invented in 1948 at Stanford University (Ref 82), and several good reviews are available (Ref 83, 84). The material is relatively dense (3.67 g/cm^3), and it has a high effective atomic number that is due to iodine (Z = 53) in the compound. This results in a high electron density, which is an important parameter in determining overall registration efficiency.

Characteristics of Sodium Iodide Spectrometry. When gamma rays either Compton-scatter or are absorbed through the photoelectric effect in the scintillator material, recoiling or ejected electrons interact to produce a cascade of secondary electrons. These also scatter before coming to rest, until all of the energy from the original interaction is

deposited. The result is to excite electrons that remain electrostatically bound to the hole produced in the valence band, forming an electron-hole pair, or "exciton."

These excitons can wander through the lattice until they encounter the thallium activator (about 0.1 to 0.3% doping), an impurity that creates a high probability of secondary excitation, followed by radiative decay. The overall effect is to cause a relatively fixed portion of the original energy deposited to transform to light by fluorescence of the impurity. Thallium was selected for wavelengths that match the photocathode response curve and to which NaI is transparent. These are broadly peaked near 413 nm and range from 300 to over 500 nm, well into the visible wavelengths.

Decay time for this light pulse (to 1/e of original intensity) is about 230 ns, which is typically larger than the photomultiplier transit time, but smaller than the amplifier shaping time (usually about 1 μs). Much faster electronic designs are available, but are not needed for the very low counting rates typical of SLA. Constant fraction discrimination or time-of-pulse-peak determination using differentiation and zero-crossing circuits can even circumvent the phototube and scintillator time restrictions to achieve subnano-second resolution.

The basis for SLA is that total fluorescence intensity is proportional (with statistical variations from the number of photons involved) to the excitation produced. This is, in turn, proportional to energy deposited by the original gamma ray. The major function of the multichannel analyzer, then, is to sort these pulses by height, producing a spectrum plotting intensity (or counts) as a function of detected gamma energy. The process is therefore called pulse-height analysis. A schematic diagram of this process is shown in Fig. 11.

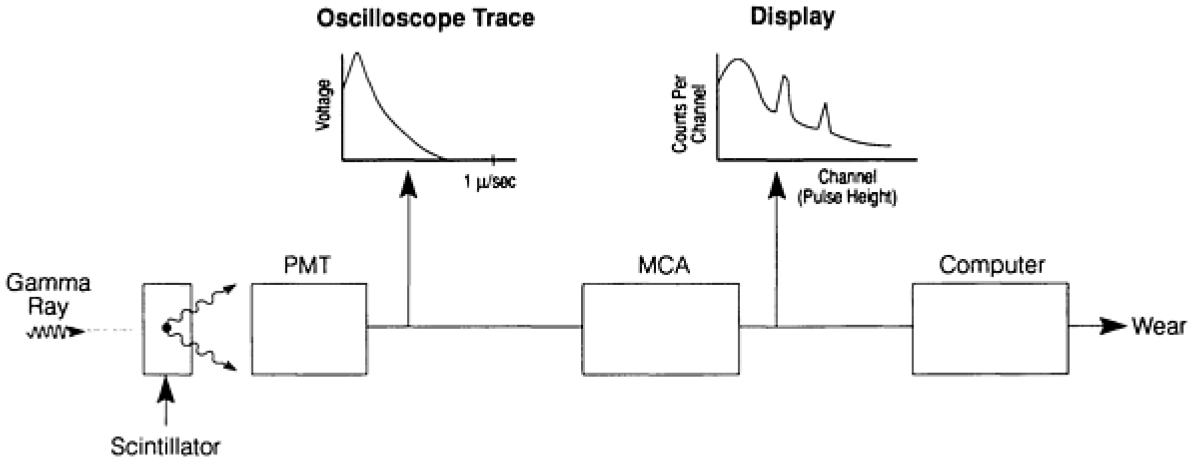

Fig. 11 Components in pulse-height analysis

Spectrum Details. The resulting spectrum has a number of features, some of which are useful, and some of which either constitute an interfering background or combine to form a noise continuum. The most important feature for SLA, and spectrometry in general, is the so-called photoelectric peak produced by complete absorption of the original gamma-ray energy in the detector. This occurs most frequently through photoelectric absorption or through secondary absorption of a Compton photon that also scattered in the scintillator. The object for SLA is to resolve a photopeak from others and from background contributions. Many techniques for achieving this resolution and interpreting the results are described in available literature (Ref 85, 86, 87).

If a Compton photon escapes after scattering, the partial energy deposited registers below the full-energy photopeak. Because this energy and cross section for scattering are angle dependent, Compton scattering combined with photon escape creates a broad plateau. The upper energy boundary is referred to as the "Compton edge" formed when the gamma ray scatters backward 180° from incidence.

A complementary Compton peak often appears below the Compton edge, because of photons absorbed after backscattering outside the scintillator. The positions of the Compton edge and peak can be calculated using the Compton equation:

$$E' = E/[1 + (1 - \cos\theta)\, E/mc^2] \qquad \textbf{(Eq 3)}$$

where E and E' are the incident and scattered photon energies, θ is the scattering angle, and mc^2 is the rest mass energy of the electron, 0.511 MeV.

The recoiling electron energy and, therefore, the registration energy given by $E - E'$ have a maximum value for backward scattering, where $\theta = 180°$. Consequently, the Compton edge occurs at:

$$e_{max} = \frac{2E^2}{mc^2 + 2E} \qquad \textbf{(Eq 4)}$$

and the Compton peak occurs at:

$$E_{max} = \frac{E}{1 + 2E/mc^2} \qquad \textbf{(Eq 5)}$$

Photons detected after multiple scattering form a low-energy continuum, which merges with electronic noise because of random thermo-electric emission in the photomultiplier and amplifier circuits. Representative spectra are shown in Fig. 12 and 13. For very weak signals, noise that is due to externally generated background photons can be reduced somewhat by shielding the detector.

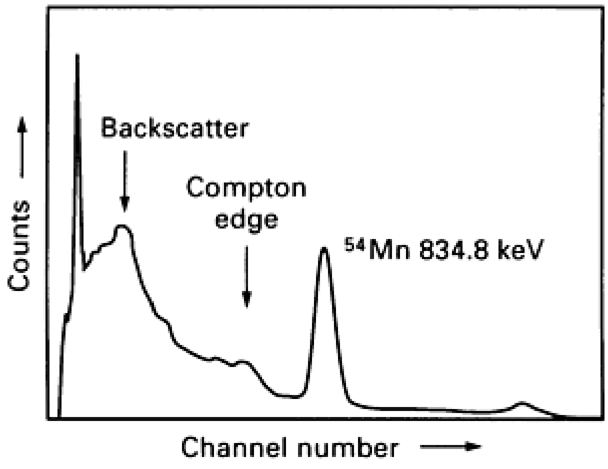

Fig. 12 Typical gamma spectrum for ^{54}Mn

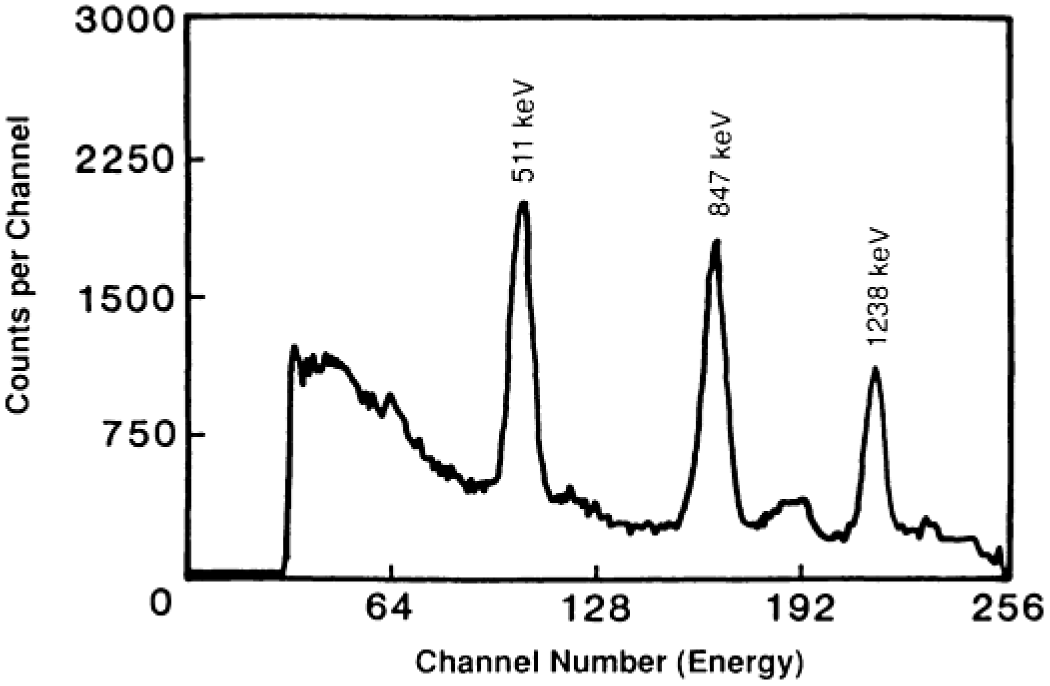

Fig. 13 Typical gamma spectrum for ^{56}Co with multiple peaks indicated

Statistical Considerations. Data reduction to separate peaks from background is critical to ensure reliable SLA measurements. In most situations, spectra are relatively simple in that they contain contributions from only one or two nuclides. The only difficulty is that the signal strength is often low, and prolonged counting may be needed to ensure minimal statistical variation.

At least 10,000 counts are needed under an isolated photopeak to ensure a 1%, one uncertainty. When the signal is comparable to background "noise," shielding or coincidence arrangements can be used to improve the separation of signal counting rate from background. Because this is effectively a subtraction, uncertainties add in quadrature. Therefore, many more counts are needed under the peak to ensure precision.

Source strength, attenuation, and detector efficiency together determine measured counting rate under the peak which, in turn, determines length of each measurement interval to produce a particular level of scatter in the data. For marker measurements, this relation of interval and variability is virtually fixed, once the detector and source are installed. Intervals can only be shortened during operation by sacrificing some precision. Consequently, some planning is needed to ensure a reasonable counting rate. A larger source, larger detector, or better mounting position may be needed.

For markers, the best counting rate occurs at the start of monitoring. As testing continues, both surface loss and natural decay reduce the counting rate. Thus, either measurement intervals must increase or precision will decrease with testing. An artificial limit of 90% of the profile depth is well advised, because similar limits to accuracy apply in producing the profile calibration.

For tracers, the original signal is zero, or very close to it. When wear begins, the signal typically jumps dramatically to a nonzero value, and counting statistics continue to improve as wear increases. This gives tracers and advantage in detecting onset of wear, because it is generally easier to detect a doubling or tripling of a small counting rate, than to detect a 1% drop in a larger marker counting rate.

Detector Mounting. Because the way the detector is mounted can create other adverse effects, some planning is again needed to ensure an effective mounting. Dominant concerns are to:

- Maximize counting rate while avoiding cross talk (from other sources or debris accumulations)
- Ensure a fixed geometry relative to source and attenuator

- Minimize temperature changes
- Avoid hazards to detector integrity (vibration, shock, and rapid temperature changes)

As previously discussed, counting rate can be increased by reducing either the source-to-detector range or attenuation, or both. However, this is generally subject to constraints on threats to the detector. In proximity to engines or power systems, the detector often must be wrapped in a blanket of thermal insulation or water cooled (Fig. 14). The mounting frame must be heavy enough to prevent large-amplitude vibrations or motion.

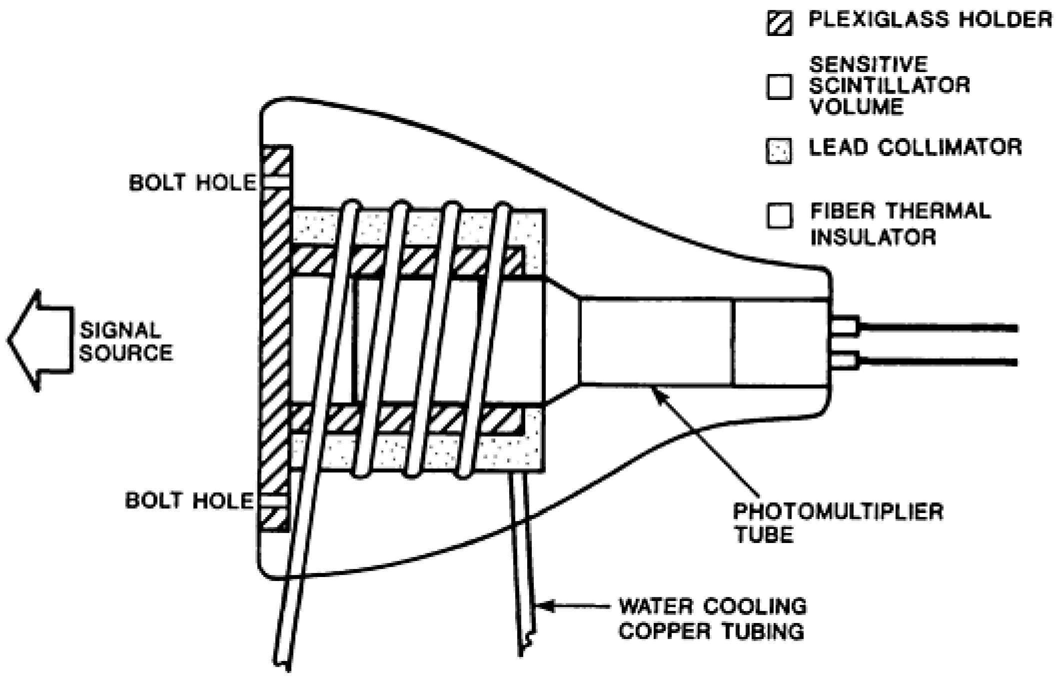

Fig. 14 Commonly used detector insulation and cooling scheme

Another concern is that wear debris containing the active nuclide must be positively removed from the area of the detector to produce a valid measurement. Generally, this is guaranteed by early planning of the program, which considers the action of lubricants, or fluids, in the system.

Sometimes additional shielding is needed to prevent debris in oil lines, traps, and filters from continuing to affect the detector. If other sources are monitored in the same system or if radiation is in the test environment (thorium is often used in engines to make refractory components), then the detector may require shielding all the way around, creating a telescopic tube, or collimation.

Temperature of the detector is another possible concern, particularly if operation of the system is intermittent so that heat flow frequently changes. In addition to the need to protect the detector from thermal shock that is due to rapid temperature changes (greater than about 7 °C, or 12 °F, per hour for larger NaI crystals), it is possible that photo-conversion efficiency and photomultiplier tube gain can both be affected by temperature.

Fortunately, efficiency changes are relatively minor effects near room temperature for NaI(Tl), as shown in Fig. 15. This is an important advantage for this type of detector. Operation at higher temperatures is also possible, but stability becomes more critical. Because the phototube produces its own heat, starting with a cold detector that is below 10 °C (50 °F) can cause thermal shock to the scintillator or damage to the dynodes.

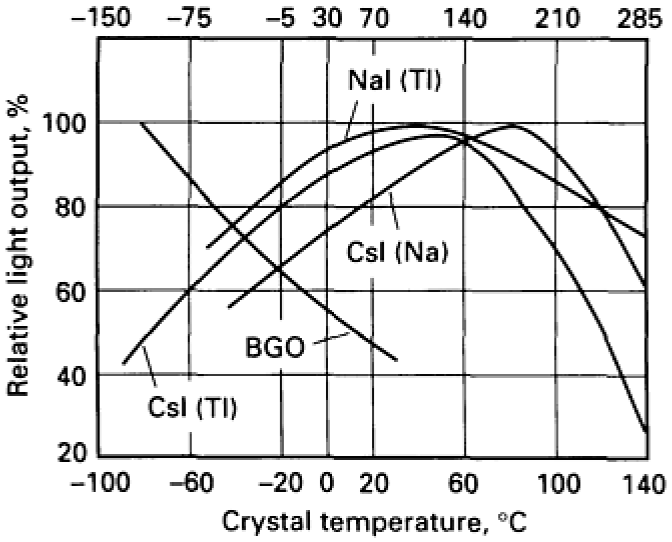

Fig. 15 Scintillator efficiency as function of temperature for several detector materials

Temperature-based changes in photomultiplier gain are primarily an annoyance, causing the photoelectric peak to move, but the area under the peak should be constant. There can be other causes of peak drift, as well. All can be corrected in analysis or by adjusting the amplifier gain to compensate.

Attenuation changes that are due to expansion of the mechanical system being monitored are only significant if temperature varies over a very large range during measurements and heavy attenuation is involved. The size of the effect depends on details of the system, but for less than 100 mm (4 in.) of steel, changes of less than 275 °C (500 °F) can usually be neglected. When thermal expansion effects are significant, initial no-wear reference readings should not start until the system is warmed to near operating temperatures. In some systems, measurable wear or erosion occurs during this warm-up. Therefore, readings must be extrapolated back to determine a warmed, but unworn, reference counting rate.

A more insidious, but potentially more problematic effect of system warm-up is due to movement of heavily attenuating components relative to the detector. These can cast a shadow on the detector, which moves as the system changes temperature. Thermal expansion causes minute effects, compared to those of a moving shadow. Consequently, care must be taken to avoid geometries with mobile shadows, even if a reduced average counting rate results.

Future Trends

SLA tracers and markers have been demonstrated to be ideal for unobtrusive measurement of μm-scale wear in operating systems, with many successful applications to engine components, such as pistons, cylinders, rings, liners, bearings, cams, and gears. Large industrial systems have also been effectively monitored, including steam turbine components, chemical reactor systems, piping, valves, orifice plates, fittings, and nozzles. Surface layer activation can also be used to study changes in composition or structure in off-line analysis to optimize engineered materials.

The precision offered by this type of technique can produce significant savings by reducing the test time required to produce measurable surface loss or to distinguish materials that are similar in durability. Parameters that influence surface loss can be varied rapidly to optimize conditions or to determine effects of related processes such as chemical (corrosive) reactions.

Consequently, the future of surface layer activation is quite promising. Because technical requirements have been thoroughly explored in the last two decades, new applications have become almost routine. In particular, techniques for producing reliable measurements from minimal sources, such as shallow markers, efficient detectors, collimation, and analysis methods, have made surface layer activation attractive to many smaller testing facilities that would not consider the reactor-nuclide-tracer methods common in the 1960s. Most modern marker applications do not even require licensing.

There are also high-temperature surface loss problems in industry and propulsion that benefit from this type of precision measurement. Because detectors operate outside the monitored system, it is relatively simple to protect them from harsh environments and heat. Industrial systems that operate at more moderate temperatures, but in corrosive or erosive environments, have already benefited from SLA capabilities.

The ability to precisely measure durability on-line, or to study migration of elemental components off-line, will be critical to development of advanced materials and coatings. SLA measurement offers a convenient and extremely precise way to meet modern requirements for *in situ* monitoring.

Eventual on-board wear monitoring in both ground (Ref 88) and flight (Ref 89) vehicles is also expected to be valuable, if not absolutely necessary, in systems that are designed to operate near critical design limits. Surface layer activation may eventually be required for routine diagnostic monitoring of critical engine components. Deeper profiles could be used for such long-term applications, and readings might be incorporated into the instrument displays to warn of potential component failure.

Introduction to Laboratory Characterization Techniques

A.W. Ruff, National Institute of Standards and Technology

MANY WELL-ESTABLISHED TECHNIQUES for the measurement and characterization of bulk materials and their surfaces have been successfully applied in published tribological investigations. In addition, specialized techniques have been developed in many instances to provide information for unique questions that have arisen in such investigations. The following articles discuss the most commonly used characterization techniques along with selected special methods, and they provide both examples and references to successful applications. The purpose of these presentations is to give the reader a broad picture of the choices available among the laboratory characterization techniques, and also to provide brief descriptions of the fundamentals involved with each technique. The emphasis in the presentations is on the methods themselves, on equipment requirements, and on illustrative examples.

Most of the characterization techniques discussed in these articles are reasonably well developed (light microscopy, for example); however, their application to friction, lubrication, and wear investigations has introduced new and difficult challenges. The authors of the following articles are expert in the techniques described, and in most cases they have some specific experience with tribological applications. However, the range of issues associated with tribological technology is so wide that readers are cautioned to be alert to significant differences that may exist between their application and any particular example being discussed.

The techniques described in the following articles would customarily be applied in a laboratory setting to either laboratory specimens from testing or research programs, or to specimens intended for or removed from service, that is, actual components in tribological systems. In any case, it is essential that *all* parts of the tribological system be considered. There is ample discussion elsewhere in this Handbook of the complexity of friction, lubrication, and wear phenomena. Both the type and the significance of each process involved in the overall tribological phenomenon varies from case to case. The correct and useful application of information obtained from the applied characterization techniques depends on a thorough, comprehensive consideration of all aspects: the solid bodies, the environment, and any damage products from the operation or test.

This caution to the investigator cannot be overemphasized. As an example, consider the premature wear-out of a component in a lubricated mechanical system. Such a problem could be caused by periodic overloading due to transient excessive loads, or by overheating and degradation of the lubricant, or by corrosion effects resulting from process stream leakage, or many other reasons. Correct analysis of this problem can hardly be expected if information is not obtained on the loading history of the device, or on temperature excursions of the lubricating system, or on corrosive contaminants in the lubricant, to list only a few areas of concern. Failure in a tribological system is frequently the result of various factors acting in combination. For this reason, the investigator usually must apply a combination of characterization techniques and integrate the results in order to obtain a correct explanation.

The order of presentation of the articles on the individual techniques is somewhat arbitrary, and it is not meant to represent a recommended sequence for any particular investigation. Each author presents some discussion of the appropriateness of the technique, and the type of information that it yields, in order to guide the reader in making choices in this complex area.

Surface Texture

J.F. Song and T.V. Vorburger, National Institute of Standards and Technology

Introduction

TRIBOLOGISTS are concerned with what happens when two solid surfaces slide over each other, under either dry or lubricated conditions. They often measure and compare the surface texture and roughness parameters before the after the wear process, and at intermediate stages as well. Understanding the relationship between wear properties and surface texture can lead to the specification of optimized surface textures and manufacturing processes for various surface function needs.

The term "surface texture" refers to the fine irregularities (peaks and valleys) produced on a surface by the forming process. By convention, the texture comprises two components; roughness and waviness. Roughness consists of the finer irregularities characteristics of the process itself, such as the grit spacing of a grinding wheel or the feed of a single-point tool. Waviness consists of the more widely spaced irregularities that are often produced by vibration in the machining process. Usually, however, the terms "surface texture" and "roughness" are used interchangeably, because roughness is specified and measured much more often than waviness. The surface topography includes these surface texture components as well as any other irregularities, such as error of form.

There are two types of profiling techniques for surface texture, depending on whether the height measurements are made simply along a line (profile methods) or over an area (raster area methods). Both types of techniques develop quantitative knowledge of the surface peaks and valleys by point-by-point measurement with a high-resolution probe. Surface profiles are generally measured across the surface lay, the direction of uniaxial machining marks caused by most surface forming processes. The profile may be produced by a contacting stylus that traverses the surface, by a noncontacting probe, or by optical interferometric fringes. The stylus method has been widely used (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10) by engineers, opticists, and tribologists. Therefore, the stylus technique will be discussed in some detail in this article as an important example of surface profiling. Other techniques are discussed elsewhere (Ref 11, 12).

Surface Statistics

In general, surface textures are highly complex, because many surface finishing processes, such as polishing, grinding, and shot blasting, are statistical by nature. To characterize such surfaces, two types of statistical descriptors are used: parameters, such as root mean square (rms) roughness, which attempt to quantify some aspect of the surface statistics with a single number, and statistical functions, such as the power spectral density, which by their nature yield an array of information about the surface.

Surface Parameters

There are a great variety of surface parameters, many of which have been developed to characterize the function of engineering surfaces for particular applications. In fact, about 50 to 100 parameters have been defined for industrial use, and many of these appear in national standards as well. Nevertheless, surface parameters can generally be classified as height parameters, wavelength parameters, shape parameters, and combinations of these, known as hybrid parameters.

Height Parameters. The most common statistical descriptors of surface height are the roughness average, R_a, and the rms roughness (also called R_q). These are closely related and are given by the following formulas, shown in integral and digitized form:

$$R_a = \frac{1}{L}\int_0^L |y(x)|\,dx = \frac{1}{N}\sum_{i=1}^{N} |y_i| \quad \textbf{(Eq 1)}$$

$$R_q = \left[\frac{1}{L}\int_0^L y^2(x)dx\right]^{1/2} = \left[\frac{1}{N}\sum_{i=1}^{N} y_i^2\right]^{1/2} \quad \textbf{(Eq 2)}$$

where $y(x)$ is the surface profile, sampled by the set of N points y_i over the length, L, as shown in Fig. 1. The parameters R_a and R_q are useful estimators of the average heights and depths of surface profiles. The rms roughness is commonly specified for the surfaces of optical components. In general, the lower the rms roughness of an optical component, the less stray scattered light and thus the higher the quality of the component. Roughness average is used in the automotive and other metalworking industries to specify the surface finish of many types of components, ranging from cylinder bores to brake drums (Ref 13). In addition to these two averaging height parameters, an assortment of other height parameters have been defined for various applications, including several for characterizing peak-to-valley height (Ref 4, 14).

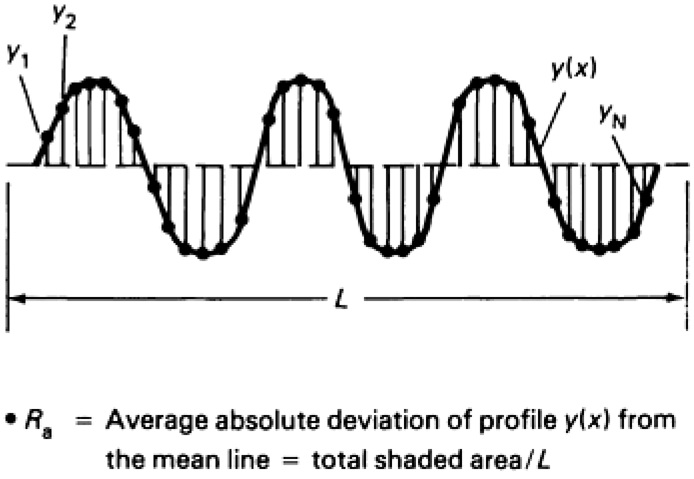

Fig. 1 Idealized stylus profile showing the mean line; the evaluation length, *L*; the digitized points, y_i; and a definition of the parameter R_a

Wavelength parameters are used to characterize the spacings of the peaks and valley of the surface. The spacings or wavelengths are often characteristics of the process that formed the surface, such as the shot size used for abrasive blasting, the grit size of a grinding wheel, or the feed of a tool. A typical wavelength parameter, recognized as standard by the International Organization for Standardization (ISO), is the mean peak spacing S_m (Ref 14), defined for a surface profile as the average spacing between two successive negative crossings of the mean line (see Fig. 2).

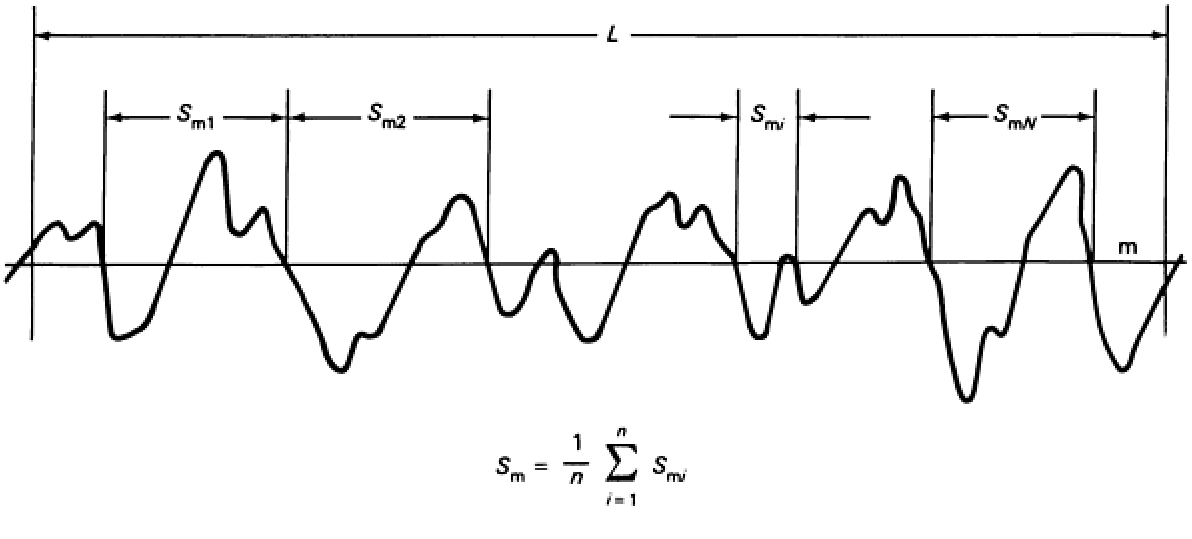

Fig. 2 Surface profile showing the ISO definition for the peak spacing parameter, S_m

Shape Parameters. The periodic profiles in Fig. 3 all have the same R_a and wavelength, but have different shapes and thus may perform differently in different applications. In particular, the profile in Fig. 3(b) represents a good load-bearing surface, and the profile in Fig. 3(a) represents a poor one. Because of its facets, the profile in Fig. 3(c) is best used as a diffraction grating, whereas one of the other surfaces may be most suitable for lubricated sliding. Shape parameters help to quantify the differences between these surfaces. The most important parameter, the skewness, is a measure of the symmetry of the profile about the mean line. It is defined as:

$$R_{sk} = \frac{1}{NR_q^3} \sum_{i=1}^{N} y_i^3 \quad \textbf{(Eq 3)}$$

According to this definition, the skewness of the profile in Fig. 3(a) is positive, whereas its opposite number (Fig. 3b) has negative skewness. The other two profiles (Fig. 3c and Fig. 3d) are symmetrical and have zero skewness.

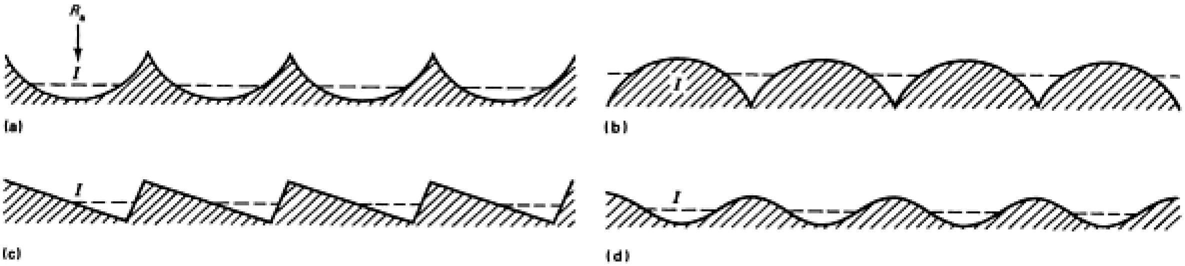

Fig. 3 Profiles for four different surfaces with the same roughness average, R_a, and wavelength but varying skewness, R_{sk}. (a) $R_{sk} > 0$. (b) $R_{sk} < 0$. (c) $R_{sk} = 0$. (d) $R_{sk} = 0$. The dotted line shows the position of the mean value.

Hybrid Parameters. Slope and curvature are two examples of quantities that combine the concepts of height deviation and lateral displacement and are thus termed hybrid parameters. They may be defined analytically or digitally in several ways. Hybrid parameters have been used in a number of areas of tribology, such as theories describing elastic contact (Ref 15) and thermal contact conductance (Ref 16).

Statistical Functions

More complete statistical descriptions of the properties of surface profiles can be obtained from statistical functions, such as those used in random process theory and time series analysis (Ref 17, 18, 19). Four important statistical functions are the amplitude density function or height distribution, the bearing area curve, the power spectral density, and the autocorrelation function. The definitions and applications of these functions are described in several sources (Ref 2, 6, 7, 17, 18, 19, 20, 21, 22, 23). The power spectral density and the autocorrelation function will be discussed in detail here.

The power spectral density (PSD) decomposes the surface profile into its spatial Fourier component wavelengths. It is given analytically by:

$$\text{PSD}(F) = \lim_{L \to \infty} \left(\frac{1}{L}\right) \left| \int_0^L y(x) \cdot e^{-2i\pi Fx} dx \right|^2 \quad \textbf{(Eq 4)}$$

and is estimated in digitized form by:

$$\mathrm{PSD}(F) = \mathrm{PSD}(k) = \frac{1}{N\Delta} \left| \sum_{j=1}^{N} y(j) \cdot e^{-2i\pi kj/N\Delta} \right|^2 \quad \text{(Eq 5)}$$

In Eq 4 and 5, Δ is the lateral point spacing (sampling interval) of the digitized data points, the total length of the profile, *L,* is equal to $N\Delta$, and the set of spatial frequencies, *F,* in the digitized PSD is given by *k/L,* where *k* is an integer that ranges from 1 to *N*/2. Calculation of the digital Fourier transform in Eq 5 can be greatly speeded by using fast Fourier transform (FFT) algorithms (Ref 24, 25).

Figure 4 illustrates the sensitivity of the PSD to the different characteristics of surfaces produced by different processes. Figure 4(a) shows the PSD plotted for a highly sinusoidal surface, a prototype of those available from the National Institute of Standards and Technology (NIST) as standard reference materials (Ref 26, 27). The Fourier amplitude at the fundamental frequency of 0.01 μm^{-1} (wavelength = 100 μm, or 10^6 Å) is the dominant feature in the curve, but imperfections in the sinusoidal nature of the surface are also evident from the presence of higher harmonics in the spectrum. By contrast, Fig. 4(b) shows a more random surface produced by the grinding process and its PSD (Fig. 4c) that has a fairly decaying, albeit somewhat randomized, distribution, with little evidence of periodic components.

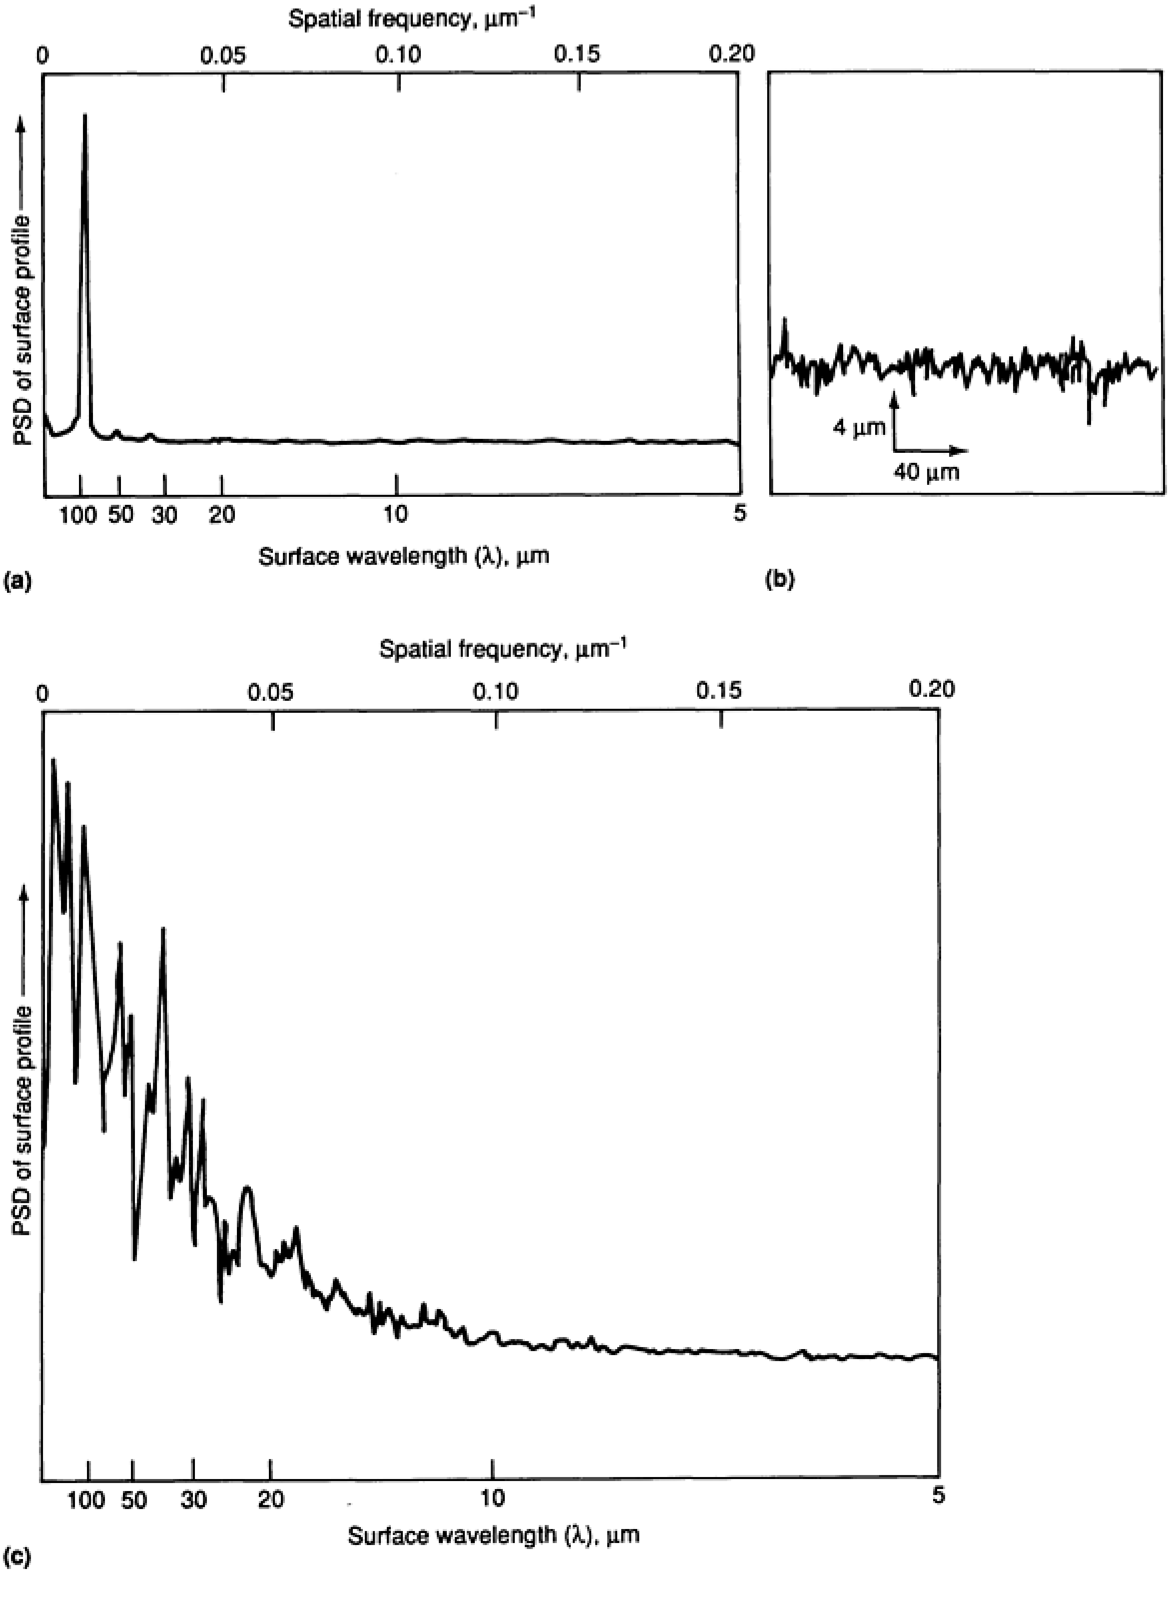

Fig. 4 Power spectral density functions for profiles of two roughness specimens. (a) Sinusoidal roughness specimen machined by diamond turning with R_a of 3 µm (120 µin.) and spatial wavelength of 100 µm (10^6 Å). (b) Roughness profile of a commercially ground surface whose PSD is shown in (c). (c) Commercially available specimen of a ground surface with R_a of 0.6 µm (24 µin.). Both power spectra are calculated for profiles having trace lengths of 3.8 mm (0.15 in.). The ordinate values are equal to the square root of the power spectral density values and are plotted in arbitrary units.

Autocovariance and Autocorrelation. The complementary function to the power spectral density is its Fourier transform, the autocovariance function, $C(\tau)$:

$$C(\tau) = \int_{-\infty}^{\infty} [\mathrm{PSD}(F)] e^{2i\pi F\tau}\, dF \qquad \text{(Eq 6)}$$

Alternatively, the autocovariance function can be calculated directly from the profile itself. That formula is given by an overlap integral of shifted and unshifted profiles:

$$C(\tau) = \frac{1}{L}\int_{0}^{L} [y(x)][y(x+\tau)]dx \qquad \text{(Eq 7)}$$

where the quantities L and $y(x)$ have been defined previously.

The value of the autocovariance function at zero shift ($\tau = 0$) is by definition equal to the mean square roughness, R_q^2, of the profile, provided an appropriate mean line has been subtracted from the profile to calculate $y(x)$. When the autocovariance function is normalized by dividing by the zero shift value, the result is known as the autocorrelation function (ACF), $c(\tau)$:

$$c(\tau) = \frac{C(\tau)}{R_q^2} = \frac{\int_{0}^{L} [y(x)][y(x+\tau)]dx}{\int_{0}^{L} [y^2(x)]dx} \qquad \text{(Eq 8)}$$

If the fact that the overlap between the shifted and unshifted profiles decreases as the shift distance increases for a finite length profile is taken into account and the digital formulation is simultaneously used, the ACF can be estimated by:

$$c(\tau) = \left(\frac{1}{N-j}\right)\left(\frac{\sum_{i=1}^{N-j} [y(i)][y(i+j)]}{\sum_{i=1}^{N} y^2(i)}\right) \qquad \text{(Eq 9)}$$

The autocovariance and autocorrelation functions are useful for visualizing the relative degrees of periodicity and randomness in surface profiles. For example, Fig. 5 shows ACFs for germanium and silicon surfaces calculated from surface profiles measured by a stylus instrument (Ref 28). Both surfaces were machined by diamond turning under similar conditions, but the periodicity imposed by the feed of the tool was much stronger on the silicon surface and thus its ACF is highly periodic. Because of its more random surface topography, the germanium surface exhibits a strongly decaying ACF, with only a small amount of periodicity shown as a barely visible oscillation.

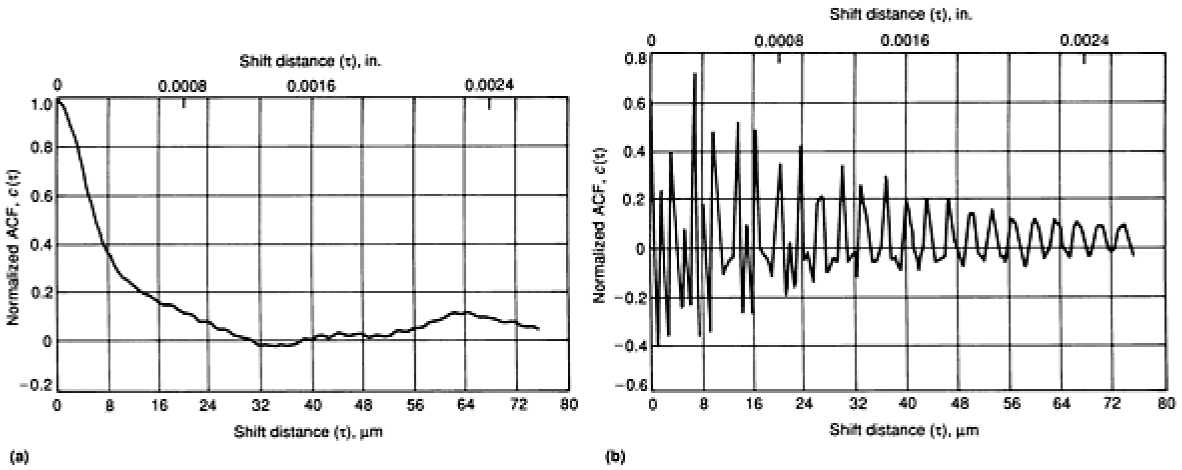

Fig. 5 Autocorrelation functions for single-crystal surfaces machined by diamond turning. (a) Germanium. (b) Silicon. The curve for germanium is an average of three ACFs measured at different positions on the surface. For silicon, the curve is an average of four ACFs.

Therefore, as measures of the lateral structure of surfaces, the PSD and the ACF seem to be useful in different ways. The PSD is useful for studying the strengths of various periodic components in the surface profile and for comparing these with the strength of the broad spectrum of random components. The ACF is useful for observing directly the lateral extent of the random structures on the surface by studying the decay in the function near zero shift.

Other Descriptors

As stated previously, scores of parameters and functions have been developed to quantify stylus profiles of surfaces, many of these for applications in tribology and engineering. The choice of roughness parameters and/or statistical functions to characterize the surface function adequately is critical for each application. An example from the automotive industry will be discussed here.

Finishing of engine cylinder bores by the plateau honing process (Ref 29) may result in an optimal cylinder bore surface texture. This surface has a negative skewness, R_{sk}, which results in good performance for running-in, long-term running, and lubrication of the cylinder bores. In such situations, the traditional roughness parameters, R_a, does not adequately estimate the performance of cylinder bore surfaces. The deep valleys, which can be used as oil reservoirs during engine operation, are better quantified by combining R_a with R_{sk}. Indeed, other parameters, such as the R_k family (Ref 30), have also been developed as functional descriptors of these types of surfaces.

Therefore, it may be possible to optimize the functional performance of engineering surfaces by combining the specification of surface texture parameters, material, and manufacturing process with the development of quality control procedures. This combination has been called "surface texture design" (Ref 31).

It is likely that in surface science, too, other topographic parameters can be developed that correlate well with performance. For example, Blakely and Somorjai (Ref 32) and others correlated the ability of a surface to foster certain surface chemical reactions with the presence of lattice steps on the surface. These ideas could be quantified in terms of a step density parameter that might be defined as the fraction of surface atoms that are adjacent to lattice steps.

Experimental Issues for Stylus Instruments

The height resolution and range of stylus instruments depend largely on two factors: the transducer and the mechanical noise and straightness of the traverse mechanism. In many research instruments, the transducer is a linear variable differential transformer (LVDT) (Ref 3) that, together with demodulation and amplification circuitry (Ref 33), produces an output directly proportional to surface height. Another type of transducer based on optical interferometry also produces a signal directly proportional to height (Ref 34). Inductive and piezoelectric transducers that are sensitive to the vertical motion of the stylus (that is, the time derivatives of the stylus tip height rather than the height itself) are also

available (Ref 33, 35). These types are generally more economical than LVDTs and are more generally used in industrial shops than in research or metrology laboratories.

An example of an LVDT is shown schematically in Fig. 6. As the stylus moves vertically, the ferrite core is displaced from the balance position of an alternating current (ac) bridge, to which the coils are connected, and which is driven at a high carrier frequency. The out-of-balance voltage signal that is demodulated and amplified is proportional to the vertical displacement of the stylus. Some transducers are so sensitive as to have rms noise levels of about 0.1 nm (Ref 7), which means that surface structures approximately one atom high can be detected. Other LVDT transducers have vertical range as large as several hundred micrometers or more, and, in general, the ratio of range to resolution is on the order of 10^5. One version of the optical transducer (Ref 34) mentioned above has an even wider range (~4 mm, or 0.16 in.) and a resolution of approximately 0.01 μm.

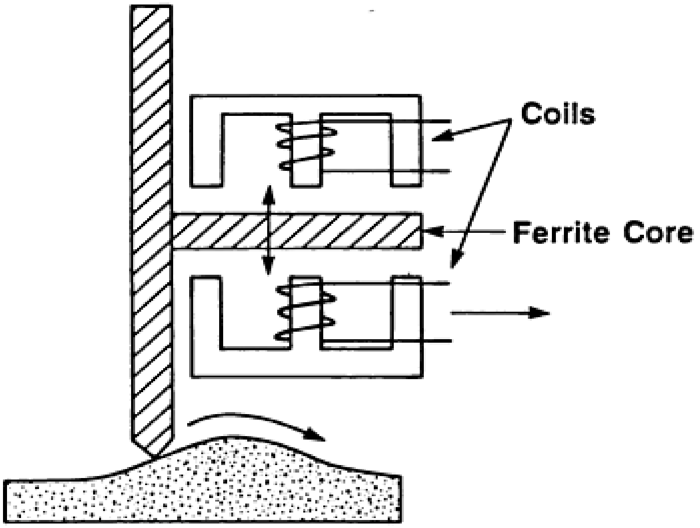

Fig. 6 Schematic showing key components of a high-sensitivity LVDT. As the stylus traverses the peaks and valleys of the surface, the ferrite core moves vertically with respect to the coils.

Three types of designs for achieving low scanning noise and good straightness of travel are shown in Fig. 7. The least expensive method involves the use of a skid (Fig. 7a), which traces a references line on the surface very near to the LVDT. The vertical position of the stylus is measured with respect to the path of the skid. The skid also serves as a high-pass mechanical filter because it averages over a fairly wide swath of surface peaks. Mechanical noise in the drive mechanism can be significantly reduced by this approach, because such noise does not couple well into relative motion between the stylus and the skid to which it is referenced.

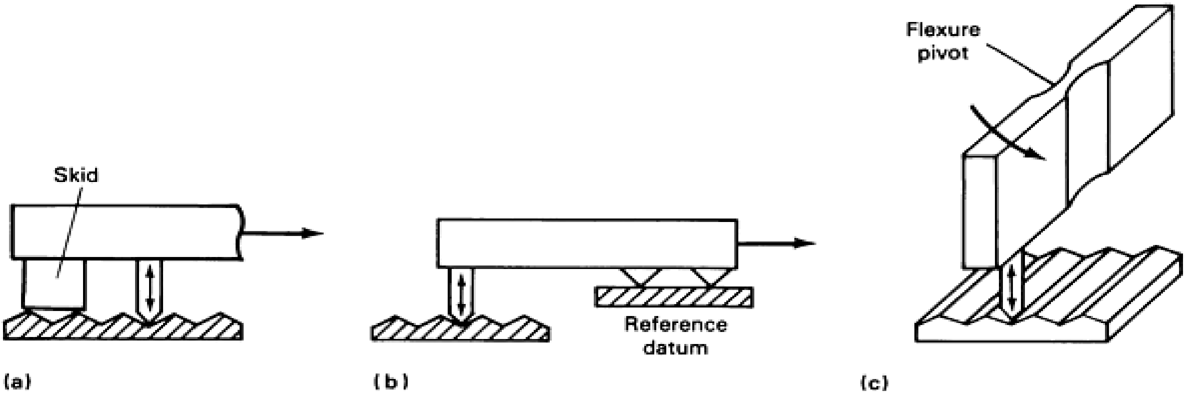

Fig. 7 Schematic showing three types of configurations used to constrain unwanted motion of the stylus. (a)

High-pass mechanical filter skid. (b) External reference datum to guide tracer motion. (c) Flexure pivot setup

Figure 7(b) schematically shows an external reference datum surface that guides the motion of the tracer. Well-engineered tracing systems may minimize the Abbé offset (Ref 36) between the reference surface and the measured surface by placing the stylus contact and the set of reference contacts as close to the same vertical line as possible. Alternatively, such systems may minimize the amount of angular motion and vibration in the carriage.

The design shown in Fig. 7(c) involves no sliding components at all. Rather, a flexure pivot or a set of pivots constrains the motion to a plane that is perpendicular to the axis of the pivot. The solid construction provides highly noise-free motion. One commercial design has been shown to provide approximately 0.1 nm rms noise (Ref 7) over a trace length of 1 mm (0.04 in.). Another variation of the flexure approach (Ref 37) involves multiple sets of flexures to allow for motion in two directions.

For measurements of smooth surfaces that require high vertical magnification, the straightness error of the traverse mechanism can seriously distort the measured profile. Figure 8(a) shows a distorted profile of a 91 nm (3.6 µin.) step-height specimen (Ref 31). The use of the skid can substantially eliminate this error (see Fig. 8b), because the reference datum is a portion of the surface located very close to the stylus. This consideration is closely related to the Abbé principle in dimensional measurement (Ref 36). The skid approach works well as long as the skid is traversing on a smooth reference surface. However, use of the skid can lead to unwanted distortions in the profile, particularly in cases where the surface contains isolated peaks (Fig. 9). Another problem with skids is the potential for surface damage, because the skid loading on the surface may be hundreds of times larger than the stylus force.

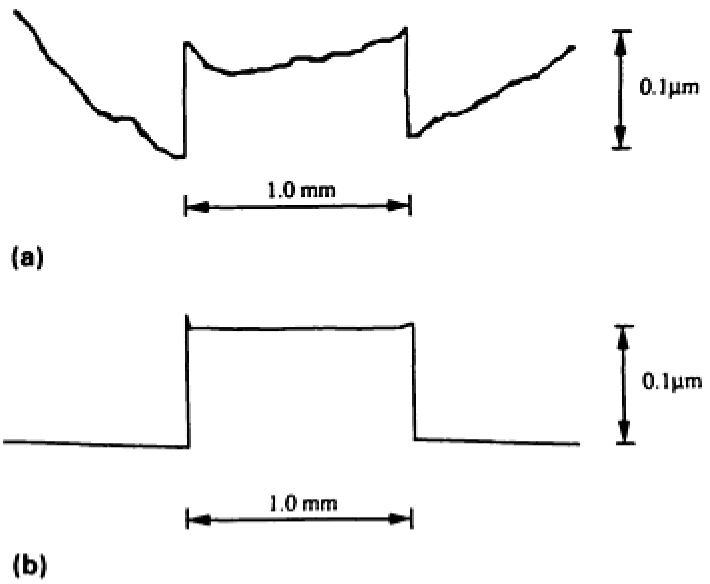

Fig. 8 Profile of a 91 nm (3.6 µin.) step-height specimen distorted by the straightness error of the traverse mechanism of the stylus instrument. (a) Stylus without skid. (b) Stylus with skid

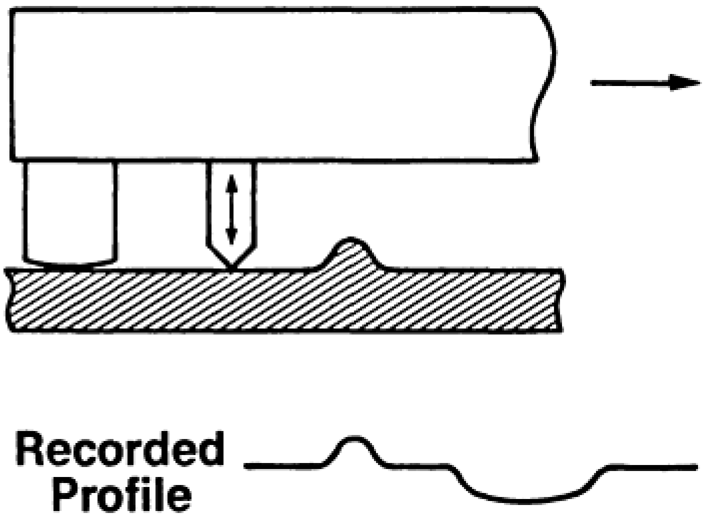

Fig. 9 Schematic showing an isolated peak on the specimen surface generating a false valley in the profile that was measured by a stylus instrument incorporating a skid

Lateral Resolution and Range. The draw-back of flexure designs is that the trace length is limited by the degree to which the flexure may be bent before the elastic bending forces become too large. In the two designs discussed above, that trace length limit is about 2 to 3 mm (0.08 to 0.12 in.). However, as a rule, lateral range is not a problem for stylus instruments. The lead-screw drive mechanisms of many instruments permit trace lengths on the order of 100 mm (4 in.) or more.

Because a stylus profile represents the convolution of the surface structure with the end form of the stylus, the lateral resolution depends critically on the size of the stylus tip and to a lesser degree on the flank angle. Styli are often flattened at the end, the width across the flat essentially determining the lateral resolution. A commonly available width is 2 μm (80 μin.), but pyramidal styli with tips as small as a nominal 0.1 × 0.1 μm (4 × 4 μin.) are also used. In some instances, highly spherical styli are also produced. Bennett and Dancy (Ref 7) and Vorburger *et al.* (Ref 38) show micrographs for these. Figure 10(a) shows a stylus with a tip width of ~0.05 μm as measured by the razor blade tracing technique (Ref 38, 39). One year later, after dozens of traces, the profile graph of the same stylus (Fig. 10b) shows a certain amount of wear, because the width has increased to approximately 0.15 μm (6 μin.).

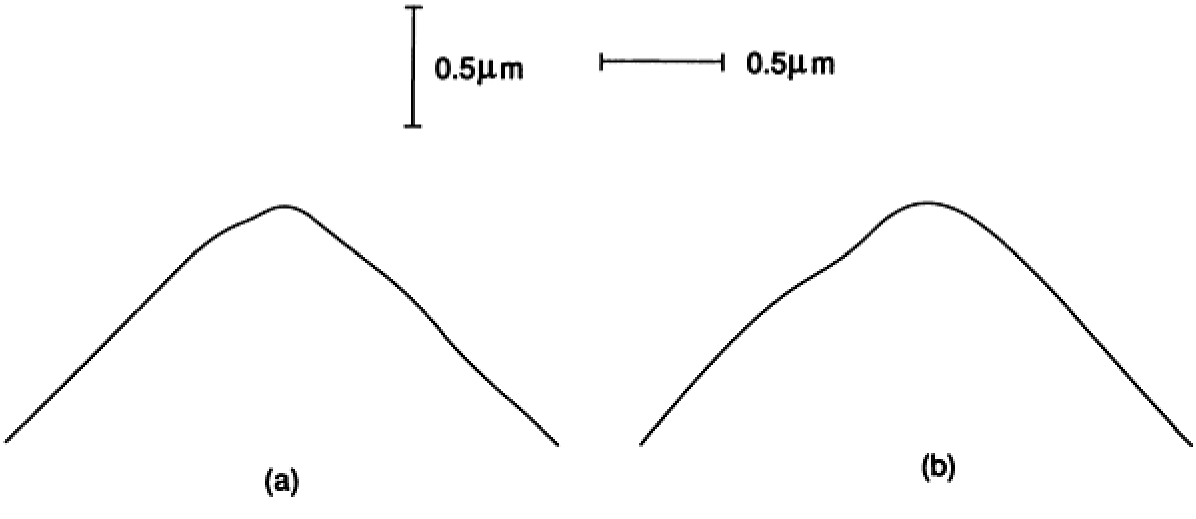

Fig. 10 Profile graph of low-usage stylus related to profile graph of identical stylus after 15 months of service. (a) Measured in March 1988 with a tip width of approximately 0.05 μm (2 μin.). (b) Measured in June 1989;

width is approximately 0.15 μm (6 μin.) after dozens of traces.

If the stylus tip is spherical, the lateral resolution can be smaller than the tip radius, *r*. Figure 11 shows the geometrical construction when a spherical stylus first contacts a step, which is assumed to be infinitely sharp. If $h \ll r$, the point of initial contact occurs at a position $\sqrt{2hr}$ to the left of the step edge; thus, $\sqrt{2hr}$ represents the width of the transition and the effective resolution of the stylus. The calculation assumes that no deformation occurs at the single point of contact. In the case of a 1 μm (39 μin.) radius stylus and a step of height 10 nm, the calculated transition width is 0.14 μm (5.5 μin.).

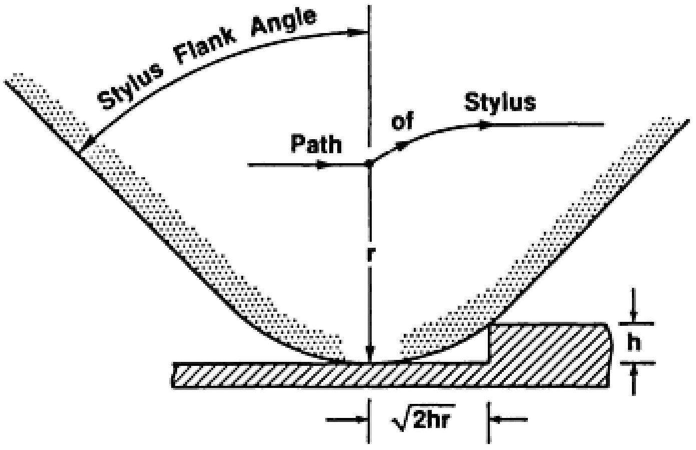

Fig. 11 Schematic showing the path traced by a spherical stylus tip traversing over a small, sharp step

The flank angle of the stylus (Fig. 11) also affects its resolution. The stylus cannot accurately profile over slopes greater than the flank angle (usually ±45°). This is not a problem for most types of smooth surfaces where the average surface slopes are only a few degrees, but it does complicate measurements of surfaces with steep cracks or holes, such as those on ceramics or cast materials.

An example of the lateral resolution capability of a stylus instrument is illustrated in Fig. 12(a) (Ref 39), which shows a profile of a 6000 lines/mm grating measured using a flexure-pivot-type stylus instrument with a 0.05 μm (2 μin.) tip width (Fig. 10a) and 0.6 μN stylus loading. A piezoelectric stage was used to drive the surface under the stylus to obtain the high lateral magnification. By contrast, Fig. 12(b) shows a profile of the same surface with a much wider (0.5 μm, or 20 μin.) stylus tip.

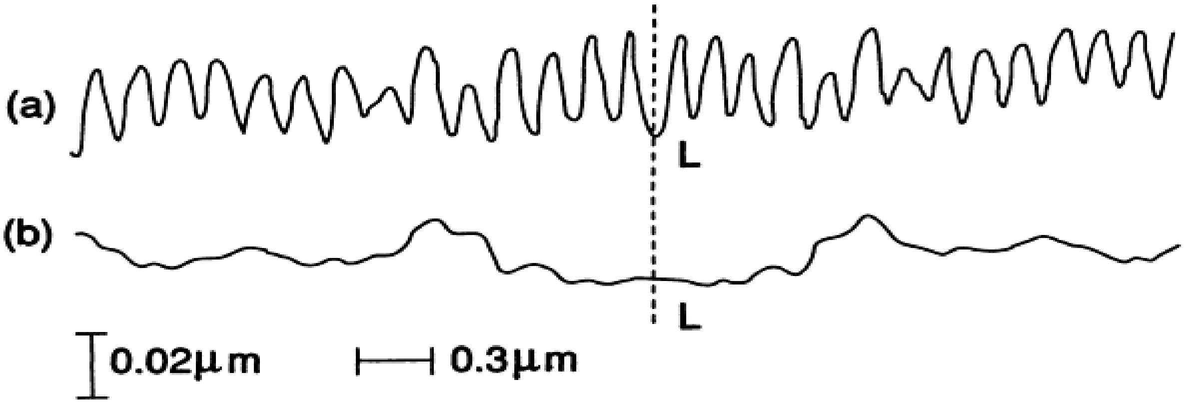

Fig. 12 Surface structure of the 6000 lines/mm grating recorded by a flexure-pivot-type stylus under a 0.6 μN

load. (a) Measured by a 0.05 μm (2 μin.) width stylus. (b) Measured by a 0.5 μm (20 μin.) width stylus

To summarize, the convolution of the stylus with the surface reduces the widths of valleys and increases the widths of peaks in the output profile. The minimum detectable valley width is roughly equal to the stylus tip width itself, but may be smaller for spherical styli tracing over very shallow valleys. From geometrical arguments, the minimum detectable peak width can be quite small in principle, but if it becomes considerably smaller than the stylus tip width, the area of contact would be decreased, the stylus pressure would increase, and the stylus might tend to deform such an asperity. However, peak spacings of 0.05 μm (2 μin.) have been detected (Ref 39) on the surfaces of random-profile precision roughness specimens (Ref 40) using commercially available stylus tips.

Bandwidth Limits for Surface Metrology. The foregoing discussion leads to the important concept of bandwidth limits (Ref 28) for surface metrology. Stylus instruments are sensitive to a certain bandwidth of surface spatial frequencies, limited at the high-frequency end by the stylus width and the sampling interval and at the low-frequency end by the traverse length or by high-pass electrical filtering. One of the most important considerations in stylus profiling is whether or not the wavelength domain of interest on the measured surface falls in the flat portion of the transmission function of the instrument. For example, at position X in Fig. 13 (Ref 41), there is essentially no attenuation caused by the factors that limit either range or resolution. One type of instrument has a traverse of 2.5 mm (0.1 in.) and can employ stylus tips having widths as small as 0.1 μm (4 μin.). Therefore, the effective band-width of spatial wavelengths sensed by this instrument extends over the range of approximately 0.1 to 2500 μm (4 to 10^5 μin.) for its unfiltered operation. For many industrial applications,the standard stylus has a radius of 10 μm (400 μin.) and the long-wavelength cutoff (λ_c) is determined by a standard high-pass electrical filter that is often set to 800 μm (3 × 10^4 μin.). The spatial wavelength bandwidth of these instruments extends approximately over 10 to 800 μm (400 to 3 × 10^4 μin.). Spatial wavelengths larger or smaller than this range are detected with reduced or nil sensitivity.

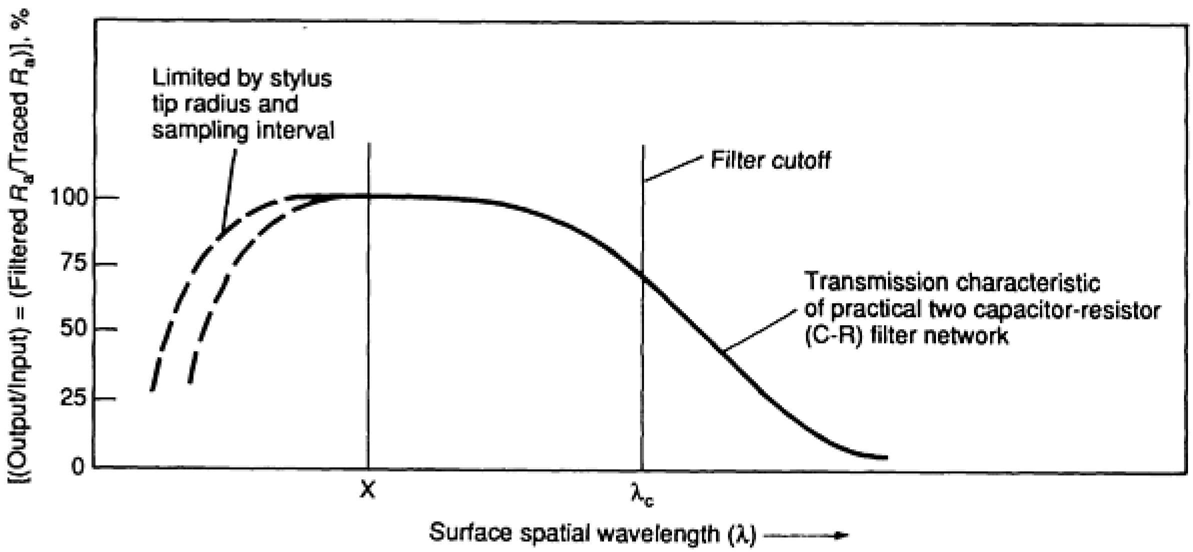

Fig. 13 Transmission characteristics of a stylus instrument as a function of surface spatial wavelength. Source: Ref 41

It is important for the operator to use a bandwidth that encompasses the spacing of the surface roughness structures to be evaluated. This means that, on the one hand, the finest surface features to be assessed must be more widely space than the stylus tip width or radius and, on the other hand, that the nominal instrument cutoff must be several times longer than the most widely spaced features to be assessed.

However, the bandwidth also affects the arms noise of the measurement. The wider the bandwidth, the more noise enters into the output profile. The noise contribution to a roughness measurement can be checked for most stylus instruments by measuring an optical flat, because such a specimen ordinarily has a roughness that is smaller than the noise resolution of the instrument. The resulting value of measured R_a or R_q represents the noise resolution of the instrument, including both the mechanical noise of traversing and the electrical noise over the finite spatial bandwidth as discussed above.

Stylus Load and Surface Deformation. The logical parameters that determine whether surface damage will be caused by stylus load are the surface hardness, the stylus force, the stylus tip width, and, to a lesser extent, the stylus speed. A stylus tip width of 1 μm (40 μin.) should not produce detectable damage on metal surfaces as soft as gold as long as the stylus force is smaller than about 0.03 mN.

Many types of stylus instruments use stylus forces of 0.5 mN and higher, but these are normally used with stylus tip sizes on the order of 10 μm (400 μin.). Because the pressure is inversely proportional to the area of contact, the pressure on the surface caused by stylus loading is smaller for a 10 μm (400 μin.) stylus with a 0.5 mN force than it is for a 1 μm (40 μ in.) stylus with a 0.03 mN force. Even if the stylus leaves a visible track, the resulting profile is likely to be accurate, because the variation in the depth of the track over the surface should be significantly smaller than the depth itself. However, if a skid is used for stylus profiling, the measured surface can be seriously damaged by the skid, whose loading is hundreds of times larger than the stylus loading.

The above discussion pertains only to plastic or irreversible deformation of the surface by stylus loading. Characterizing the elastic or reversible deformation (Ref 6) is much more difficult, but the elastic deformation is expected to be very small (Ref 42).

In a study of plastic damage, Song and Vorburger (Ref 39) measured a 2160 lines/mm gold grating with a 0.5 μm (20 μ in.) stylus tip width. When the stylus loading increased from 0.6 to 100 μN, the grating profile in the same position was attenuated (Fig. 14a-d). When the stylus loading was reduced again to 0.6 μN (Fig. 14e), most of the periodic structure of the profile in Fig. 14(a) had been plastically eliminated by the previous loading conditions and did not reappear. However, a few of the fine peaks did reappear, and the difference between the profiles in Fig. 14(d) and 14(e) suggests that some features were only elastically deformed by the increased stylus loading.

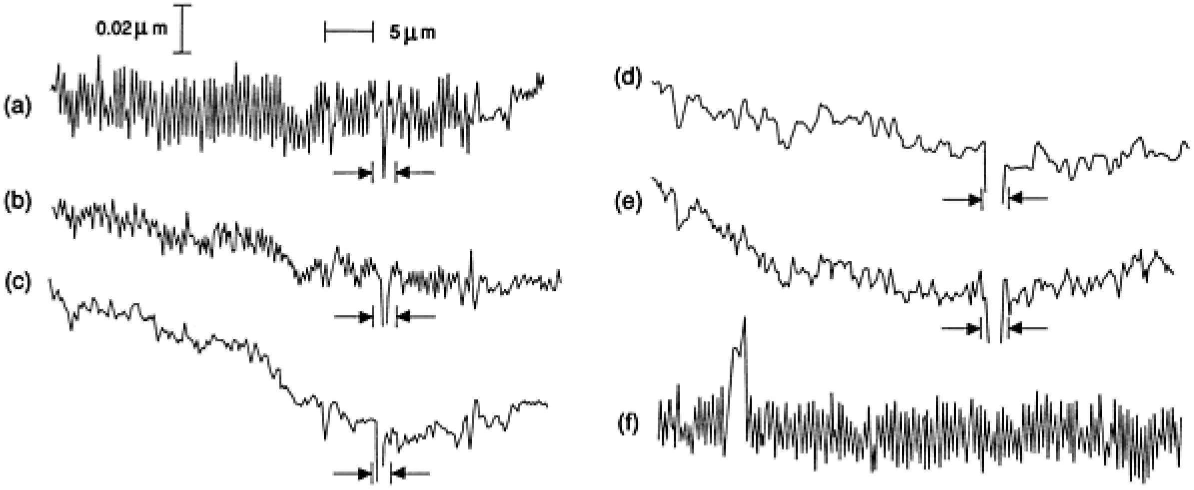

Fig. 14 Effect of stylus loading on the surface of a gold grating with 2160 lines/mm. Nominal stylus radius of 0.5 μm (20 μin.). Stylus loading: (a) 0.6 μN. (b) 25 μN. (c) 50 μN. (d) 100 μm. (e) 0.6 μN. (f) 0.6 μN, different position

Other Distortions. Stylus flight (Ref 43, 44, 45) and profile digitization are two other sources of profile distortion. Stylus flight can occur when the stylus encounters a sharp change in the surface topography, such as a steeply rising surface step. The logical parameters that affect this phenomenon are the stylus speed, the stylus force on the surface, the stylus tip size, the damping constant in the vertical direction, and the rate of change of the surface slope. A key tradeoff occurs between stylus force and speed. A magnetic phonograph cartridge with a force of 20 mN can have a record disk traverse beneath it at a tangential speed of 500 mm/s (20 in./s) without losing contact, but a stylus with a force of 0.5 mN must travel much more slowly, about 1 mm/s (0.04 in./s), to maintain contact. The usual symptom of stylus flight is a peak in the measured profile with a sharp rise and slower tail occurring after the stylus encounters a sharp peak on the surface. The accuracy of such features can be verified by remeasuring the same profile at a slower speed.

Stylus profiles are routinely digitized for the purposes of computer processing and mass storage. In order to obtain an accurate digital representation of the profile, the peak-to-valley height of the profile should consist of many vertical

quantization levels, and the widths of the surface features to be studied should consist of many lateral sampling intervals. In addition, if a distribution of surface peaks and valleys is being characterized, there should be enough points in the profile to give an adequate statistical sampling of the variability of these structures. A system at NIST used 4096 vertical quantization levels and 4000 digitized points. These values seem to provide adequate resolution for many applications.

Finally, a ubiquitous source of confusion is simply the difference between the horizontal and vertical magnification of surface profile records. The ratio of vertical to horizontal magnification can be 100:1 or higher in some applications. This effect is not a source of error, but leads to misperceptions of the true appearance of surface texture because the resulting profile records have highly sloped and sharply peaked structures. Figure 15, taken from Reason (Ref 33), shows a comparison between a profile measured with a 1:1 ratio and one with a 25:1 ratio. The qualitative impressions derived from the two pictures are quite different. In reality, surfaces are much less jagged than they appear from conventional profile records.

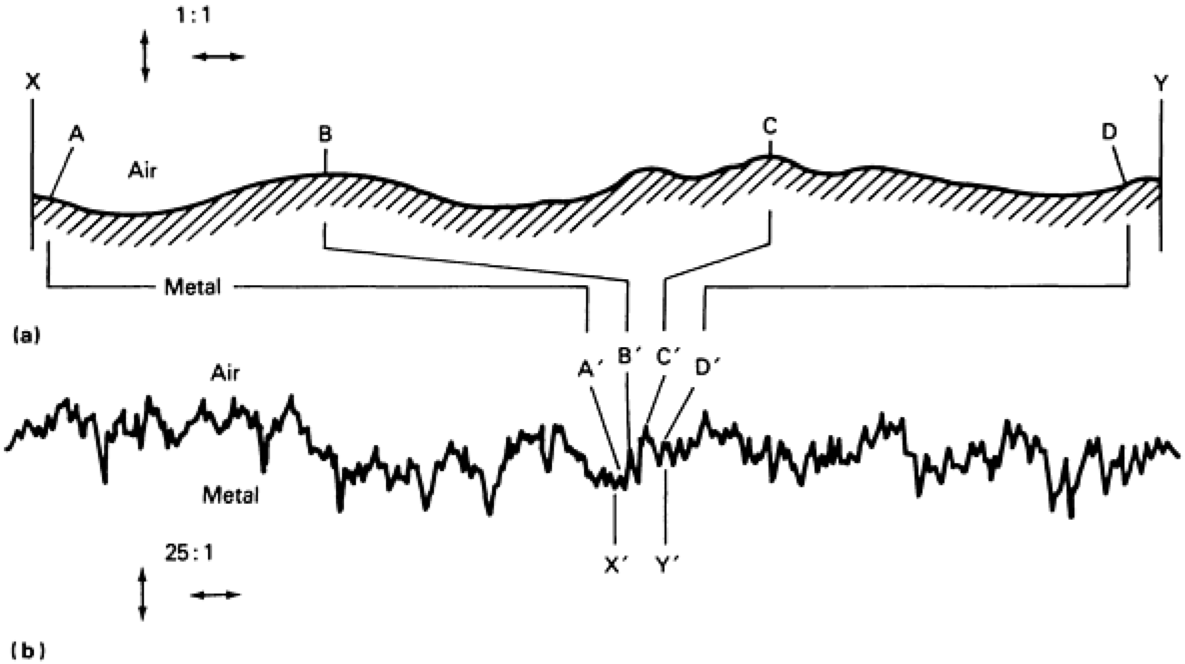

Fig. 15 Stylus profiles obtained with two different aspect ratios. (a) Undistorted 1:1 representation. (b) Plot in which the horizontal scale has been compressed by a factor of 25 with respect to the vertical scale. Source: Ref 33

Examples of Roughness Measurement Results. Of all the surface profiling concepts discussed in this article thus far, the most widely used output parameter is a roughness average, R_a, and perhaps the most important instrument parameter is the long-wavelength cutoff. A few measurement results for R_a from typical metal finishing processes will now be discussed, with the instrument cutoffs noted as well.

The surfaces of metal components can be finished by any of a number of different processes. Typical ranges for the roughness average achieved by a large number of processes are given in Ref 4. The ranges of measurements made by the authors for a few of these processes are shown in Table 1, along with the long-wavelength cutoffs used. These results represent the highest and lowest values that were obtained on roughness comparison surface replicas for each type of finishing process. Nearly all the replicas are commercially available.

Table 1 Extremes of arithmetic average surface roughness, R_a, as a function of selected metalworking finishing processes

Finishing process	Measured values of surface roughness[a]							
	Minimum				**Maximum**			
	R_a		**Cutoff**		R_a		**Cutoff**	
	μm	**μin.**	**mm**	**in.**	**μm**	**μin.**	**mm**	**in.**
Ground	0.024	0.96	0.8	0.03	3.0	120	0.8	0.03
End milled	1.4	56	0.8	0.03	11	440	No cutoff	
Side milled	1.2	48	2.5	0.10	14	560	No cutoff	
Shaped or turned	0.6	24	0.8	0.03	18	720	2.5	0.10
Electrical discharge machined (EDM)	0.4	16	0.8	0.03	7.5	300	0.8	0.03
Cast	0.9	36	0.8	0.03	72	2900	16	640

(a) For various finishing processes as measured and recorded by J.F. Song and T.V. Vorburger between 1976 and 1991. These values do not necessarily represent the entire range of values obtainable by these processes.

The cutoffs were chosen either to be several times longer than the typical spacing produced by the surface finishing process or to be 0.8 mm (0.03 in.) as a minimum. In general, the spacing of the machining marks increases with roughness; therefore, for the same finishing process, rougher surfaces require longer instrument cutoffs.

Ceramic materials are being increasingly used in industrial machinery. Although surface finishing processes are more expensive for ceramics than for metals, the ranges of roughness values achievable for both materials are generally similar. However, many types of ceramic surfaces are porous, and thus the finished surface is characterized by fairly smooth plateaus and deep holes. Therefore, values of skewness tend to be negative, and the values of peak-to-valley parameters tend to be larger relative to R_a for ceramic surfaces than for metal surfaces.

Instrument Calibration

Tribologists often make comparisons of surface texture to determine the existence, extent, and causes of surface wear. These comparisons can be confused by differences in surface measurements taken under different conditions. Are these differences caused by the measuring instruments, the measured surface, or the variation of measuring conditions? How can surface measurements be made accurate and when can they be compared? These questions involve both instrument calibration, correct measuring procedures, and the use of various calibration and check specimens.

General Calibration Issues. The measurement conditions that should be defined, calibrated, or checked for a stylus instrument are (Ref 31, 41, 46):

- Magnification, both in the vertical and horizontal directions
- Stylus tip
- Stylus loading
- Type of skid or reference datum
- Type of filter, reference line, and cutoff length
- Profile digitization
- Algorithms for calculating parameters
- Number and distribution of profiles on the surface

Four types of calibration specimens can be used for this purpose according to ISO standard 5436 (Ref 41): step-height specimens for calibrating the vertical magnification, specimens with fine grooves for checking stylus condition, specimens with periodic profiles for checking vertical and horizontal magnification as well as the character of an electronic filter, and specimens with random profiles for checking the overall response of an instrument (Ref 31, 41).

The vertical magnification of a typical commercial stylus instrument is generally accurate to 10% or better, depending on the fineness of the application. For accurate dimensional measurement of surface structures, the instrument must be calibrated. This is often done by measuring the recorded displacement produced by traversing a step whose height has

been calibrated by interferometric measurement. Calibration in the vertical direction becomes difficult at very high magnifications where the desired resolution may be at the nanometer or subnanometer level, somewhat beyond the resolution capabilities of conventional interferometric techniques. In that case, interferometric techniques that incorporate electronic phase measurement (Ref 47) constitute one approach to providing calibrated measurements of small step heights. The sources of uncertainty in surface height calibration and estimates of their magnitudes are discussed elsewhere (Ref 31, 46, Ref 48).

In the lateral direction, the relative displacement of the stylus over the surface can be measured directly by a laser interferometer (Ref 37). Alternatively, calibrated grids or other types of periodic surface specimens (Ref 26) can be used as secondary displacement standards.

Comparison of Roughness Parameters. In order to make surface measurements results comparable, the measurement conditions mentioned above should be precisely defined and specified, especially the stylus size and cutoff length, which limit the bandwidth of the measured profile. The accuracy of surface measurements of manufactured parts is aided further by a well-established measurement procedure, such as the following (Ref 31):

1. Calibrate the vertical magnification of the instrument using a step specimen whose calibrated step height covers the range of surface heights of the engineering surfaces to be measured
2. Verify that the calibration was correct by measuring either the calibrated step height again or a roughness specimen with calibrated R_a, such as a sinusoidal specimen (Ref 27)
3. Measure the engineering surfaces of interest
4. Check the measurement by measuring a check specimen with a waveform identical or similar to that of the measured surface. The R_a or other roughness parameter value of the check specimen should have been calibrated under the same measuring conditions with the same instrument characteristics as the measurement in step 3

In addition, the instrumental parameters, such as filter setting, stylus loading, and straightness of the mechanical motion, should be checked periodically.

Existing roughness calibration specimens can be used as check specimens for a wide range of engineering surface measurements. For example, when the measured engineering surfaces have highly periodic profiles, such as those obtained by turning, planning, or side-milling processes, periodic roughness specimens with triangular, cusped-peak, or sinusoidal profiles can be used as check standards. When the measured engineering surfaces have random profiles, as obtained by grinding, lapping, polishing, and honing processes, the random roughness specimens originating from the Physikalisch Technische Bundesanstalt in Germany (Ref 49) or the Chang Cheng Institute of Metrology and Measurement in China (Ref 40, 50) can be used. These sets combined would cover the range of R_a values from 1.5 to 0.012 μm (59 to 0.5 μin.). If the checking measurement shows that the difference between the measured result for the check specimen and its certified value under reference conditions was within a given tolerance, the measurement of the engineering surface is considered to be under good quality control (Ref 31).

In tribology experiments, if surfaces measured under identical conditions are being compared, the instrument is needed only as a comparator and its absolute calibration is of secondary importance. In such case, only a pilot specimen may be needed for surface measurement quality control. The pilot specimen could be selected from the measured engineering parts or could be an engineering surface with the same surface texture pattern and a similar roughness parameter value as the test surfaces, produced by the same manufacturing process. It should also have good surface texture uniformity. The stylus instrument should be checked for measurement repeatability by measuring the same trace approximately 15 to 20 times. After that, several measurements should be made daily at positions evenly distributed in a small measuring area designated on the surface of the pilot specimen. The user should then be able to detect a significant change in the characteristics of the instrument.

Comparison of the surface profiles often yields more useful information in tribology experiments that the simple comparison of roughness parameters. However, profile comparison requires that the tested surface be relocated in the exact same place from one measurement run to the next. Discrete, recognizable surface features, either natural or artificial, could be used for relocation. In Fig. 14, for example, a deep valley on the measured gold grating surface (see arrows) provided a means of orienting these profile graphs from run to run.

Applications

Metalworking. Measurements of surface roughness for metalworking components likely form the bulk of surface roughness measurements throughout the world. The automotive industry is one example where the manufactured surfaces are carefully specified. Table 2, now about 16 years old (Ref 13), shows roughness specifications in terms of the roughness average, R_a, for a number of automobile components. It is likely that these specifications were drawn up empirically and were probably similar to specifications elsewhere in the automotive industry. However, there is no real collective body of knowledge that describes these types of specifications and the reasons for them. As far as can be told, the information is scattered throughout the literature or is proprietary.

Table 2 Typical surface roughness specifications of 1976 model year automotive engine components

Components	Manufacturing process	Car No. 1		Car No. 2

Griffiths (Ref 51) attempted to systematize some of the knowledge on surface function. Table 3, taken from his paper, lists the correlations between surface physical properties and various causes of component failure. The circles are taken from previous work of Tonshoff and Brinksmeier (Ref 52) and the squares from Griffiths' additional research. The surface texture influences failure occurring by plastic deformation, fatigue, and corrosion. Griffiths also listed the influence of surface parameters on component performance (Table 4). This table discusses not only roughness and waviness, but also the metallurgy and chemistry of the surfaces and other qualities as well. Roughness is particularly important for sealing, dimensional accuracy, preserving the cleanliness of the component, optical reflectivity, and several other functions.

Tribology and Wear. An important research direction in tribology is to determine the relationship between surface texture and wear properties, and the variation of surface texture during the water process. Many investigators use standard test geometries for wear and friction tests, such as pin-on-disk or four-ball tests (Ref 53, 54, 55, 56). The amount and structure of damage to these compounds is of great interest in such tests. Key measurable parameters are the volume of material removed by wear and the surface area of the water scar.

As discussed by Whitenton and Blau (Ref 55), both two-dimensional analysis of profiles and three-dimensional analysis of surface topography maps can be used to assess wear damage. In the two-dimensional approach, a profile of the wear scar is obtained and the area lost or gained in the wear region is estimated. By projection, the volume can be estimated as well. The profile can be obtained by stylus measurements or by image analysis of the scar.

In the three-dimensional approach, the measurement system generates a matrix of X, Y, and Z values that describe the topography of the surface after the test. Parameters such as surface area can be determined from this matrix. In addition, the volume removed by wear can be obtained by comparing the surface map with that for the unworn surface. An

important advantage of this method is its accuracy; it produces the most direct measurement of the wear volume. One disadvantage is that it is more time consuming than the two-dimensional method.

Figure 16 shows the surface topography that resulted from measuring a bottom ball in a four-ball test (Ref 56) that used 6.35 mm (0.25 in.) radius α-alumina balls. These three-dimensional data of the wear scar surface were carefully filtered to remove extraneous instrumental errors.

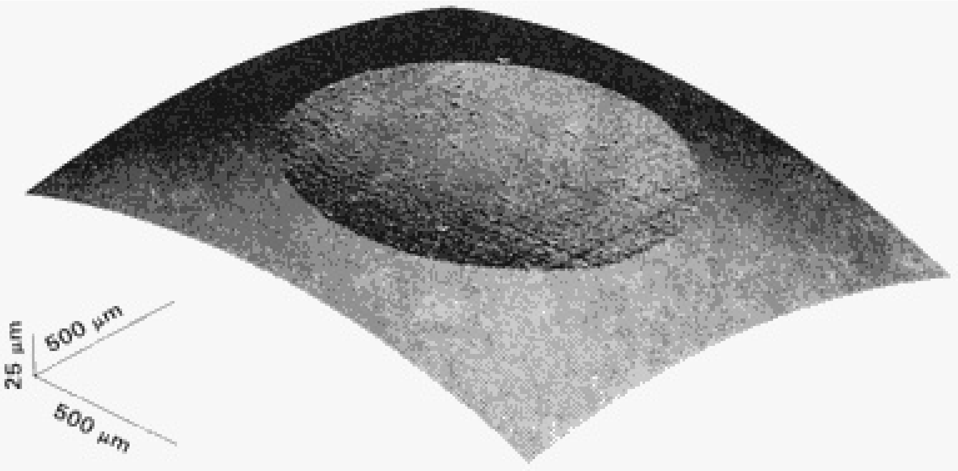

Fig. 16 Bottom-ball topographic data for a four-ball test showing a round wear scar. Source: Ref 56

Figure 17 shows the relationship between the wear volume of the top ball scars and the bottom ball scars in the four-ball test. Five sets of balls were tested at room temperature while immersed in paraffin oil. Because there are three bottom balls which were simultaneously, three times the wear volume for one ball is plotted along the *x*-axis. The scar volume of the top ball is plotted along the *y*-axis. Under the five different sets of experimental conditions, the total wear volume lost for the bottom ball scars as calculated from surface profiling appears to be about equal to the wear volume lost for the top ball scar.

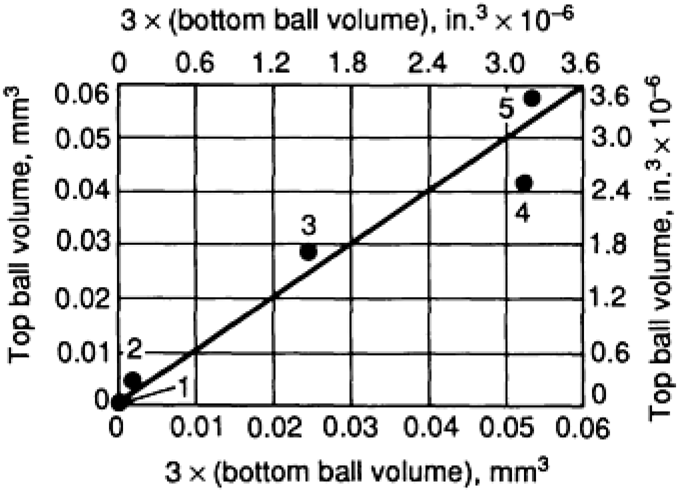

Fig. 17 Relation of the wear volumes of the top-ball wear scars to the bottom-ball wear scars. Because there are three bottom balls, three times the wear volume for one ball is plotted along the *x*-axis. The top-ball scar volume is plotted along the *y*-axis. A 1:1 45° line is also drawn. The numbered data points correspond to the test numbers. Source: Ref 56

Another application of surface texture measurements in tribology is the examination of used components to gain information on the wear mechanism (Ref 57). For example, the mechanism of scuffing involves the destruction of surfaces by the welding and fracture of asperity contacts. Such surfaces are easily distinguished from those produced by controlled running-in wear. Many engines use specially formulated "first-fill" lubricants designed to assist the running-in of the surfaces. This running-in is crucial for obtaining satisfactory service life.

Bovington (Ref 57) has observed how a properly run-in surface can be distinguished from a scuffed surface. Generally, the run-in surface contains a number of flat plateaus, the peak-valley roughness is about half that of the new surface, and the skewness, R_{sk}, is negative. Running-in proceeds in a controlled manner, that is, with the truncation of surface peaks but without abrasive or adhesive wear processes. The truncations or plateaus result in a reduction of the contacts pressures, and their presence is a good indication of long service life. Scuffing, on the other hand, generates new surfaces. Therefore, the peak-valley roughness does not decrease, and the R_{sk} parameter does not become progressively more negative.

Bovington (Ref 57) has also observed that modern engine design and lubrication technology are so advanced that the old methods of evaluation of wear, such as weight loss, are becoming irrelevant. The lubricant industry needs to begin defining wear in terms of changes in surface texture.

Davis *et al.* (Ref 58) measured the three-dimensional topography of various places in a honed engine cylinder bore and related the topography to component wear. Based on detailed results, they developed a chart showing oil volume in cubic millimeters versus the amount of the surface that would be truncated by the wearing process. The oil volume is related to the volume of the surface valleys, calculated from their three-dimensional topographic measurements. Their mathematical truncation process was a simulation of a wear process that cuts off the surface peaks. For an engine cylinder bore, oil volume is of crucial importance. Figure 18 shows data taken from the analyses of one of their three-dimensional topographic maps. As the truncation proceeds, the oil volume in the valleys decreases. Based on their information and measurement results, Davis *et al.* (Ref 58) predicted that the component would begin to fail at a truncation level between 60 to 70%, because the oil volume would decrease to unacceptable levels.

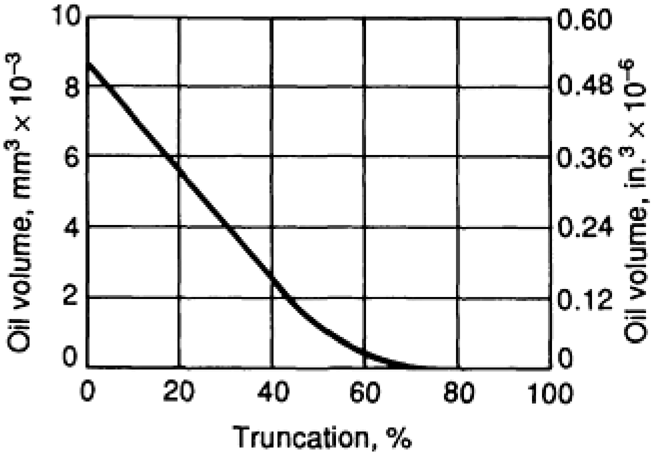

Fig. 18 Oil volume for cylinder bores estimated by mathematical truncation of a surface topography map. Source: Ref 58

Magnetic Storage. Tribology is especially important to the functioning of tapes and disks in the magnetic recording industry (Ref 59), including the hydrodynamic properties of flying read heads, the lubrication of tapes and disk, and the sliding contact between a disk and a read head upon startup. Surface roughness is also important. Figure 19 shows results from Bhushan *et al.* (Ref 59, 60) for the measured coefficient of friction of six CrO_2 magnetic tapes sliding against a glass head as a function of the rms roughness measured with an optical profiler. The tapes all had the same composition; the variation in rms roughness was achieved by using different calendering pressures during the finishing process. The coefficient of friction decreased rapidly up to an rms roughness of about 40 nm,then seemed to remain fairly level. However, when the friction results were plotted versus the real area of contact (normalized to the applied load), an

excellent linear correlation was obtained (Fig. 19b). The quantity plotted along the abscissa is based on Greenwood and Williamson's formula (Ref 15) for the real area of contact, A_r, in the elastic regime:

$$\frac{A_r}{A_a p_a} = \frac{3.2}{E^* \left(\frac{\sigma_p}{R_p}\right)^{1/2}} \quad \textbf{(Eq 10)}$$

where A_a is the apparent area of contact, p_a is the apparent pressure, σ_p is the standard deviation of the composite peak-height distribution of the contacting surfaces, R_p is the composite peak curvature of the contacting surfaces, and E^* is a composite modulus that is a function of the Young's modulus and Poisson's ratio of the contacting material. The linear relationship obtained by Bhushan *et al.* (Ref 59, 60) was duplicated by Miyoshi *et al.* (Ref 61) for the same six magnetic tapes sliding on a nickel-zinc ferrite pin in a pin-on-flat experiment.

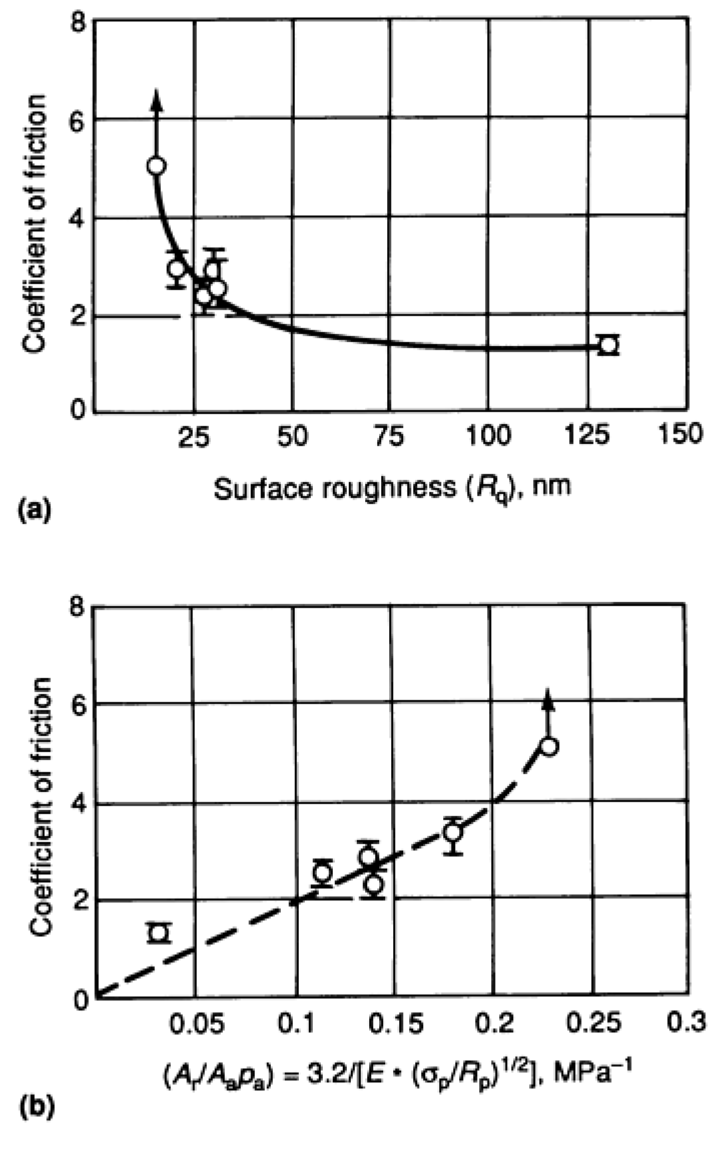

Fig. 19 Coefficient of friction for six CrO_2 magnetic tapes as a function of two parameters. (a) Coefficient of friction versus rms roughness, R_q. (b) Coefficient of friction versus the real area of contact, A_r (normalized to contact load). Source: Ref 59, 60

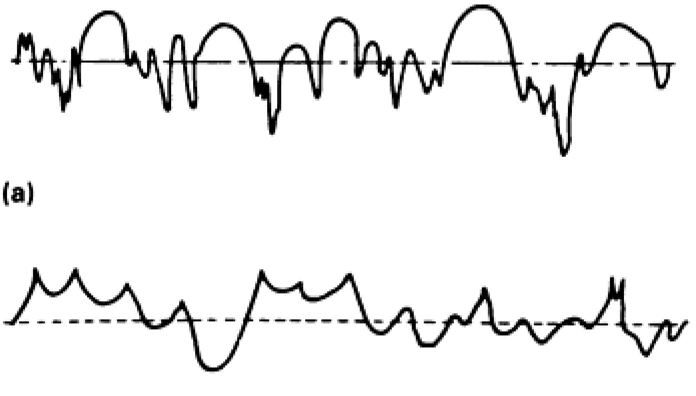
Lip Seals. Thomas *et al.* (Ref 62, 63) used pattern recognition techniques to correlate surface texture and lip sealing performance. They measured surface profiles of a set of rubber lip seals, some good and some leaky, and calculated a

number of surface parameters from the profiles, such as R_a, R_{sk}, and peak curvature. The groups of parameters for the good and bad seals were then separated by pattern recognition techniques. From these results, they constructed model profiles for successful and leaky sealing surfaces (Fig. 20). Although this approach is highly empirical, it can lead to a sound understanding of surface function by enabling the engineer to focus on the most probable parameters affecting performance.



(a)

(b)

Fig. 20 Reconstructions from pattern recognition analysis of profiles of the contacting surface of lip seals. (a) Ideally good seal. (b) Ideally bad seal. Source: Ref 63

Wherever possible, engineering surfaces should be assessed by evaluating those surface parameters that strongly correlate with the component function. The type and control values of these functional parameters can be determined by controlled experiments. This example of lip seals again highlights the importance of surface texture design (Ref 31). The functional performance of engineering surfaces can be optimized in a comprehensive way by proper design of their surface texture, specification of the material and manufacturing process, and development of quality control procedures.

Surface Topography and Image Analysis (Area)

Eric P. Whitenton, National Institute of Standards and Technology

Introduction

SEVERAL CONCEPTS and methods involved in the topography and image analysis of engineered and worn surfaces are described in this article, in terms of the past, present, and future of this characterization technique. Although linear profilometry has long been used in materials research to study both machined and worn surfaces (Ref 1), there is typically more information about a surface in a scanned area profile (Ref 2). The fact that both computers and machines that can perform scanned topographical profile measurements over an entire area are becoming more powerful and less costly, combined with the scanned area profile advantage, represent two of several reasons why the techniques for analyzing profile information are becoming similar to techniques used for analyzing optical and scanning electron microscope (SEM) images in materials research.

Image analysis of optical and SEM photomicrographs have been used for many years for various purposes related to materials science (Ref 3, 4, 5). Both optical and SEM images are essentially two-dimensional *x*,*y* arrays of numerical values. Each value represents the intensity of the image at that *x*,*y* location. Generally, area profiling machines also produce an *x*,*y* array, but each value represents a *z* height at that location. If intensity and *z* height are allowed to be interchangeable, where one can be substituted for the other, then the same equipment, techniques, and computer software can be used to analyze both. This simplifies the data analysis tasks of the researcher by unifying many of the techniques that must be learned. One machine that applies this approach uses much of the same hardware and software to interchangeably perform laser scanning tomography, infrared (IR) transmission photomicroscopy, and noncontact optical profilometry (Ref 6).

Historically, the topographical analysis of machined surfaces has predominantly consisted of compiling statistics of geometrical properties, such as average slope or the root mean square (rms) of the *z* heights. The theory behind this is described in detail in the literature (Ref 1). Techniques like this have been of limited use in the characterization of worn surfaces, particularly those that are severely worn, but can be efficiently performed in an image analysis environment. Examples are given in this article.

Image analysis is also becoming increasingly useful to pick out, characterize, manipulate, and classify the features on a surface individually, as well as in groups. It seems unlikely that purely statistical techniques will ever reach this level of sophistication. Investigators may soon see surfaces described in terms of the organizational structure of features, instead of rms. This article discusses a few of the potential pitfalls, capabilities, and opportunities of this evolving tool.

A novel example of how image analysis and profiling are interrelated is in the measurement of pigment agglomeration in rubber (Ref 7). The standard procedure is to microtome the frozen rubber and examine it under an optical microscope. Using image analysis techniques, the darker-colored agglomerates are differentiated from the lighter-colored rubber, and the dispersion is computed. The researchers noticed that a stylus profile tracing of the rubber, sliced with a knife blade at room temperature, essentially yields a flat plane that has distinct holes and bumps. This is because the soft rubber "cuts" in a flat plane, whereas the harder agglomerates are not cut and protrude through the cutting plane. The number of peaks per unit area, a method long used in both image and profile analysis, is used to compute the dispersion. This method was judged to be very accurate and fast.

Definitions and Conventions. Where possible, cited reference works were selected because they present techniques in "cookbook" form. It is hoped that this encourages readers to try such techniques on their own systems.

A *topographic image* refers to an image where each *x,y* location represents a *z* height. This image is generally acquired by a scanning profiling machine. An *intensity image* refers to an image where each *x,y* location represents an intensity, and is normally obtained by SEM or video camera. A *binary image* is derived from either a topographic or an intensity image. Each *x,y* location has a value of either "0" or "1," indicating which locations in the original image have some property, such as *z* height above a threshold value or the edge of a feature as determined by local slopes. Some of the techniques discussed in this article are performed on binary images, which are described more fully in the section "Computing Differences Between Two Traces or Surfaces" and portrayed in Fig. 5. The word *image,* by itself, is intended to be very generic. It can refer to a topographic image, an intensity image, and, in certain circumstances, individual traces. A single trace is, in fact, the special case of an image with only one row of data. Note that what makes a topographic image different from an intensity image is simply the meaning of the value at each *x* and *y,* and not how it is displayed, or *rendered.* If an isometric line drawing of an intensity image is displayed, the image is still an intensity image, even though it "looks" as though it were a topographic surface. It should be remembered that all images are *single-valued functions,* which is to say that for any given *x* and *y* value, there is one and only one *z* value. The ramifications of this are discussed throughout this article.

*Motifs*were the first profile analysis technique developed especially for use on computers (Ref 8). Using a set of four simple and easily understood rules, a complex trace can be reduced to a simpler one. This technique has been used in the French automotive industry for many years, and numerous practical uses have been found (Ref 8, 9, 10, 11). Currently, these rules only apply to a two-dimensional trace. If appropriate rules were discovered, this technique could also be performed on three-dimensional images.

Surfaces are sometimes referred to as either deterministic, nondeterministic, or partially deterministic. A *deterministic surface* is a surface in which the *z* heights can be predicted if position on the surface is known. Sinusoidal (Ref 12) and step-height calibration blocks are examples. A *nondeterministic surface* has random *z* heights, such as a sand-blasted surface. Some surfaces have both a deterministic and a nondeterministic character. A ground surface often has a distinct, somewhat predictable, lay pattern with a random fine roughness superimposed on it. Such a surface is often termed *partially deterministic.*

Leveling refers to the process of defining $z = 0$ for an image. For example, a single-profile trace is taken across a flat specimen. If one side of the specimen were higher than the other side, then the trace could be leveled by subtracting a line from that trace. For an engineered surface, the line would typically be determined by performing the least-squares fit of a line to all of the data in the trace. For a worn surface, where part of the trace includes the worn area and part includes the unworn area, only some of the data in the trace would be used to determine the least squares line. The data in the unworn area only would be used to determine the least-squares line when the worn volume, or wear scar depth, was to be determined.

Implementation on Personal Computers and Data Bases. Both software (Ref 13, 14) and books (Ref 15, 16, 17, 18) have become readily available to perform image analysis on personal computers. At least one source (Ref 18) not only describes many of the techniques, but also includes software. If a profiling or other image-producing machine, such as a microscope, were under heavy use, then users could take a floppy disk containing the stored images to another work station and free the measuring equipment for others to use. Some data base programs allow images to be stored along with other textual and numeric information (Ref 19). It is also possible to have the images themselves as part of the querying process, where a user "enters" an image and the computer finds similar images (Ref 20). Thus, both the topography, or topographic image, and visual appearance, or intensity image, of a surface can be an integral part of a data base.

Point Spacing and Image Compression

The issue of how many *x,y* points to acquire in an image generally involves a compromise. If too few points are used, then valuable information can be lost. It has been shown, for example, that a surface with an exponential correlation function appears as a Gaussian correlation, unless there are at least ten data values per correlation length (Ref 21). The determination of even a simple parameter, such as rms roughness, is also affected (Ref 22, 23). When too many points are used, more mass storage and computing time per image are required than necessary. Also, the determination of noise-sensitive parameters can be adversely affected (Ref 24). This is because extremely fine point spacings may enhance the ability of the computer to record the noise in the profiling system, along with the topographic information.

One solution is to acquire as many points as possible and later discard the redundant or unimportant values. There are a variety of image data-compression techniques that remove redundant or unimportant information when the image is stored in memory or disk. The best compression technique depends on which aspects of the image are redundant or not

important to image quality. Several data-compression techniques have been proposed for surfaces of materials. One technique uses Fourier transforms (Ref 25, 26). By storing only the "important" frequencies, the amount of data can be reduced. The selection of which frequencies are not stored implies that features of that lateral size range can either be extremely small in vertical height, compared to other features, or are unimportant. Other procedures attempt to determine the "optimum" point spacing using autocorrelation functions (Ref 27), bandwidths (Ref 24), or information content (Ref 28). If variable point spacings are allowed, then motifs provide another technique (Ref 8). Many of the possible data-compression techniques do not appear to have been tried on images of surfaces of materials.

Walsh or Hadamard transforms, where a surface is modeled as a series of rectangular waves, can be used in place of Fourier transforms. This often results in less noise in the reconstructed image, although Fourier transforms may better reproduce the original peak shape (Ref 26). Although there do not appear to be any references in the literature on usage as a data-compression technique specifically for the surfaces of materials, the coefficients have been used to characterize these surfaces (Ref 29, 30). Many other data-compression techniques are also available.

Potential Pitfalls

Many of the potential pitfalls in intensity image processing are potential pitfalls in topographic image processing as well. For example, when determining the roundness of an object, the number computed is dependent on the magnification used (Ref 31). A computed area or length also depends on the scale used, this being one of the basic concepts behind fractals, which are discussed in detail in the section "Fractals, Trees, and Future Investigations" in this article.

Another pitfall is the fact that the surface is being modeled as a single-valued function in *x* and *y,* when it may in fact not be. One example is a case where a "chip" of material is curled over the side of a machined groove. There are at least three *z* heights: the top side of the curled chip, the underside of the curled chip, and the top surface of the bulk material below that chip. A profiling machine would report only the top side of the curled chip as the *z* height at that *x,y* location. Any estimate of volume would obviously be larger than the actual volume of material. Thus, an image of a surface is actually made up of only the highest points on the surface. A top view is the only truly accurate rendering of the image; other renderings, such as isometric or side views, are only approximations. This is because these other renderings give the appearance of "knowing" what is below those highest points.

An analogous situation in intensity images is the "automatic tilt correction" on some SEMs (Ref 31). Suppose an intensity image of a sphere on a steeply sloped plane is acquired and that slope is removed in software so as to make the plane appear horizontal. A side view of this situation is shown in Fig. 1. When the software attempts to "level" the image, the radius of the sphere will be elongated in the direction of the tilt and remain constant in the orthogonal direction. The sphere will then appear as an ellipsoid, and not as a sphere.

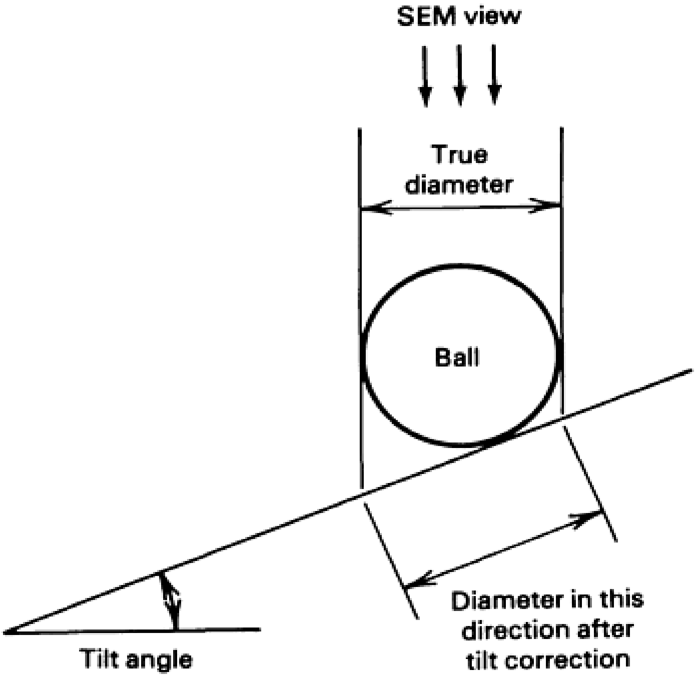

Fig. 1 Side view of a sphere on a sloped plane

Estimation and Combination of Intensity and Topographic Images

Simply displaying a topographic image as though it were an intensity image (which can be a very powerful tool) does not show the user how the surface would actually appear under a microscope. The heights are known, but the color, reflectivity, and translucency of the surface are not. Conversely, a microscope image gives clues as to the surface heights, but does not do so quantitatively. It may be obvious that a surface is pitted, for example, but the depth of those pits are not known. Three issues are therefore addressed: (1) The manipulation of an optical or SEM image to yield topographic information; (2) The rendering of topographic information that actually looks like the surface; (3) The combination of optical and topographic information together onto one rendering.

Transforming an intensity image to a topographic image can be approached in several ways. All approaches involve a "nicely behaved" characteristic of the surface. One approach matches stereo pairs. Each feature in a left-eye image is matched to the same feature in a right-eye image. When the two images are compared, the amount of lateral displacement of each feature is related to its z height. Thus, a z height image can be created. The features must be distinct and well defined for this approach to work well. An example of this in use is in the measuring of integrated circuit patterns (Ref 32).

Another approach assumes that the optical properties of the surface are relatively constant. If the original surface does not have this property, then a replica can be made and examined, instead. When properly lighted, each gray level in the intensity image is proportional to the slope of the surface at that location (Ref 33). The topographic image can therefore be found by integrating the intensity image.

An example of a third approach is a wear scar on a ball. The volumes of such scars are often determined by measuring the scar width in an intensity image and assuming that the scar is relatively flat or of a fixed radius in z (Ref 34). However, the scars may be of unknown or varying radii. More accurate volume estimates can be obtained by outlining the edge of the worn scar and assuming the outlines are connected by lines or curves across that scar (Ref 35). This is shown in Fig. 2, where the surface has, in effect, been estimated from its intensity image and the known geometries in that image.

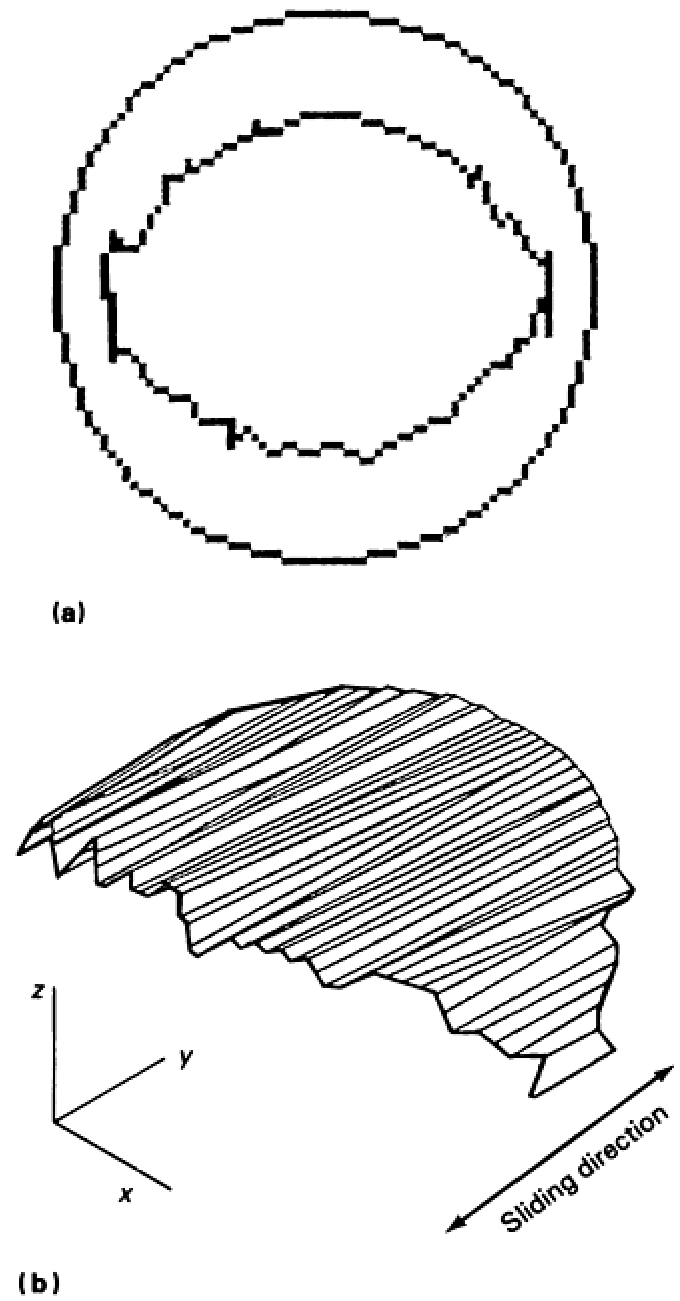

Fig. 2 Example of estimating a topographic image from an intensity image using known geometries

A nonrotating ball was slid repeatedly against abrasive paper in the *y* direction, forming a scar on the ball. An optical photomicrograph that looks down onto the scar was taken, digitized, and the intensity image was shown on the computer screen. The user then traced the outline of the scar using a pointing device. This is shown as the near-elliptical shape in Fig. 2(a). The software then assumed that the *x,y* location of the center of the scar coincided with the *x,y* coordinate of the center of the ball. Knowing the radius of the ball, the software then computed the *z* heights of all the *x,y* points on the outline of the scar, because they must lie on the sphere. To estimate the *z* values inside the scar outline, the values of the outline were connected by straight lines in the *y* direction, as shown in Fig. 2(b).

Rendering and Combining Images. Actually transforming a topographic image to an intensity image is rarely done for surfaces of materials. The appearance of a surface under a microscope is typically approximated by simply rendering the topographic image as an isometric view. Isometric views can be generated by most image analysis software. The simplest isometric view is a stick-figure type of drawing, where no attempt is made to show how a light source would interact with the surface (Ref 18). These views may or may not have hidden lines removed. The next level of sophistication assumes that the optical properties are constant across the entire surface. One or more light sources are

assigned locations in space, and the view is "shaded," giving a more realistic appearance. Some software takes into account the shadows that one feature casts onto another, whereas others do not. Often, however, the optical properties of real surfaces are not constant across the entire surface.

Given optical properties maps of reflectivity, for example, some software can create very realistic renderings (Ref 36). An intensity image of a properly lighted surface can be used as a reflectivity map. Therefore, such software can be used to combine an intensity image and a topographic image of the same area to produce a rendering that exhibits both optical and topographic qualities of the surface.

Relating Two- and Three-Dimensional Parameters

Situations in which researchers have preferred the more traditional two-dimensional parameters have occurred. One example is the case where a large body of two-dimensional data has already been collected and there is a need to compare newly acquired data with previously obtained values. Even in these cases, the ability to select which two-dimensional trace to use for analysis from a three-dimensional topographic image is sometimes necessary (Ref 37). Additionally, the repetitive application of the analysis for a large number of traces can provide statistical information as to the repeatability of the results obtained for a given specimen (Ref 38, 39, 40, 41, 42). When applied to worn surfaces, a two-dimensional parameter can often be plotted as a function of sliding distance, giving clues as to the mechanisms involved (Ref 43). It is possible to estimate three-dimensional parameters from two orthogonal traces. This has been applied to mold surface finish (Ref 44) and has been used in the comparison of the fractal dimension (discussed later in this article) both with and across the lay of engineered surfaces (Ref 45).

However, better results are often obtained from full images (Ref 46). Many of the customary two-dimensional parameters are easily extendable to three dimensions. Perhaps the best-studied parameters in both two and three dimensions are roughness parameters, such as rms values. Generally, two-dimensional roughness parameters have smaller values than their three-dimensional counterparts for nondeterministic surfaces, and have about equal values for deterministic surfaces. This result is derived from both theoretical work (Ref 1) and actual data (Ref 38).

There are two explanations for this result. One is that single traces have a high probability of missing the highest peaks on a surface, whereas an area profile has a much better chance of taking these into account (Ref 1). Another explanation involves the fact that nondeterministic surfaces have waviness in both the x and y directions (Ref 47). Waviness in the x direction is generally removed by filtering for both the two- and three-dimensional roughness calculations. The two-dimensional calculation always removes waviness in the y direction, because each trace is leveled individually. The three-dimensional calculation, where the same plane is subtracted from all of the trees, does not do so unless a filter is specifically applied to the image in the y direction. Thus, the three-dimensional roughness parameter may or may not include the waviness in the y direction, depending on how the parameter is computed.

When analyzing worn surfaces, some area profiling machines use the unworn part of a surface as a reference. This is done by fitting the unworn part of each trace to a line, and subtracting the line from that trace (Ref 41, 43). An example of this is shown in Fig. 3. Typically, this is performed because of drift problems while the traces are being acquired and to make the worn volume measurements more accurate. The effect is to filter the waviness in the y direction. One might therefore expect that a three-dimensional roughness parameter computed from this image would be more nearly equal to the two-dimensional equivalent than the same parameter applied to an image acquired by a machine that only uses its own reference plane. However, this does not appear to have been rigorously demonstrated.

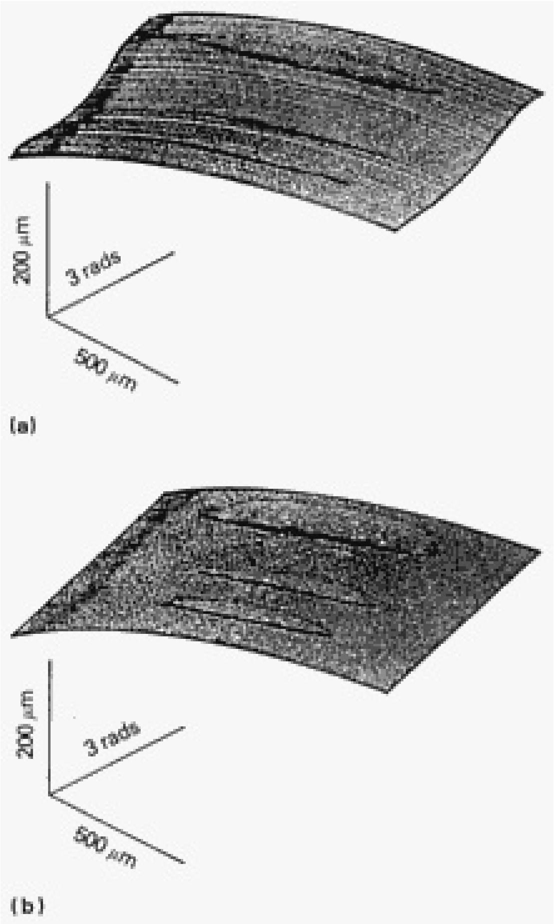

Fig. 3 An x,θ,z coordinate image of the doughnut-shaped scar on the top ball in a four-ball test

Figure 3(a) shows the "as traced" data. Note the vertical undulation of the surface. This is due primarily to mechanical errors in the motor stage used to hold the ball during image acquisition. For each trace, the unworn area can be fit to a line, and that line used to make the trace level with respect to the other traces. This is shown in Fig. 3(b).

The relationships between the two- and three-dimensional values for other parameters are not as well documented as roughness. Other statistical parameters, such as skewness and kurtosis (which help characterize the distribution of *z* heights), have been computed for both engineered (Ref 42, 46) and worn (Ref 48) surfaces. Aspect ratio parameters have been proposed for circular wear scars (Ref 40) and for the features in worn areas (Ref 43). Fractal dimensions can also be determined in three dimensions (Ref 49, 50). It should be remembered that the values obtained for many two-dimensional parameters are often quite different, depending on the direction of the trace. Rms roughness (Ref 51), autocorrelation (Ref 52), and fractal dimension (Ref 45) are examples of this.

Lessons from Two-Dimensional Analysis

Example 1: Understanding How a Parameter Behaves.

In the late 1970s, it was discovered that there is nearly the same linear relationship between the log of the wavelength and the log of the normalized power spectral density for a very large variety of surfaces (Ref 53). These surfaces span almost nine orders of magnitude in size. Values for motorways, concrete, grass runways, lava-flows, ship hulls, honed raceways, ground disks, ring-lapped balls, and other surfaces were used. An amazingly universal characteristic of real surfaces was discovered. Today, it is known that this occurs because these surfaces are fractal in nature (Ref 45). Imagine that a researcher does not know of this universality, but notices that this relationship exists for a particular set of surfaces. It might be tempting to assume that something was unique about these particular surfaces, when, in actuality, certain parameters behave in certain ways regardless of the type of surface.

Example 2: Determining a Reference Line or Parameter Value on a Pitted or Grooved Surface.

Certain features on the surfaces of some materials do not affect performance and should be ignored when leveling, fitting, or determining roughness parameters. An application where a small roughness is required on a surface, except for periodic deep scratches to contain lubricant, is one example. The porosity in many ceramics is another.

One approach to evaluating these types of surfaces is to be able to selectively ignore certain *z* values, based on an appropriate criterion. One example of this is to ignore *z* values that are several standard deviations away from the average (Ref 54). Wide scratches can be detected and ignored by looking for clusterings of these outliers.

It should be noted that a single trace cannot distinguish between a scratch and a pit. In some applications, such as the characterization of corrosive pitting, that information may be desirable. Image analysis can determine such differences in several ways, such as by computing aspect ratio parameters and by pattern matching.

Example 3: Designing Parameters.

When two-dimensional parameters became commonly used in materials research, a proliferation of many similar, but not identical, parameters appeared in the literature. One study used correlation analysis to examine 30 parameters applied to various engineered surfaces (Ref 55). Many of these parameters were found to be highly correlated, and several were selected as being the least redundant. It was suggested that all or some subset of these few should be used to study engineered surfaces, because they each revealed a different characteristic of these surfaces.

Other researchers have performed similar studies using correlation (Ref 56) and cluster analysis (Ref 57). The popularization of three-dimensional parameters may, in some ways, worsen the proliferation of parameters. However, image analysis can be thought of as either a language or tool box of techniques for optimizing parameters to suit particular needs. Evaluation procedures can be custom built from combinations of relatively standard image operations.

The idea of designing a parameter for an application has found its way into two-dimensional parameters. Examples include the German standard DIN 4776 (R_k) (Ref 11, 58), functional filtering (Ref 1, 10), and the French standard NF05-015 (motifs) (Ref 8, 9, 10). Invariably, some combinations will prove useful in a wide range of applications, whereas others will fall into obscurity.

Selecting an Appropriate Coordinate System

Figure 4 shows a few of the worn specimen/coordinate system combinations possible. Figure 4(a) shows an x,y,z coordinate system used for the wear track on a flat in a pin-on-flat test. The left side of Fig. 4(b) shows an x,θ,z coordinate system used for the wear track on a fixed cylinder in a rotating cylinder on a fixed-cylinder wear test. The right side of Fig. 4(b) shows an $x,\theta z$ coordinate system used for the wear scar on a top ball in a four-ball test. Figure 4(c) shows a θ_1, θ_2,z coordinate system used to characterize an entire ball surface after having been used in a ball-bearing assembly.

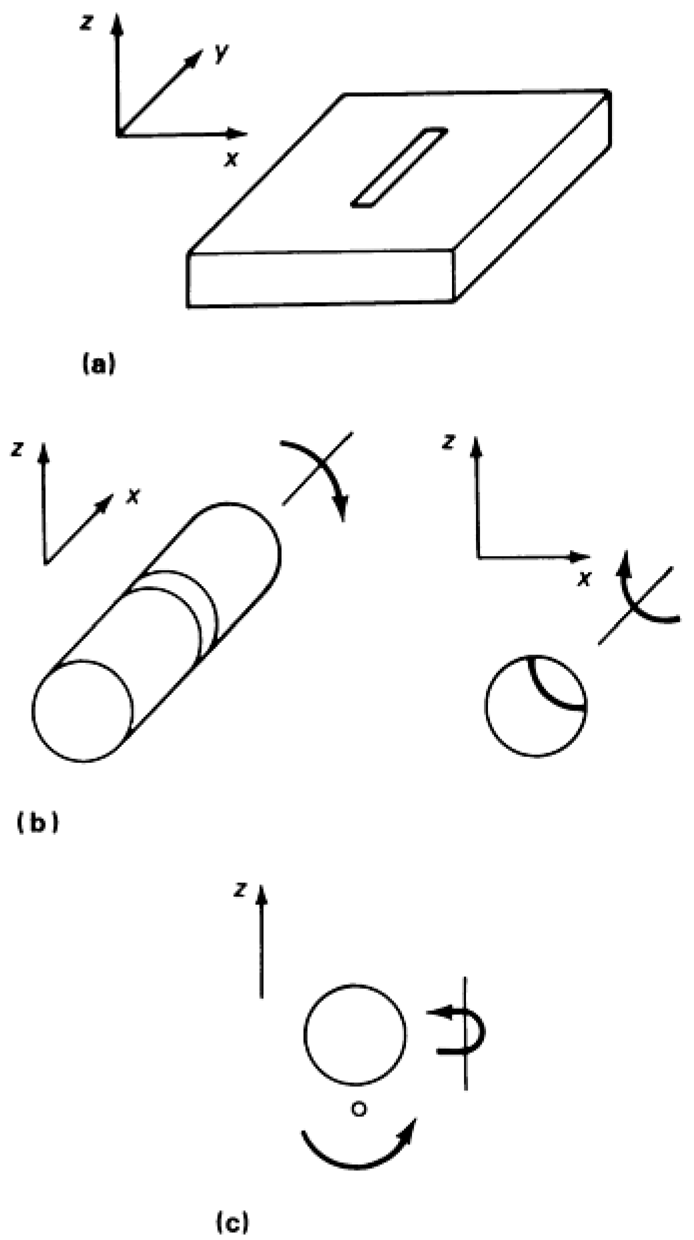

Fig. 4 Possible worn specimen/coordinate systems

The geometry of the area of interest generally determines which coordinate system is the most efficient to use. Take the example of a ball. The typical *x,y,z* coordinates can be used if the feature of interest were the wear scar on a ball in a test where the ball slides on a flat without rotating. However, an $x,\theta z$ system may be more efficient if it were the scar on the top ball in a four-ball test (Ref 40). A θ_1, θ_2,z system can be used if the entire ball surface is of interest, as in the case of ball bearings in head/disk assemblies (Ref 59) or in the evaluation of sphericity (Ref 60). Combinations of coordinate systems can be used on the same ball (Ref 61). A θ_1, θ_2,z system can be used to get an overall view of the ball, and an *x,y,z* system can be used to "zoom in" on specific features. Sometimes, $\theta_1\theta_2,z$ coordinate systems are scaled as though they were *x,y,z* coordinates (Ref 41). This can easily be done if the diameter of the ball is known. Bores and holes (Ref 62), as well as valve seats (Ref 63, 64), have been characterized in x,θ,z coordinate systems.

The x,θ,z coordinate system is sometimes referred to as a cylindrical coordinate system. However, as Fig. 4 shows, both cylinders and spherical balls can require the use of this system. The x,θ_1,θ_2 coordinate system is sometimes referred to as a spherical coordinate system. As noted above, a spherical ball can be profiled using *x,y,z* or x,θ,z coordinates, as well. Thus, these names should be used carefully. When reading the literature, for example, it is occasionally easy to confuse a cylindrical specimen with a cylindrical coordinate system.

The type of analysis to be performed can also affect the coordinate system chosen for use. For example, a planar machined surface can be traced using an x,θ,z coordinate system, where the traces radiate from some central location. When used in conjunction with autocorrelation functions, these can be used to graphically characterize the lay of a surface (Ref 52). When used in conjunction with cross-correlation functions, these can also be used to quantify the isotropy of a surface (Ref 65, 66).

Specialized hardware is generally required for the acquisition of images using alternate coordinate systems. The analysis software may need to be modified, as well. The calculation of worn volume, for example, may require a different equation for x,y,z and x,θ,z coordinate systems (Ref 40).

Computing Differences Between Two Traces or Surfaces

Perhaps the most commonly performed manipulation of topographic data, whether in the form of linear traces or images over an area, is computing the difference between two traces or images. This fact is important, because although it is one of the simplest manipulations, it is also prone to potentially large errors if not done carefully. Examples that illustrate this point and techniques for avoiding these errors are discussed below. It is important to remember, particularly in this section of the article, that the word "image" is used for both single tracings from a standard two-dimensional profiling machine and true images.

Example 4: Determining a Reference.

Often, a second image is computed from an original image and the difference between the two is derived. When leveling, for example, a reference line or plane is often fit to some or all of the image, and that line or plane is subtracted from the image. Different types of fits can be performed, and different reference lines or planes will result. Research has been conducted to compare various types of fits (Ref 67). It was found that the least-squares fit is acceptable for nearly level surfaces; orthogonal least-squares fit is better for steeply sloped surfaces; and geometric mean is preferred when the data values in the image have a log-normal distribution. The problem of ignoring outliers in the determination of a reference has been discussed above.

Example 5: Roughness, Waviness, and Error of Form.

Another example of computing a second image and deriving the difference is in the separation of an image of a machined surface into roughness, waviness, and error of form (Ref 68). Roughness consists of the finer irregularities. Waviness is the more widely spaced component of surface texture. The two components together are referred to as surface texture. Error of form is the deviation from the nominal surface not included in surface texture. These components generally result from different aspects of the machining process. An example is a ground surface. The roughness can result from the grinding wheel-workpiece interaction, the waviness from machine vibration, and error of form from errors in the guides that control the movement of the grinding wheel over the workpiece.

Roughness is often modeled as the high-frequency component, waviness as a mid-frequency component, and error of form as the lowest-frequency component of a surface. In theory, if an image of a surface was divided into these separate components, and these components were recombined, the result would be to recreate the original image. In practice, however, significant distortions often result.

Perhaps the best-known example of this is the acquisition of a roughness trace from a standard profiling device (Ref 69). Electronic filters allow the higher frequencies in the z height signal to pass through while blocking the lower frequencies. Thus, an image of the roughness component of the original image is obtained. The difference between the roughness image and the original image gives an indication of the waviness and error of form components of the surface. However, the roughness image is distorted, because of time lags in the electronic filters. The difference image of the other surface components is therefore also distorted. This effect can be minimized using modern digital filtering techniques, which do not introduce time-lag errors. Standards are currently being developed for these (Ref 70).

Example 6: Error Correction.

The differences between two images are also used to correct for errors in the z reference plane. Most profiling devices have some form of a precisely flat surface, which defines $z = 0$. Errors in this reference plane are often reproducible and

can be measured. An error image can thus be created and stored for later use. When the device is used to measure surfaces, this error image can be recalled and subtracted from the acquired topographic images to increase their accuracy (Ref 71). A similar technique can be used for intensity images to compensate for uneven illumination.

Example 7: Comparing Mated Surfaces.

Wear studies that examine the difference between two mated surfaces have been made. In one study, the differences in the roughness images of two surfaces that had been in sliding contact with each other were used to characterize the conformity between them (Ref 72). Errors associated with using a roughness image have been discussed above. Ignoring waviness when modeling the way that two surfaces interact can adversely affect the results in some situations and therefore must be done with care (Ref 73). Another issue is that of the elastic deformation of the surfaces while they were mated. The topographies of the two surfaces while they were pressed together under load is undoubtedly different from their topographies while traced. Various researchers have attempted to model this (Ref 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84).

Example 8: Determining Worn Volumes.

Described below are four areas of concern.

The Difference Image. The worn volumes of wear scars are often computed by first subtracting the image of an idealized unworn surface from the image of a worn surface. Either lines or planes can be used for a flat specimen, and circles for a ball or cylinder (Ref 40). Figures 3, 5, and 6 exemplify this. Figure 3(b) shows an image with x,θ,z coordinates of the doughnut-shaped wear scar of the top ball in a four-ball wear test. For each trace in the image, a least-squares circle is determined from unworn areas on either side of the scar, and that entire trace is then subtracted from this circle.

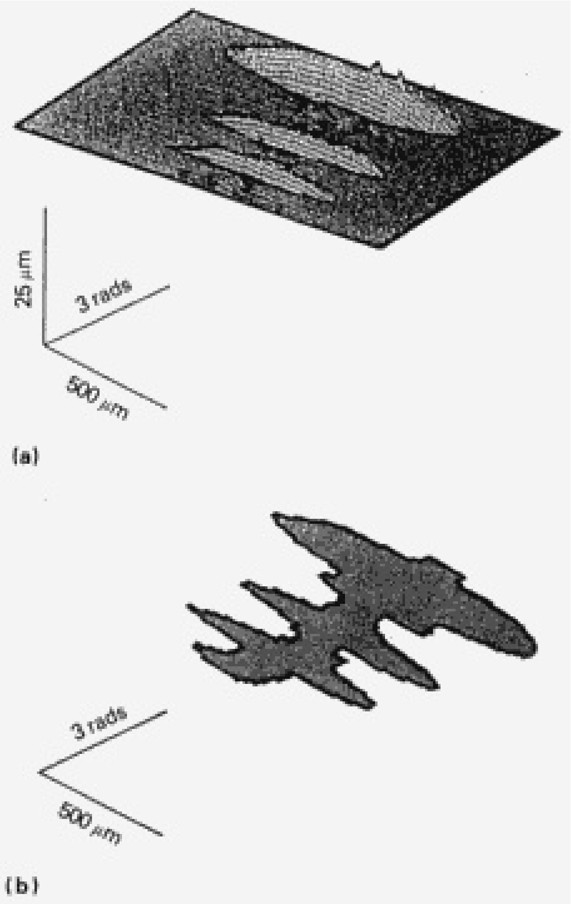

Fig. 5 (a) Difference image derived from image in Fig. 3(b). (b) Binary image

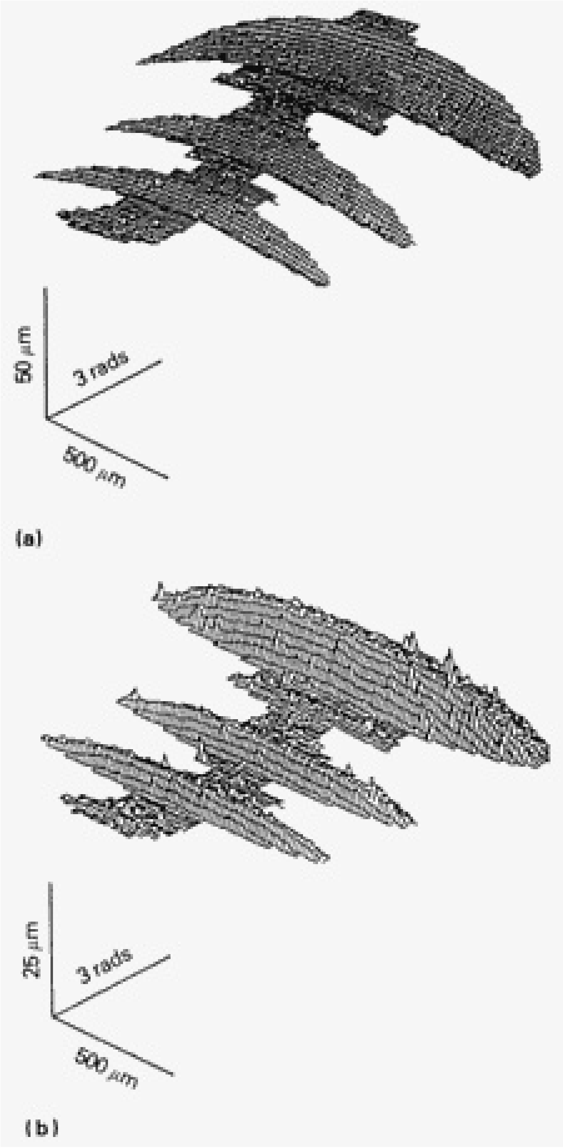

Fig. 6 (a) Worn area of image in Fig. 3(b). (b) Worn area of difference image shown in Fig. 5(a)

This new image is referred to as a difference image, and is shown in Fig. 5(a). It represents the difference between an unworn and worn ball. Where there has been a net loss of material, the difference image will have a positive value. Where there has been a net gain of material, the difference image will have a negative value. Where there has been no net change of material, the difference image will have a value close to zero. Values significantly different from zero can then be used to determine which areas of the image are worn and which are unworn.

A binary image is shown in Fig. 5(b). For each *x*,*y* location, the binary image has a value of 1 if that location is to be considered a part of the wear scar, and a value of 0, otherwise. This binary image can then be used to "eliminate" parts of the original image and difference image that are not part of the wear scar, and should therefore not be considered in any statistics computed.

Figure 6(a) shows just the worn area of the image in Fig. 3(b). Curvature, surface area, or roughness, for example, can be computed from this image. Figure 6(b) shows just the worn area of the difference image shown in Fig. 5(a). Worn volume can be computed from this image.

Alignment. The image of the unworn surface need not be idealized, but may actually have been measured before the wear test. Examples of this include the wear of copper (Ref 85), teeth (Ref 86), valve seats (Ref 63), and chemically active scuffed bearing surfaces (Ref 87, 88). The electroplating process can also be studied by comparing the topography of a surface during the various stages of plating (Ref 89). One source of error is the problem of aligning the "before" and

"after" images. Proper alignment of the worn and unworn surface images can be aided by microhardness indents (Ref 63) or other markings on the surface. If there are features on the specimen that are known to have not worn and are distinctive, then these features can be adequate substitutes for special markings (Ref 86).

Effects of Digitization. Another potential source of error when subtracting two surfaces is the fact that the worn volumes may be very small in relation to the volumes of the surfaces, especially for nonplanar specimens, such as balls. This situation results in the subtraction of large, nearly equal numbers, which is a well-known source of error in computer computations (Ref 90). After an operation, such as leveling, is performed on an image, the image should be rescaled so as to fully utilize all of the bits used to store that image. This allows subsequent operations to be performed at as high a resolution as possible, minimizing cumulative errors. The original image should be acquired and stored using as much resolution as possible. A combination of the vertical resolution of the profiling device and the number of bits actually used when the height signal is digitized, determines the useful resolution of an image.

Suppose that the noise level of a profiling device is on the order of 0.1 μm (4 μin.), with a vertical range of 1 mm (0.04 in.), represented by a voltage of 0 to 5 V. The analog-to-digital (A/D) converter acquiring the image has 12 bits over the range of 0 to 10 V. Because the A/D has a voltage range twice that of the profiling device, half of the resolution, or one bit, of the A/D will never be used. Note also that if the voltages actually digitized for this particular image range from 1.0 to 3.5 V, yet another bit has been wasted. The resolution of the A/D is about 2.5 mV, which corresponds to about 0.5 μm (20 μin.). This is a factor of five worse than the profiling device. With the appropriate electronics, the 1.0 to 3.5 V could be mapped to all 12 bits, resulting in a resolution of about 0.6 mV, or 0.1 μm (4 μin.). This more fully exploits the profiling device resolution. Of course, there are other issues that affect the useful resolution of the A/D, such as frequency response and aperture uncertainty (Ref 91).

Effects of Large Slopes and Positioning Errors. When subtracting two surfaces that contain large slopes, the result can be sensitive to lateral positioning errors. Profiling machines that acquire the topographic image while the z sensor is in motion are particularly prone to this problem, because of variations in the sensor velocity. This can be minimized by using an interferometer, linear optical encoder, or other lateral position sensor to control the data acquisition. Figure 7 shows a 10 mm (0.4 in.) diameter ball with a 2 mm (0.08 in.) wide scar.

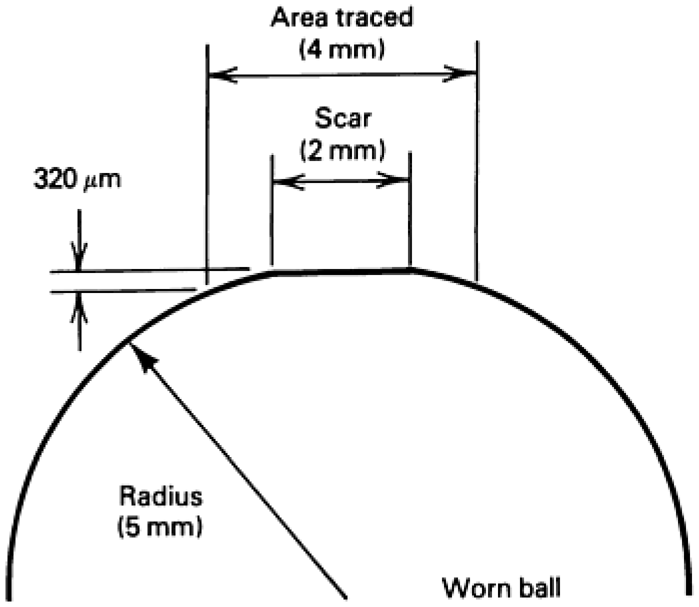

Fig. 7 Side view of a worn ball from a nonrotating ball on flat wear test, which is to be traced with a profiling device

Suppose that a 4 mm (0.16 in.) wide area is traced. This ensures that enough of the unworn portion of the ball is in the topographic image to use as a reference. The full-scale z height range would be about 320 μm (13 mils). The slope of the reference area would vary from around 11.5 to 23.6°. A lateral positioning error of 2 μm (80 μin.) therefore results in an

error of 0.4 to 0.9 μm (16 to 36 μin.) in the *z* height measurements in the reference area. This is a manageable error at a 320 μm (13 mil) full-scale height.

Suppose that the scar itself is relatively flat, with a *z* height full-scale range of 1 μm (40 μin.). When the difference between the unworn and worn ball is examined, the full-scale range of the difference image is therefore only 2 μm (80 μin.) or less. The errors in the reference area in the *z* direction are large when compared to the *z* heights of the scar itself, 20 to 45%, in this case. This situation makes it difficult to distinguish between the scar and the reference area near the edges of the scar.

An example of this actually occurring in practice is shown in Fig. 8. A topographic image (with *x*,*y*,*z* coordinates) of a ball that has an abraded area is shown in Fig. 8(a). The abraded area is difficult to see at this magnification. Figure 8(b) is a difference image representing the difference between a sphere and the image in Fig. 8(a). The worn area now appears as a lump on the surface. Note that the unworn area of the difference image is not a flat plane, as would be expected. There is a sinewave-like pattern to it in the *x* direction. The *z* sensor of this particular profiling device is coupled through a clutch to a motor, which drives it in the *x* direction. The length in *x* of one period of the sinewave corresponds to the distance traveled by the *z* sensor during one revolution of the clutch. When a linear optical encoder was used to control data acquisition, the vertical size of this sinewave decreased by almost two orders of magnitude.

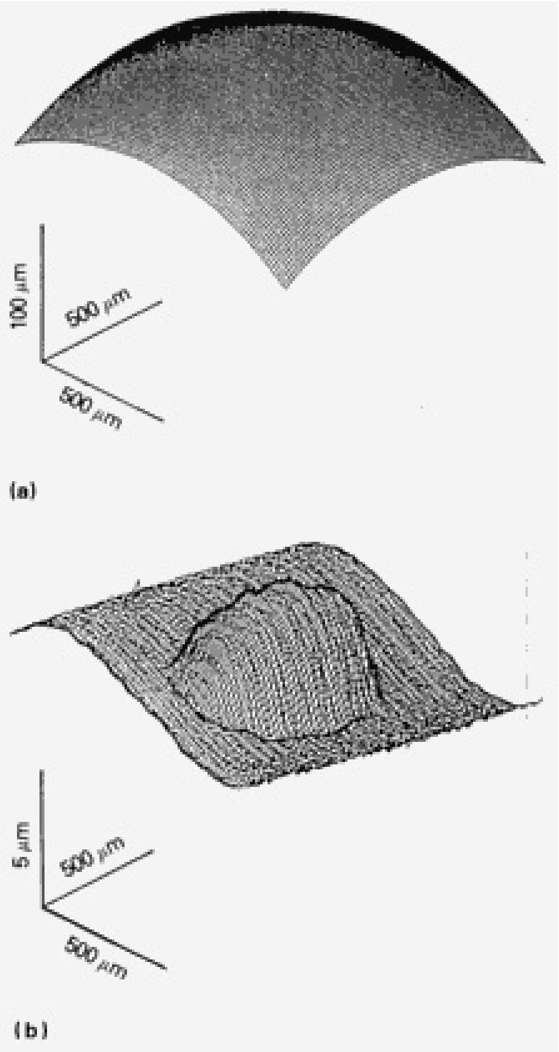

Fig. 8 (a) Topographic image with *x,y,z* coordinates of a ball with abraded area. (b) Difference image representing the difference between a sphere and the image in (a)

Curvature

There are a variety of techniques related to the determination of curvature for surfaces or for features. This information is useful when examining either slopes or the overall shape. It is generally desirable to use as many data points as possible in the determination of curvature to minimize the errors that are due to noise. The arrangement of neighboring pixels can be used for binary images (Ref 92). A spectral approach can be used (Ref 92, 93, 94, 95). Polynomials or circles can be fit to the data (Ref 15, 60, 96). The intersection of tangent lines is another technique (Ref 97). Curvature can be estimated from other computed parameters (Ref 92). Circular Hough transforms, discussed below, also provide a useful tool.

Hough Transforms and Pattern Matching. The Hough transform is one technique for locating shapes of known geometry in an image. For any shape, an appropriate function that maps an image or binary image onto a parameter space can be found. This mapping results in a sharp distribution of points in that parameter space around a coordinate representing the location of a selected reference point for that shape. Thus, the location of that shape has been located in the image. These mapping functions have been determined for lines (Ref 16, 98), circles (Ref 92, 98), and ellipses (Ref 98). There is also a method referred to as a general Hough transform. Used in computer vision systems, it can be applied to any arbitrary shape. Depending on how it is implemented, it can be either sensitive (Ref 98) or insensitive (Ref 99) to rotation. The sensitivity to noise and other error-producing effects have been studied in detail (Ref 100). This technique can be performed on either two-dimensional or three-dimensional data (Ref 101). A variety of other pattern-matching techniques also can be used (Ref 16, 102).

These techniques have the potential to enable an image analysis system to select individual features from surface images. These features could then be analyzed, manipulated, and classified individually. In one study, for example, an algorithm that learns which class a feature belongs to, according to the Fourier transform of its binary image, was developed (Ref 103). After a series of examples is given, the "typical" spectrum is automatically determined for each class of feature. The algorithm is then able to classify unknown features based on that learned "experience."

In another study, individual features were connected by a minimal spanning tree (Ref 33). A tree is a connected graph without closed loops, and a minimal spanning tree is a tree with the shortest possible total edge length. Figure 9 shows both a nonminimal and a minimal spanning tree, where each circle represents a feature. A histogram of the edge lengths was used to characterize the organization of the features on the surfaces studied. Trees are a very powerful tool and will be discussed again in the section below.

Fractals, Trees, and Future Investigations

A fractal surface is one that contains a range of either regular or random geometric structures that exhibit some form of self-similarity over a range of scale (Ref 45). This self-similarity may be that the surface actually looks the same at a different magnification or that it produces the same statistics, such as roughness. A self-similar fractal (Fig. 10) is the "purest" fractal. It naturally appears self-similar, regardless of scale. At a magnification of 10×, a typical feature has a certain lateral and vertical size. If a section of this trace is selected and viewed at a higher magnification of 100×, then a typical feature has about the same lateral and vertical size as before. The process might be repeated at 1000×. Figure 10 is further discussed below.

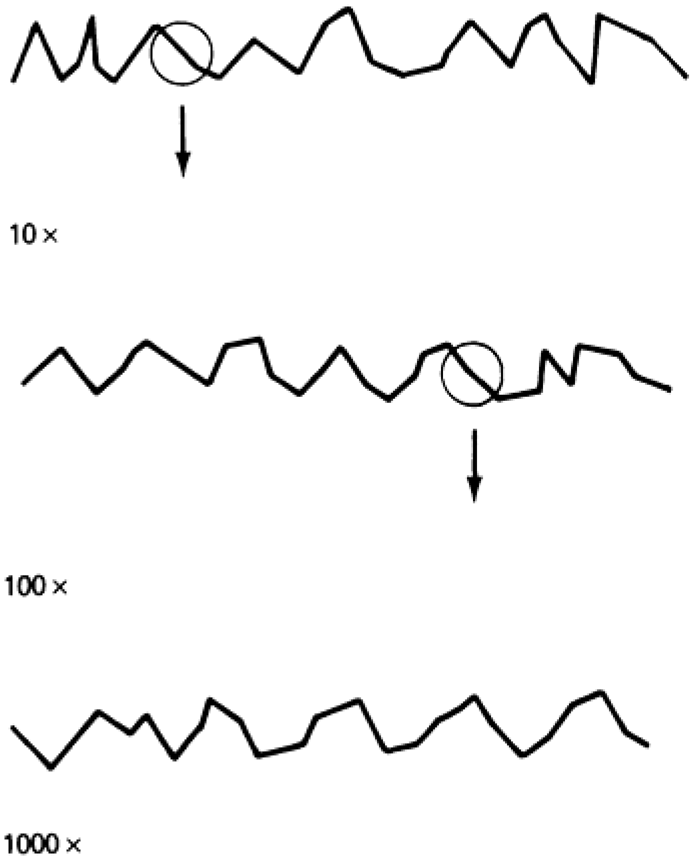

Fig. 10 Self-similar fractal

Self-similar fractals are described by their fractal dimension, which has a value from 1 to 2, for a single trace, and 2 to 3, for a surface. The integer part of the fractal dimension only indicates whether the data analyzed represent a trace (two-dimensional) or a surface (three-dimensional), and is not really important. The fractional part (on the right side of the decimal point) of the fractal dimension contains the important information.

In general, the higher the fractional part of the fractal dimension, the rougher the surface. However, many different methods of computing the fractal dimension have been derived, each yielding a different result (Ref 104). It has been shown, for example, that the fractal dimension of a fractured surface can have either a positive or a negative correlation with fracture toughness, depending on the details of how the fractal dimension is determined (Ref 105). Thus, care should be taken to know the details of how fractal dimensions are computed in an investigation. The range of sizes used in the calculation are very important and will be discussed later in this section of the article.

A self-affine fractal is only self-similar when expanded more in one direction than in another (Ref 106). Self-affine fractals require a second parameter, called the topothesy, which describes the scaling in one direction used to preserve self-similarity. Figure 11 shows an example. Like Fig. 10, sections of the image are selected and examined at progressively higher magnifications. In Fig. 10, the lateral and vertical size of a typical feature remained about constant for each magnification. However, in Fig. 11, the lateral size stays about constant while the vertical size increases. The vertical scale must therefore be compressed to maintain self-similarity.

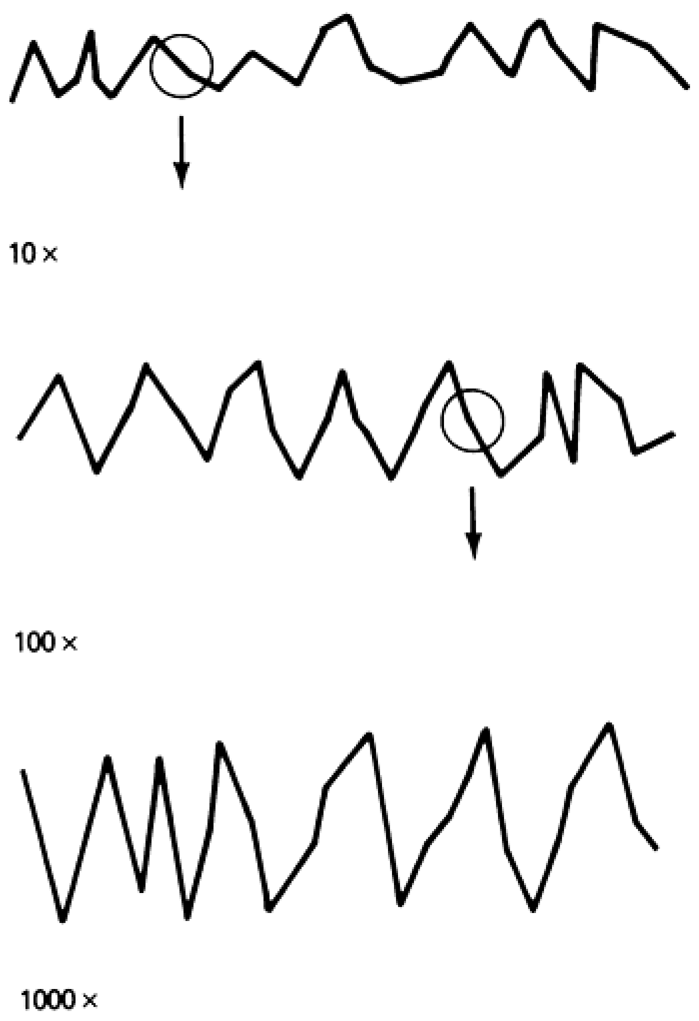

Fig. 11 Self-affine fractal

Unfortunately, self-affine fractals produce different values for most statistics at different magnifications. In fact, the variation of the standard deviation as a function of scale can be used to determine the topothesy (Ref 107). Single-valued functions can only be self-affine fractals, never self-similar. Because an image is a single-valuedfunction, images of fractal surfaces always appear as self-affine, even if the actual surface is self-similar. Thus, Fig. 10 could not actually occur unless the trace analyzed was not a single-valued function.

One example of this type of effect is a mountainous landscape on earth (Ref 107). When viewed from the top, contour lines of constant *z* height are often drawn in an *x,y* plane. These contour lines are not single-valued functions in *x* or *y* directions, and have been found to be self-similar. When *x,z* profiles of the same mountain are analyzed, they are single-valued functions of *x* in *z,* and are found to be self-affine fractals. There is also the possibility than an anisotropic surface may have a different topothesy, fractal dimension, or both, in different lateral directions (Ref 45). Some researchers have attempted to address this type of problem by using a matrix of fractal dimensions to describe surfaces (Ref 108).

Fractal behavior has been found in intensity images of surfaces of materials. The outlines of third-body wear particles in sliding (Ref 109, 110), martensite/austenite microstructures (Ref 111), and the growth of ion beam deposited alloy films (Ref 112) are examples. The topography of surfaces of materials has also been found to behave in a fractal manner, such as blasted steel panels (Ref 113, 114), coated surfaces (Ref 33), and fractured surfaces (Ref 105). One researcher examined worn rubber surfaces (Ref 110). The fractal dimensions of the surfaces were found to be limited to a finite size range and independent of the load, as long as the wear mechanism did not change. Surfaces of materials are always fractal only over some range of sizes. The largest scale possible is determined by the size of the specimen itself. The smallest scale is determined by the sizes of molecules. Any given profiling machine also covers only a certain range of sizes (Ref

22, 115, 116). If the size range of interest is too large for a single machine to characterize accurately, then images from several machines may be required.

Most surfaces appear to have several fractal dimensions, each over a different size range. One researcher describes a reasonably simple algorithm, which partially addresses this problem (Ref 49). It is assumed that there are two fractal dimensions in the image to be analyzed. The fractal dimension of the smaller, finer details is termed the textural fractal dimension. Another fractal dimension, which is found for the coarser, structural features, is termed the structural fractal dimension. If the two dimensions are not significantly different, then the surface is considered to have only one fractal dimension over the entire range of sizes analyzed. If they are different, then the scale of size where the surface changes from the one fractal dimension to the other is determined. Based on the results in Ref 107, a similar approach can be performed for topothesy.

It is possible for a surface to have different fractal dimensions and/or topothesy in different areas occurring simultaneously, even within the same size range. A groove on a worn surface may have different characteristics than a lump, for example. Though not yet documented for topographic images of materials surfaces, it is conceivable that such a phenomenon can occur. Although it is difficult to thoroughly verify this observation with current techniques, the exploration of such phenomena will now be discussed, because they serve as good examples of how future investigations might be performed.

Consider a severely worn surface that has large grooves, ridges, holes, and lumps. Each of these types of features can have smaller grooves, ridges, holes, and lumps. It may be that the grooves of various sizes, when considered separately from the other types of features, have one fractal dimension, whereas lumps have another. This could theoretically be tested by generating four new images from the original image. One image would consist of only the grooves, one of only the ridges, one of only holes, and one of only lumps. This might be accomplished using a multiscale pattern-matching algorithm (Ref 117). The fractal dimension of these images could then be compared and any differences characterized.

It is also of interest to determine if a large groove and a large lump have the same "mix" of smaller features on them. There are several ways to investigate this. One is to generate a new image, where each pixel represents the fractal dimension of the original image immediately around that location. How the fractal dimension changes as a function of lateral position can then be studied. Such a procedure has been used in medical imaging (Ref 118) and for studying the sea floor (Ref 106). The same procedure might be applied to other parameters, as well.

There is, of course, the issue of how large a sampling area each pixel in the new image should represent. A technique termed "adaptive mask selection" attempts to determine the optimal sampling area for each pixel (Ref 119).

A second approach for studying the types of smaller features that are contained on larger ones uses a multistep process. First, select a typical large groove and generate a second image of just that groove and all its internal structure. Next, filter out the longer wavelengths of the large groove to generate a third image of only the smaller internal features. These steps can then be repeated for large ridges, holes, and lumps. The topographies of the smaller features within the larger features could then be compared.

Additionally, this process could then be repeated recursively on the smaller features to determine what each of them contains. This would result in a tree structure, known as a relationship tree (Ref 120). Figure 12 depicts how part of such a tree might look. Note that the overall size of each feature is also recorded in the tree. As noted previously, much of computer science is devoted to the manipulation and classification of trees, making this form of representation very powerful.

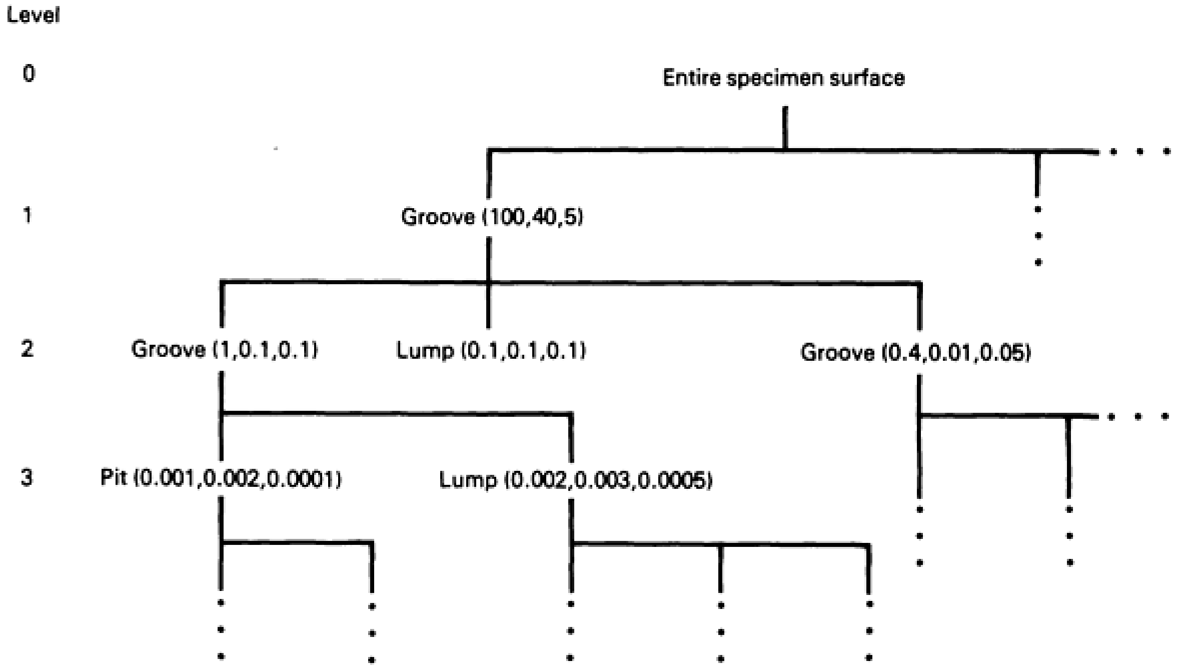

Fig. 12 Example of portion of relationship tree of larger features, each containing smaller features. Each node contains information denoting both type of feature and overall feature size in micrometers.

Confocal Microscopy

Monica A. Schmidt, Martin Marietta Energy Systems, Inc.; Robert D. Compton, NORAN Instruments, Inc.

Introduction

CONFOCAL MICROSCOPY is a relatively new technique for surface topography imaging that has applications in characterizing worn and damaged surfaces. Confocal imaging uses a special optical microscope, sometimes called a confocal scanning optical microscope (CSOM), which is interfaced to an image analyzer to allow quantitative measurements of surface topography, in both lateral and vertical dimensions. Optical images that maintain clear focus over a large depth of field can be produced. Surface roughness measurements can be made on opaque samples, and subsurface structure can be clearly imaged and characterized in optically translucent samples.

Image analysis techniques allow three-dimensional reconstruction and sectioning of surfaces (Ref 1), and generation of stereo images. Confocal microscopy is ideal for the imaging and analysis of irregular structures, such as fracture surfaces. Surfaces with large differences in height are difficult to interpret using conventional light microscopy, but are ideal for confocal microscopy.

The term confocal simply means "single focus." In a confocal microscope, confocality is achieved through the use of pinhole optics that prevent out-of-focus light from reaching the image plane. The sample is illuminated through an objective lens with a pinpoint of light, and a pinhole aperture is placed in the reflected light path. Light reflected from the sample at the focal plane of the objective lens passes back through the lens, through the pinhole, and forms an image of the illuminated spot. Reflected light from other regions of the sample is blocked by the aperture. An image of the sample is created by moving either the sample or the light source in an appropriate scan pattern, and either recording or viewing the resulting signals.

Confocal images, also called optical sections, have very good resolution and sharp contrast levels because only light reflected at the focal plane of the objective lens is imaged. Light reflected from sample features distant from the focal plane of the objective lens is blocked from the image, so that defocused regions remain dark and cannot deteriorate the resolution of the image.

Confocal microscopy offers new capabilities that can be applied to wear and abrasion studies. Surface topography can be characterized visually and quantitatively using microscopy and image analysis techniques. Scratches, gouges, and other forms of surface damage can be measured without physically contacting the surface, eliminating the risk of creating additional damage during the measurement. Induced subsurface damage in translucent materials can also be analyzed, which provides new opportunities for materials evaluation in failure analysis or from controlled wear experiments.

Confocal microscopes have found broad use in semiconductor (Ref 2), biological, and other materials applications (Ref 3). In contrast to electron microscopy, samples do not have to be electrically conductive or vacuum compatible. Applications that utilize the three-dimensional capabilities of confocal microscopy include studying internal features of polymers and inspecting integrated circuits. Microscopy of biological materials has benefited dramatically from the application of this new tool, particularly the determination of fluorescence-stained cellular and tissue structures. In these applications, confocal imaging can show the internal structures of translucent specimens that have not been dissected. Real-time imaging makes it possible to study living tissue.

Development of Confocal Microscopy. The first patent on confocal microscopy was filed by Minsky in 1957 (Ref 4). In this patent, a pinpoint of light was focused onto a specimen, reflected light was focused onto a pinhole, and light passed by the pinhole was optically coupled to the image plane. An image was created by electromechanically moving the sample in a scan pattern and using the illumination passing through the pinhole to produce an image on a long-persistence cathode-ray tube.

The next major step was taken in the late 1960s by Petran and Hadravsky (Ref 5), whose designed centered around the use of a Nipkow disk (Ref 6) (Fig. 1). The apertures of this disk simultaneously formed multiple points of light and served as pinholes to produce confocal imaging. By spinning the disk rapidly, this tandem scanning microscope (TSM) produced a real-time confocal image.

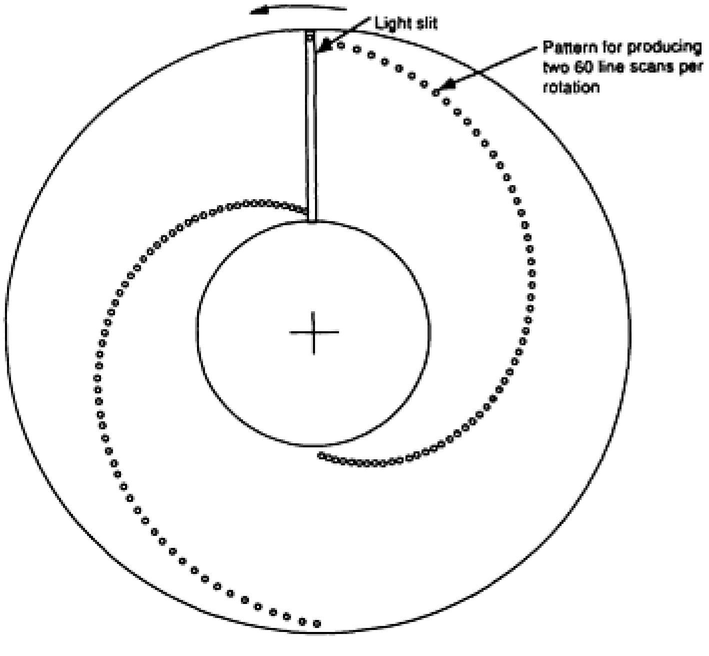

Fig. 1 Classic Nipkow disk, where light passing through the slit and the disk apertures is detected to produce a line scan of the image. If hundreds of aperture tracks are used to form a full symmetrical pattern, real-time imaging can be achieved.

In the 1970s, lasers were introduced as point sources. In 1987, the modern laser confocal scanning microscope (LCSM) was developed by Aslund *et al.* (Ref 7). This microscope employed high-speed galvanometer scanning and produced images in 1 to 2 seconds. High-performance commercial systems of both the TSM and the LCSM variety appeared in the marketplace shortly afterward. The most recent development, a real-time LCSM that was commercially introduced in 1990, features acousto-optic deflection of the laser beam.

Acknowledgements

This research was sponsored by the U.S. Department of Energy, Assistant Secretary for Conservation and Renewable Energy, Office of Transportation Technologies, as part of the High-Temperature Materials Laboratory User Program, under contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc.

The authors would like to acknowledge the support of Dr. Peter J. Blau and Dr. Charles S. Yust, who provided the specimens to demonstrate applications for confocal microscopy and who volunteered their time to review this article.

Principles of Confocal Microscopy

A confocal microscope is a specialized form of a reflected-light microscope that can measure both vertical and lateral dimensions of a specimen. Its image, called an optical section, displays a planar view of the specimen, centered about the focal plane of the objective lens and oriented perpendicular to the optical axis (Fig. 2).

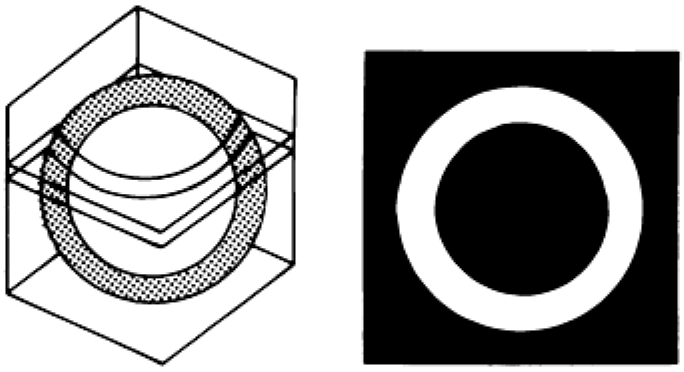

Fig. 2 Optical slice of hollow sphere

The optical section has both high resolution and contrast, because the confocal design of the microscope blocks light reflected from specimen regions distant from the focal plane of the objective lens. Thus, regions that are in focus (near the focal plane) appear bright, but regions that are out of focus (distant from the focal plane) appear dark in this optical section. Exceptionally clear images of the surface features of opaque samples can be obtained, as can internal features of transparent samples, because defocused light is removed from the image.

In a basic confocal microscope, confocality is achieved by collimating the light source, focusing light through the objective lens to form a spot on the focal plane, and focusing reflected light through the same objective lens onto an aperture (Fig. 3). Light that passes through the aperture is focused onto a detector, where it forms one point of an image. Most of the light from other areas, including scattered, reflected, and fluorescent light from out-of-focus planes, is blocked by the aperture and cannot degrade the image. Thus, the information contained in the imaged spot is limited to a narrow elevation range centered around the focal plane of the objective. Lateral scanning of either the sample or the light source is necessary to build up a complete optical section.

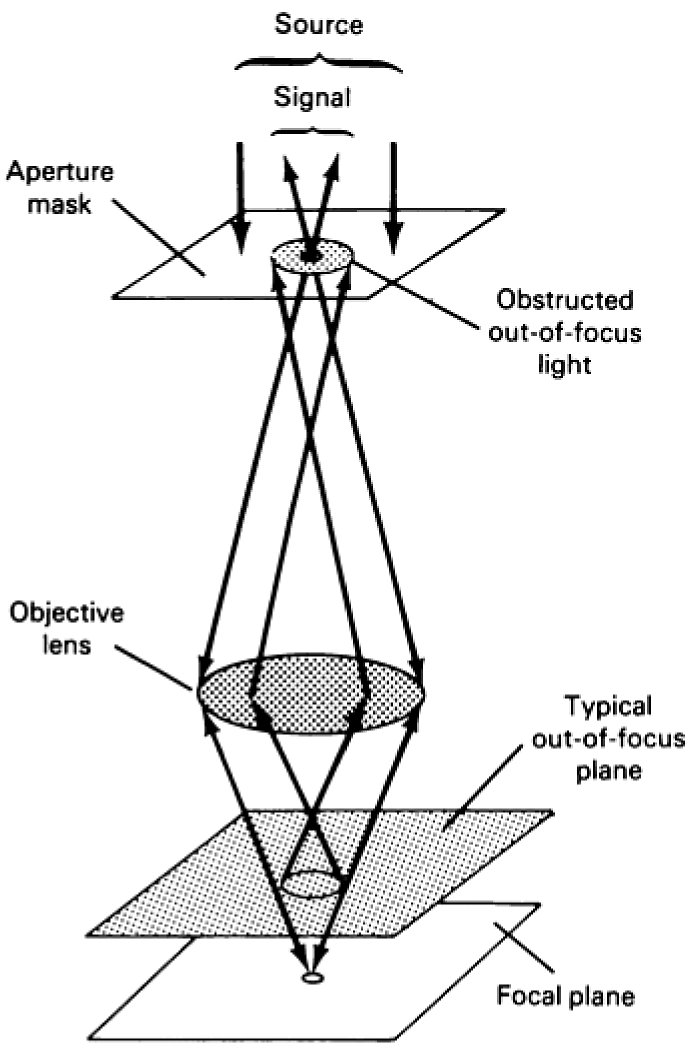

Fig. 3 Confocal principal

The vertical resolution of the confocal optical section is the function of several factors, including aperture size, wavelength of the light source, and numerical aperture of the objective lens. Thus, the operator has some degree of control, primarily by his selection of the objective lens. The vertical resolution is proportional to the square of the numerical aperture (Ref 8), and reaches a limit of about 0.4 μm (16 μin.) for a dry objective lens with a numerical aperture of 0.95. The transverse resolution also is controlled by selection of the objective lens, but is proportional to the first power of the numerical aperture. Thus, the availability of suitable objective lenses can limit applicability of the microscope, depending on the size of features to be analyzed.

The intensity of reflected light in each optical section varies inversely with the distance of the sample feature from the focal plane of the objective lens. This characteristic allows image analysis techniques to make quantitative surface topography measurements, and to construct composite images that maintain focus across large focal depths from several images spanning a range of focal positions. In a typical application, the sample is translated vertically in discrete increments relative to the objective lens. The appearance and subsequent disappearance of sample features provides an understanding of the three-dimensional nature of the sample.

Experimental Techniques

Microscope Configurations. The classification of confocal scanning optical microscopes is based on the light source and on the scanning technique used, as shown in Table 1. The two basic types use either laser or nonlaser illumination. The nonlaser configurations typically use high-intensity arc sources in conjunction with a Nipkow spinning disk for real-

time image scanning. Laser-based microscopes produce an image by scanning the beam across the sample in a TV-like raster pattern, and the data are stored, point by point, until a complete image area has been scanned.

Table 1 Hardware configurations for confocal microscopes

Microscope type	Acronym	Light source	Scanning technique
Tandem scanning reflected-light microscope	TSRLM, TSM	Nonlaser	Nipkow disk, separate illumination and image paths
Real-time scanning optical microscope	RSOM	Nonlaser	Nipkow disk, combined illumination and image paths
Laser confocal scanning microscope	LCSM	Laser	Dual galvanometer scanning of laser beam
Real-time laser confocal microscope	RLCM	Laser	Acousto-optic scanning of laser beam

In nonlaser confocal microscopes, emission from the broadband light source is collimated before illuminating a circular region of the Nipkow disk. Each aperture on the illuminated region of the disk forms one pinpoint of light (Fig. 4). Hundreds of points of light are produced simultaneously and focused on the sample. Reflected light is then refocused upon imaging apertures on the opposite side of the disk. Light that passes through the apertures forms a pattern of image points on the image plane. By spinning the disk at high speeds, the pinpoints of light scan across the sample to produce a full-color, live image. The image can be either visually observed or recorded with a video camera.

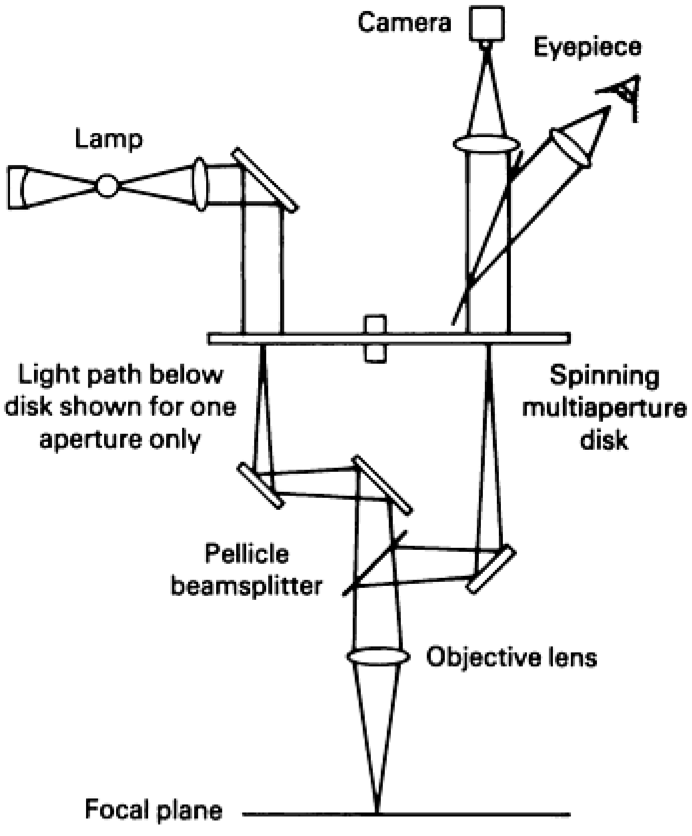

Fig. 4 Simplified optical diagram of confocal tandem-scanning reflected-light microscope

In a laser-based microscope, a single-wavelength laser beam is scanned to form a two-dimensional pattern of light pinpoints on the sample. Light reflected from the focal plane of the objective lens is focused upon a single aperture, and is then detected and stored to produce a two-dimensional image (Fig. 5). The most common scanning technique involves the use of dual galvanometers. However, a recently introduced variation involves the *x*-axis scanning of the laser beam at video rates, using acousto-optic deflection of the laser beam.

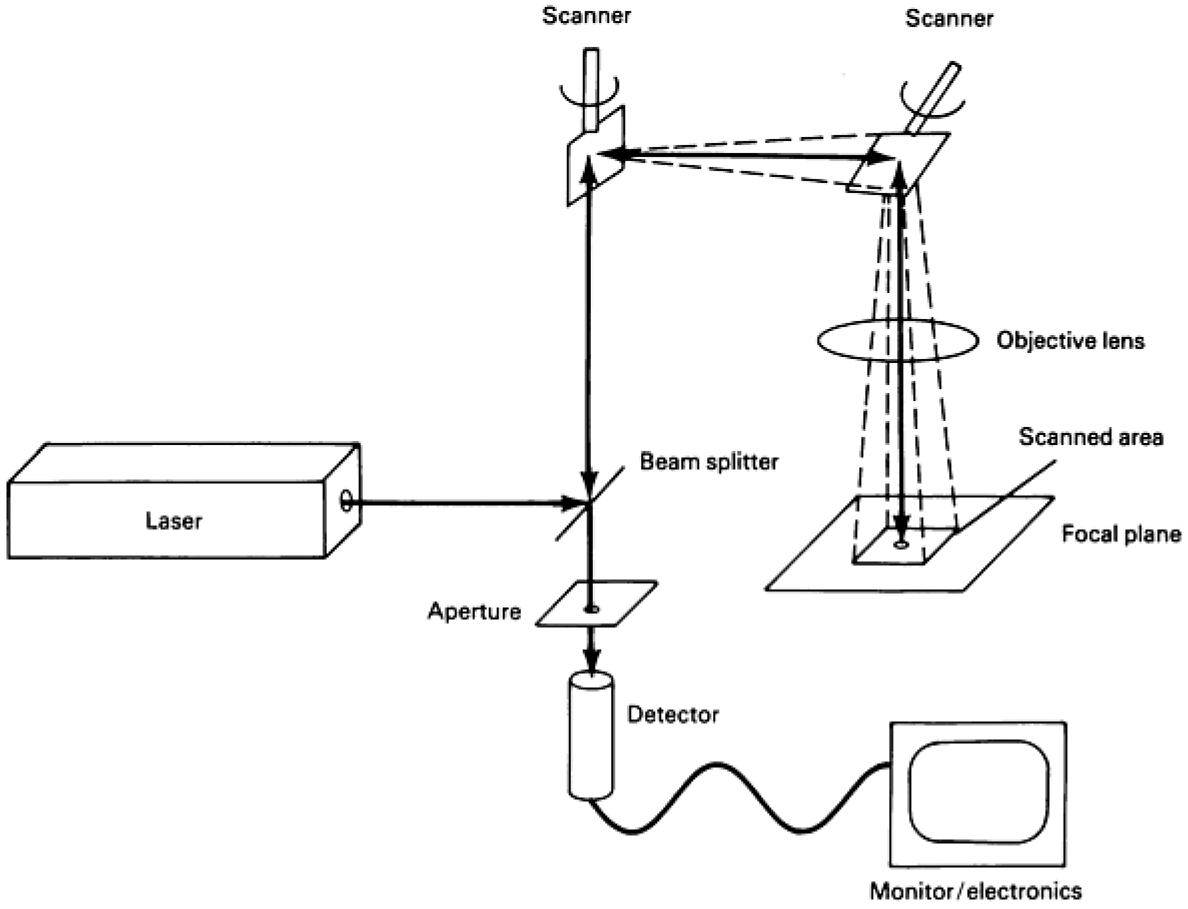

Fig. 5 Diagram of confocal laser scanning microscope

Other than the scanning technique, the primary differences between laser and nonlaser confocal microscopes involve the spectral content of the light, the brightness of the light beams, and the resolution. The nonlaser microscopes produce a full-spectrum image, rather than the monochromatic image inherent with laser illumination. For many samples, the full-color image provides many advantages that can be related to sample characteristics.

The intensity, inherent collimation, and monochromatic nature of laser illumination provide a brighter image, because the full power of the laser can be focused to a diffraction-limited spot. This spot brightness is particularly important in biological applications, where high intensities are needed to produce bright fluorescent images, but is not a significant advantage for reflective samples, such as those that are typical in metallography. The diffraction-limited spot of the laser beam also results in a 1.4× increase in the system lateral resolution.

Specimen Requirements and Limitations. Because confocal microscopy is an optical technique, specimen requirements are minimal. Samples do not need to be either electrically conductive or vacuum compatible. Opacity does determine which features of the sample can be studied, but both opaque and translucent samples can be analyzed. Although surface roughness can be measured for opaque samples, subsurface defects cannot be imaged.

Both surface and subsurface features of translucent samples can be observed, depending on the clarity of the material. In translucent specimens, the reflectivity and the tilt of the internal surface determine how well that surface will be visible in the optical section. Subsurface features that are overlaid vertically can create artifacts in computer-constructed images, and may increase the difficulty of quantitative measurements.

Two types of surface features are not suitable for analysis using confocal microscopy. Features in opaque samples that are obscured from line-of-sight view cannot be studied, because light cannot reach them. Features with nearly vertical sides, particularly cracks or pits where the depth is much larger than the width, are very difficult to measure. Because light from

these vertical features is often not reflected back to the objective lens for detection in the image, the features appear dark and out of focus.

Another limitation is the availability of objective lenses that have the optimum characteristics for viewing features of interest in the sample. Because the objective lens affects the three-dimensional resolution of the microscope, the availability of suitable lenses can limit the visibility of sample features. Critical objective lens characteristics include the working distance of the lens, and its field of view and numerical aperture. The former controls the magnitude of surface roughness that can be imaged clearly before the lens touches the sample, and the latter two control the maximum lateral size and vertical resolution limit of the features that can be analyzed.

Image Acquisition. The first step in the application of a confocal microscope is to survey the nature of a sample and determine which areas are most representative of the data being sought. Such surveys involve not only area analysis, but also depth analysis. Any existing pits, cracks, or fissures can be located and analyzed to determine whether a more detailed analysis of the area is appropriate.

The ease and simplicity of this process is one of the prime features of the tandem scanning reflected-light microscope (TSM) and the new real-time laser confocal microscope (RLCM) instruments. For some applications, such real-time analyses can be sufficient. However, for many applications, it is useful to further investigate the three-dimensionality of the sample and to extract such data in a usable form.

The next step is to acquire a series of images, known as a *z*-series, at specific increments across the total depth range of interest, and to store these images in either video or digital memories. Image capture--using a TV camera and image storage on videotape using VCR techniques--provides the fastest acquisition and lowest-cost storage method. However, the most powerful and common method is computer digitization of each acquired image as either a square or rectangular array of pixels. Each pixel typically has an intensity value that is based on 256 gray levels.

The *z*-series optical sections are typically acquired at precise vertical intervals. The proper selection of these intervals, which is based on the vertical resolution of the optical section, assures the operator that data are not missed (Fig. 6). The resulting images can be used for a broad range of sample analysis techniques that utilize computerized image processing.

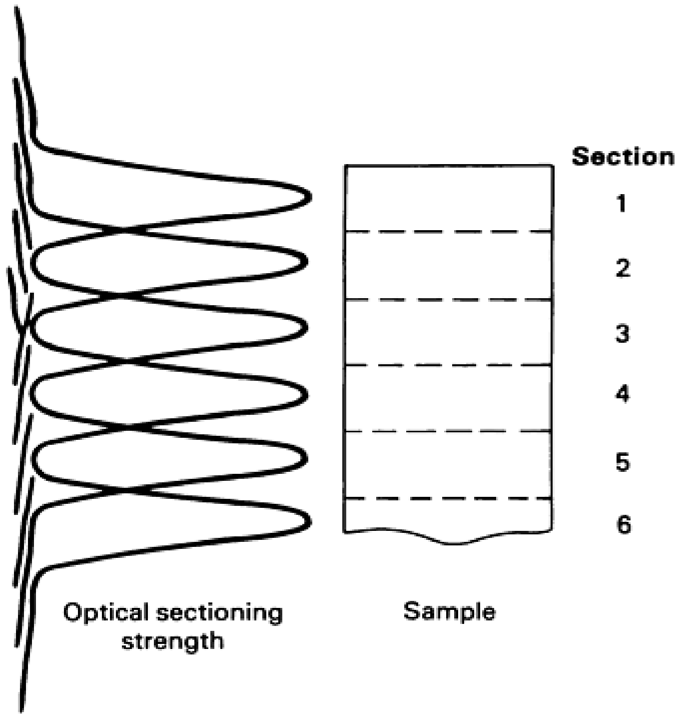

Fig. 6 Use of optical sections to completely cover entire sample depth with no missing information

Computerized Image Processing. Advanced image processing and analysis can be used with confocal microscopy to provide new techniques for studying surfaces. Both visual and quantitative data can be obtained by acquiring and processing a *z*-series of optical sections spaced in precise depth increments.

Table 2 lists image processing techniques that are used in confocal microscopy. For example, a composite through-focus image of a rough surface that maintains clear focus across the entire field can be generated. The final image comprises only the brightest (in-focus) pixels from all of the *z*-series images. Similarly, a topographic image can be produced in which the brightest pixel is gray-level coded so that it can be directly related to depth. The three-dimensional nature of these data not only allows the generation of three-dimensional images, stereo pairs, and isometric reconstructions, but makes it possible to perform profilometric and volumetric measurements. Such capabilities have proven particularly useful to researchers and technologists involved in surface morphology analyses.

Table 2 Image processing techniques for optical sections from confocal microscopy

Image type	Description	Pixel display mode
Through focus	Creates a clearly focused image with a large depth of field	Each pixel value in the final image equals the maximum intensity of any pixel at that location
Extended focus	Summation of multiple clearly focused images	Each pixel is a summation of all pixels at the same location
Topographic data	Display color or gray scale is proportional to the relative height of that feature on the surface of an opaque sample	Gray scale is proportional to the position of the optical section where maximum intensity value occurs
Topographic display	Projects the surface features in three dimensions using hidden line suppression techniques	
3-D projections	Contour lines of surface features are stacked in three dimensions for manipulations such as rotation, tilting, and cross-sectioning	
Stereo pairs	Two *z*-series are acquired by tilting the sample relative to the objective lens. Through-focus images are used to create an anaglyph image for viewing with stereo-optician-type optics	

Applications

Examples described in this section, which illustrate the application of confocal microscopy to characterize worn and damaged materials, include:

- The study of subsurface cracks that result from a scratch on the surface of a glass slide
- The analysis of arc-shaped cracks in the wear track of a SiC ceramic
- The evaluation of the topography of a wear track in a ceramic composite

Figure 7 shows a *z*-series of optical sections, spaced in increments of 5 μm (200 μin.). This series was produced by imaging below the surface of a scratch in a glass slide. The first optical section shows the scratch on the glass surface. The crack structure can be clearly observed in the succeeding optical sections as it initially descends vertically from the scratch, and then begins to branch out at 15 μm (600 μin.) below the surface. Notice that different features of the subsurface cracks come into focus at different elevations.

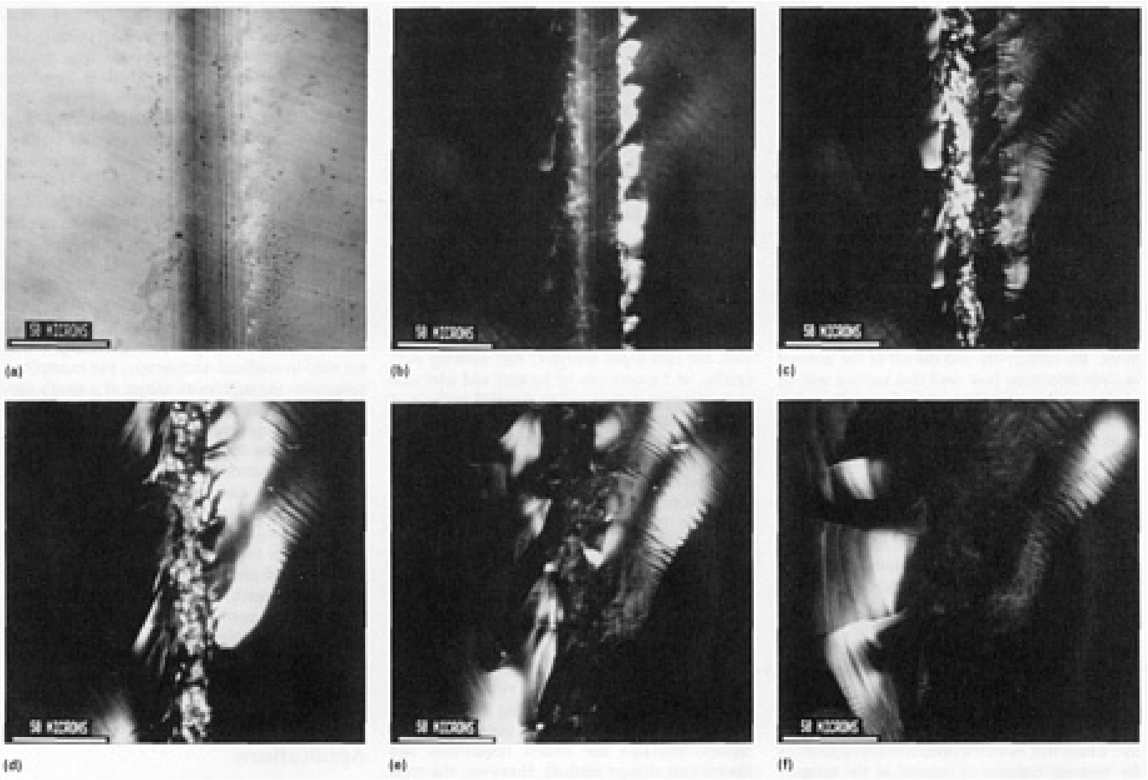

Fig. 7 Series of optical sections showing subsurface crack structure in glass slide, beginning at the surface in intervals of 5 μm (200 μin.). Scratch was made with a spherically tipped diamond stylus, 0.2 mm (8 mil) tip radius, using a 10 N (2.25 lbf) normal load and 13.0 mm/s (0.5 in./s) velocity.

Figure 8 shows the usefulness of through-focus and topographic images for analyzing the cracks produced in a wear experiment in which a SiC ceramic was tested. The through-focus image shows the entire field of view in the region of the cracks, maintaining clear focus. The corresponding topographic image displays the relative height of features using the intensity values in the image, so that the cracks show clearly in black. A linear analysis across the cracks can be used to analyze their depth, as well as width.

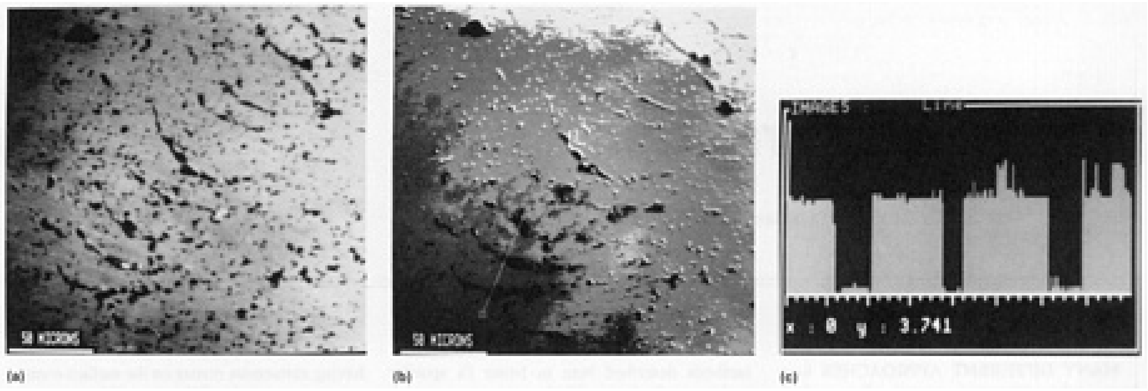

Fig. 8 Confocal microscopy analysis of a SiC ceramic wear specimen showing details of microcracks. Wear damage was produced by a silicon nitride ball sliding unlubricated over the surface with a 10 N (2.25 lbf) load and 0.1 m/s (4 in./s) sliding velocity in air at room temperature. (a) Through-focus image. (b) Topographic image. (c) Linear analysis along line displayed in (b), with a vertical range of 3.1 μm (125 μin.)

Figure 9 shows how the larger topography of a wear track can be evaluated and then displayed as a three-dimensional projection. Again, the topographic image was used to illustrate surface roughness, and linear analysis was used to quantitatively analyze the wear track. The image was then projected into three dimensions and tilted to reconstruct the surface, providing more visual details. This image is more intuitive to interpret than its source topographic image.

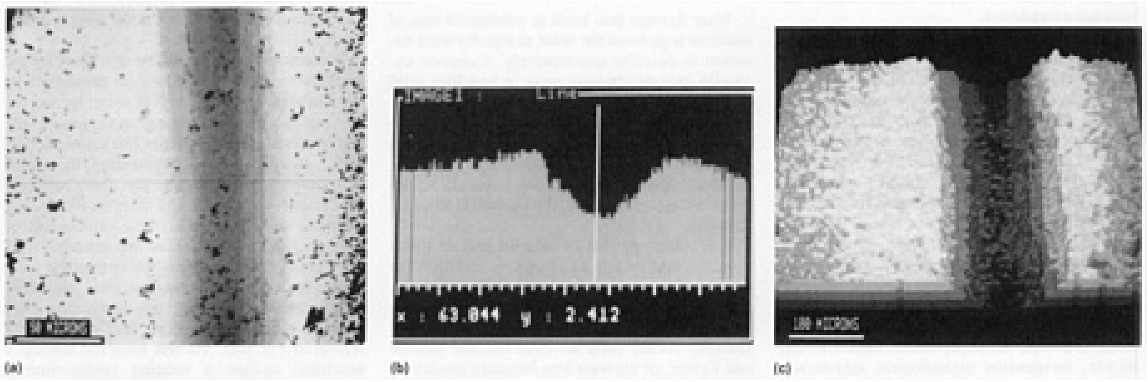

Fig. 9 Confocal microscopy provides topographic analysis of wear track. (a) Topographic image. (b) Linear analysis along line displayed in (a), with vertical range of 4.9 μm (196 μin.). (c) Topographic display using hidden line suppression techniques

Wear Measurement

A.W. Ruff, National Institute of Standards and Technology

Introduction

MANY DIFFERENT APPROACHES have been used to determine amounts of wear, both qualitatively and quantitatively. An examination of the technical literature (Ref 1 and 2, for example) and published standards (Ref 3) that relate to wear reveals the breadth of techniques that have been employed.

There are a number of reasons as to why this situation exists. One is that the type of wear damage can take several forms. If material is actually lost during wear, then a commonly used method of measurement is to determine the amount of removed material, perhaps by weight loss, as is also done in the field of corrosion. Alternatively, if the wear process leads to surface distress on some component, then surface roughening or cracking may be measured. Other forms of surface and subsurface wear damage can be encountered, as well, and can be measured by other direct and indirect methods.

The amount of wear will also influence the selection of measurement method. If large amounts of wear are experienced, then relatively simple, inexpensive measurement approaches, such as volume change or mass change determination, are usually conducted successfully. Alternatively, if very small wear amounts are experienced, then more sensitive and costly techniques are necessary to detect minute changes of mass or volume.

The type of investigation being conducted is yet another factor that influences the choice of wear measurement method. In a research laboratory, it may be essential to carry out a highly precise measurement in order to correctly identify differences among either the effects of research parameters or the materials involved. In contrast, if a field study is being conducted to determine the basis for proposed changes in usage conditions for a tribosystem, then perhaps less exacting measurement options would suffice as the basis for a valid decision.

An objective of this Volume is to provide examples of problems and solutions that are encountered in the wear field. Therefore, this article describes many of the most common methods used to measure wear, based on the literature, and presents the information in sufficient detail for the reader to make a selection for a problem at hand. It is certainly appropriate, and in some instances necessary, to modify the methods described here to better fit specific problems. Such modified wear measurement methods add to the wealth of approaches available in this field.

Mass Loss Measures of Wear

Wear damage that leads to substantial loss of material is perhaps the most straightforward situation to describe quantitatively. Common examples include abrasive wear in handling solid materials, as occurs in the mining industry. Wear loss can be determined by measuring either mass change or dimensional change, which is discussed in the next section of this article. Because most laboratories have access to equipment that weighs objects, the method is straightforward.

It is necessary that an original part or specimen (or equivalent) be weighed, and that the weight of the object after wear exposure be determined and subtracted from the original to determine the difference in weight (that is, mass change). As the parts involved become smaller and lighter, or the wear loss becomes smaller, it will be necessary to use increasingly sensitive weighing equipment. At some point, the mass change will be too small for the method to be feasible.

Other problems with this approach include the need to clean the specimen carefully to avoid having extraneous matter on the surface contribute to any weight difference. Of course, any fluids or solids used in cleaning must be thoroughly removed or dried. Another consideration is that material that was plastically displaced by the wear process but not actually removed from the part will not be included in the weight difference.

The amount of wear can be described by the absolute amount of mass loss (in grams), or by the rate of mass loss per unit of usage (grams per day), or by a fractional change in the mass of the part involved (1% change per 100 hours of operation). In many areas of engineering, the choice of reporting unit is frequently a conventional one. In most of the ASTM wear standards, the reporting unit of wear is cubic millimeters of volume, rather than mass, so that materials with different densities can be better compared.

One example in this category, from laboratory measurements, could be the application of a standard abrasive wear test, ASTM G 65. As shown in Fig. 1(a), the test involves loading a specimen against a rotating rubber-rimmed wheel while a flow of abrasive sand is directed at the contact zone. This test is widely used by industry to assist in selecting materials for abrasive wear service. Choices of loads and sliding distances are detailed in the test method. A photograph of a wear scar on a typical specimen is shown in Fig. 1(b). Because the test is a standard, it has been used in many interlaboratory studies of different materials.

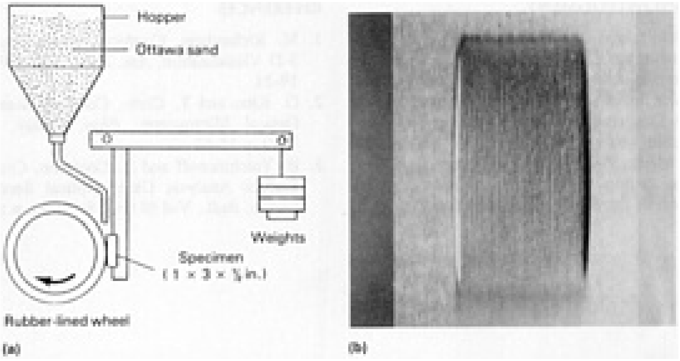

Fig. 1 (a) Schematic of standard abrasive wear test, ASTM G 65. (b) Wear scar on typical specimen

One set of results from a National Institute of Standards and Technology (NIST) study of a tool steel, shown in Fig. 2, is expressed in terms of mass loss (in grams) and wear scar maximum depth (in inches). Some idea of the observed variation from test to test can be seen. Intralab precision for this test can be as low as 3% (relative), and interlab precision, as low as 5%. Additional data on other materials can be found in the standard itself. The approach of measuring mass change in this test method is usually quick and inexpensive, and specimen costs can be low. Weld-overlay materials, coatings, ceramics, composites, and many other types of materials can be studied using this method.

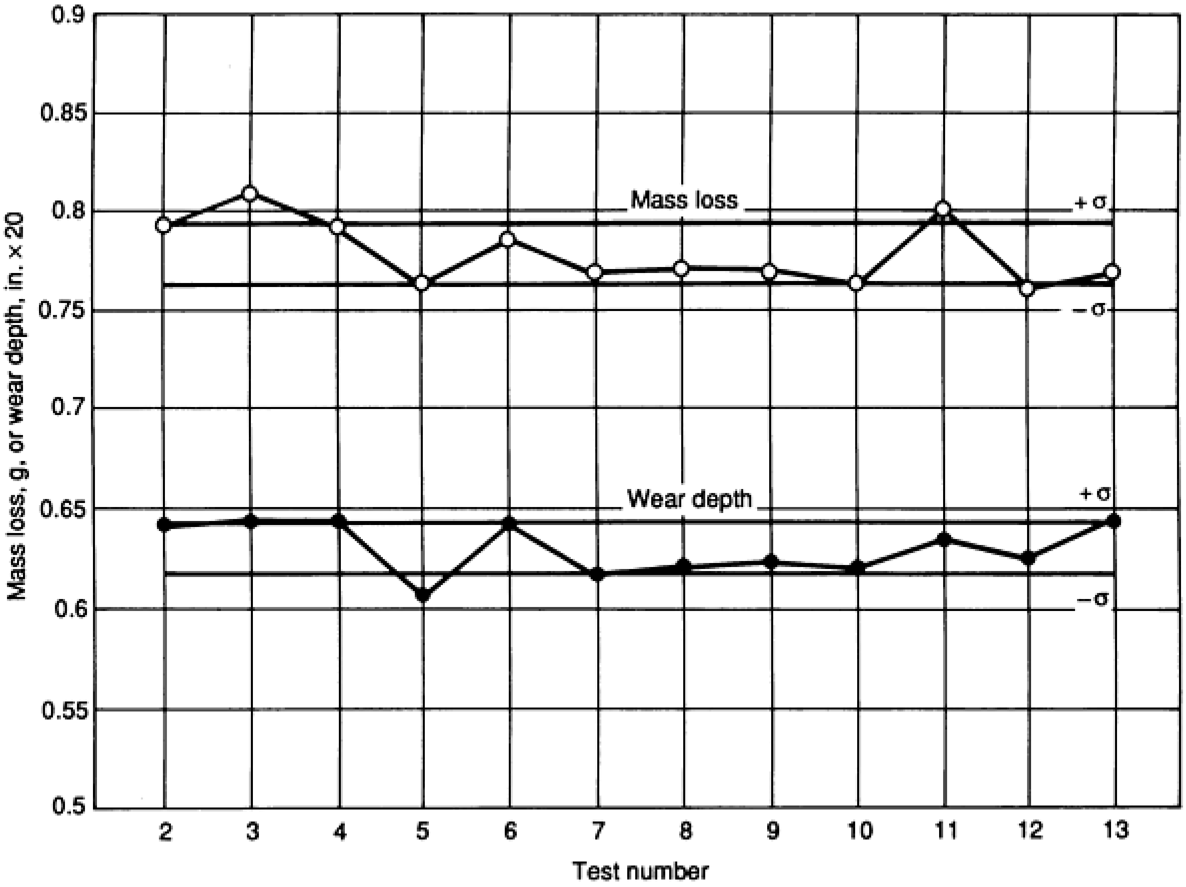

Fig. 2 Wear loss results (from a NIST study of a tool steel) expressed as mass loss (g) and wear scar maximum depth (in.). σ**, standard deviation**

Another example in this category is drawn from a report of a study of coins in circulation (Ref 4). The purpose of the study was to examine the serviceability of different coin materials, as determined by loss of mass during circulation. Figure 3 shows the results of sampling a particular denomination of coin removed from circulation. Although the variation in mass for any particular year is large, the trend of increasing wear with circulation time is clear. Because the service conditions were not controlled, the scatter in the wear data is not surprising.

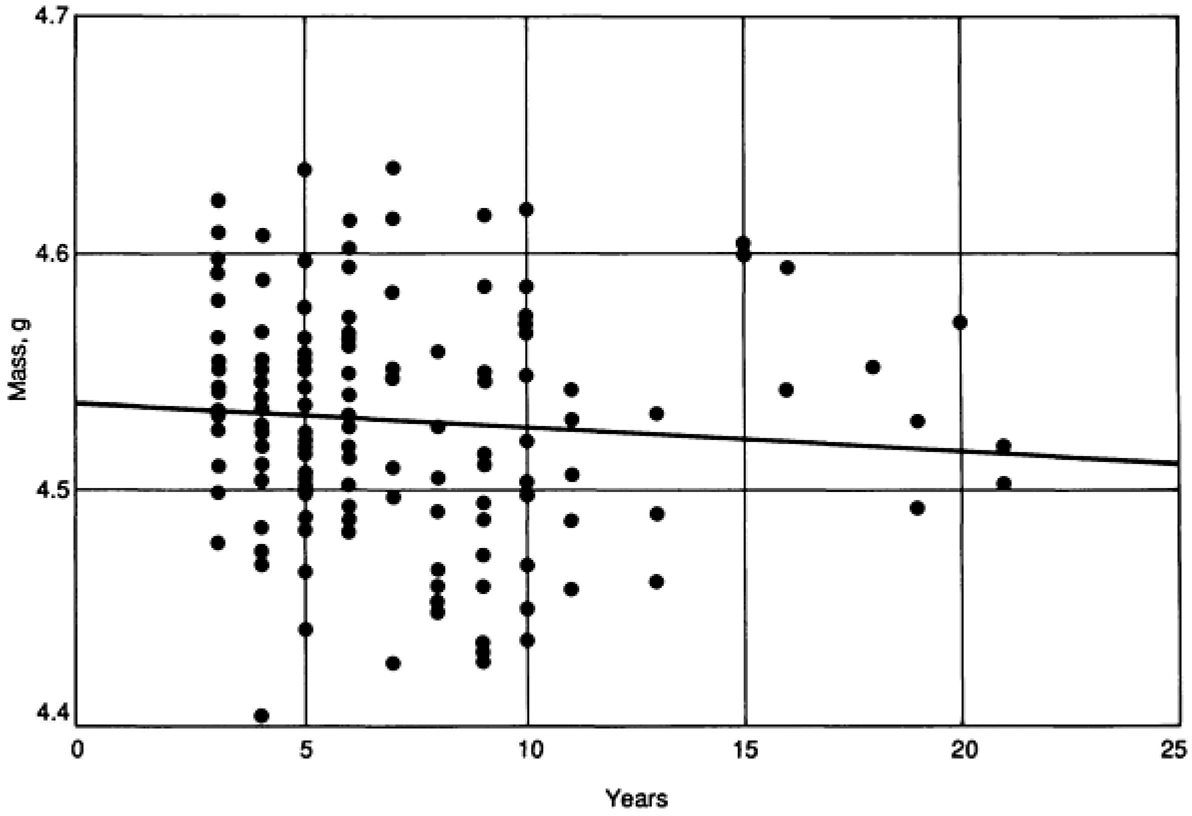

Fig. 3 Wear loss results for particular denomination of coin removed from circulation, showing a trend of increasing wear with circulation time, with considerable scatter of the data. Source: Ref 4

To simulate use conditions, a laboratory test involving tumbling of coins inside of slowly rotating cylinders under controlled conditions was developed. The tests showed the importance of surface hardness in reducing wear rate, and the influence of test parameters (for example, cylinder diameter and number of coins tested together) on the results (Fig. 4). In the laboratory study, weight loss was used as the measure of wear, and a sensitivity of 0.01% was achieved.

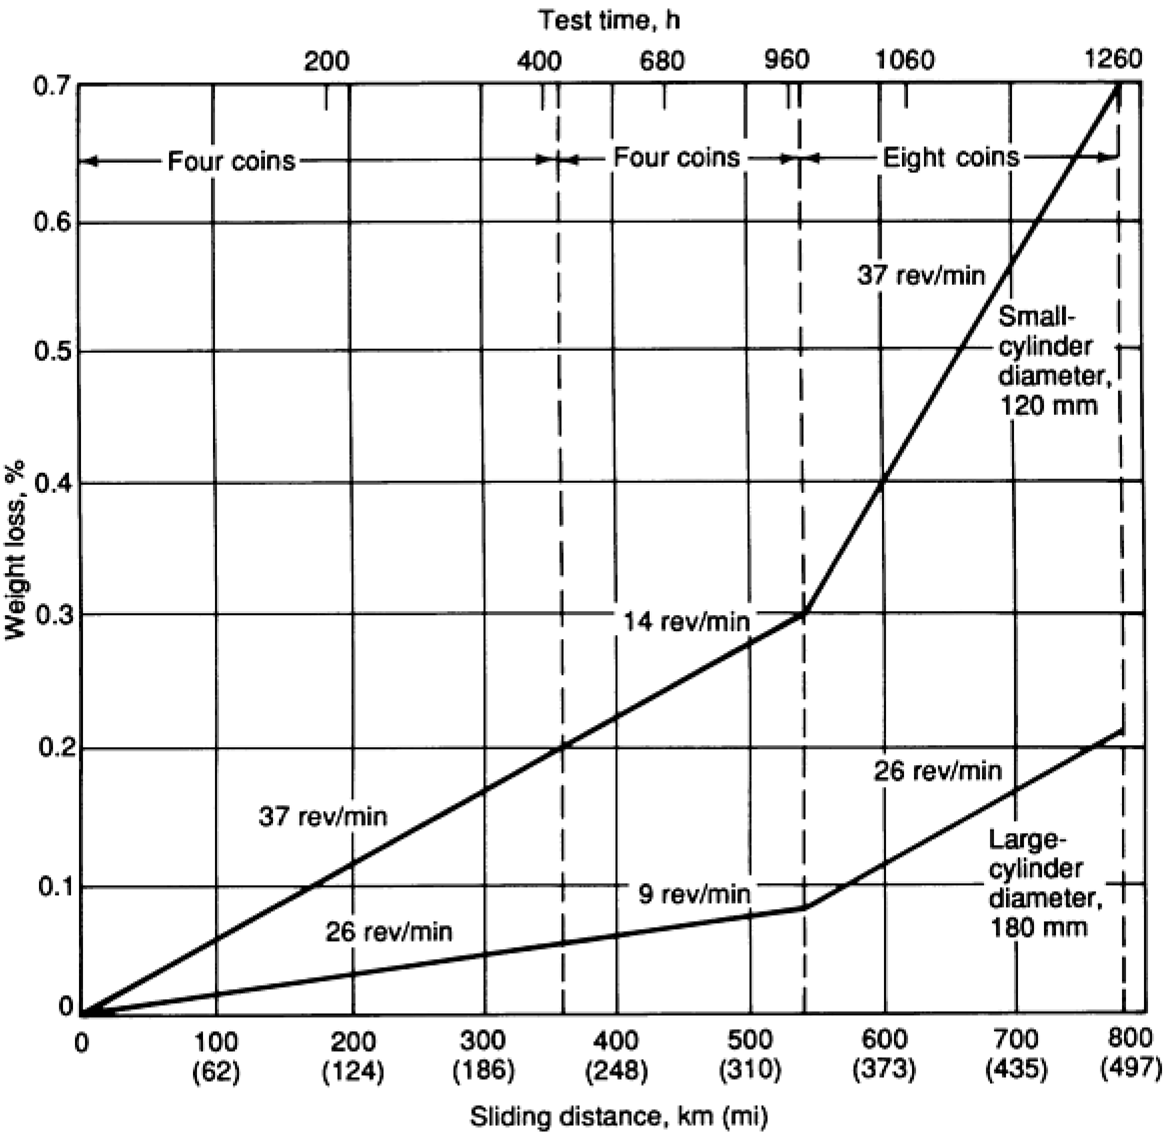

Fig. 4 Wear results from laboratory test involving tumbling of coins under controlled conditions to simulate use conditions. Source: Ref 4

Linear Measures of Wear

A common alternative to the weight loss measure of wear is to measure dimensional change. In many situations, the design of a component that is subject to wear will only allow up to a certain loss of dimension before either the integrity or function of the system is lost. In such cases, monitoring the dimensions of a part is a natural approach to assessing the amount of wear encountered. Frequently, such studies lead to the establishment of criteria for servicing or for part replacement. Examples include the wear of bushings or shafts, ball-bearing retainers, sliding actuator parts, and piston-cylinder wall contacts. Although this approach to wear measurement is frequently used, very small amounts of wear are difficult to measure, much as in the case of wear measurement by mass loss.

As one example of a linear measure of wear, consider a reported study of the abrasive wear of various types of metals used in tractor shovels (Ref 5). In the design of interest, both bucket teeth and cutting edges were involved. Therefore, a natural approach was to measure the shape changes of those components that were due to wear. Figure 5 shows a worn bucket tooth having a linear wear loss of amount *L*. Because that measure only applies to one location on the worn part, the user must be certain that the location picked is either typical or average, or perhaps shows a maximum amount of wear.

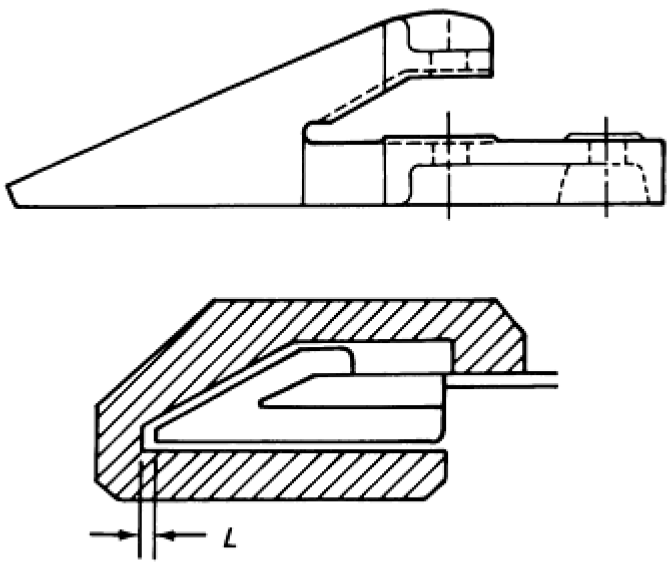

Fig. 5 Worn bucket tooth showing linear wear loss of amount *L*. Source: Ref 5

Several field test results on different bucket teeth are shown in Fig. 6. Because the wear lengths involved in this example are substantial, the precision of this measurement is not of concern. Results of this type can be directly converted into life limits (of wear) for the materials and designs of interest.

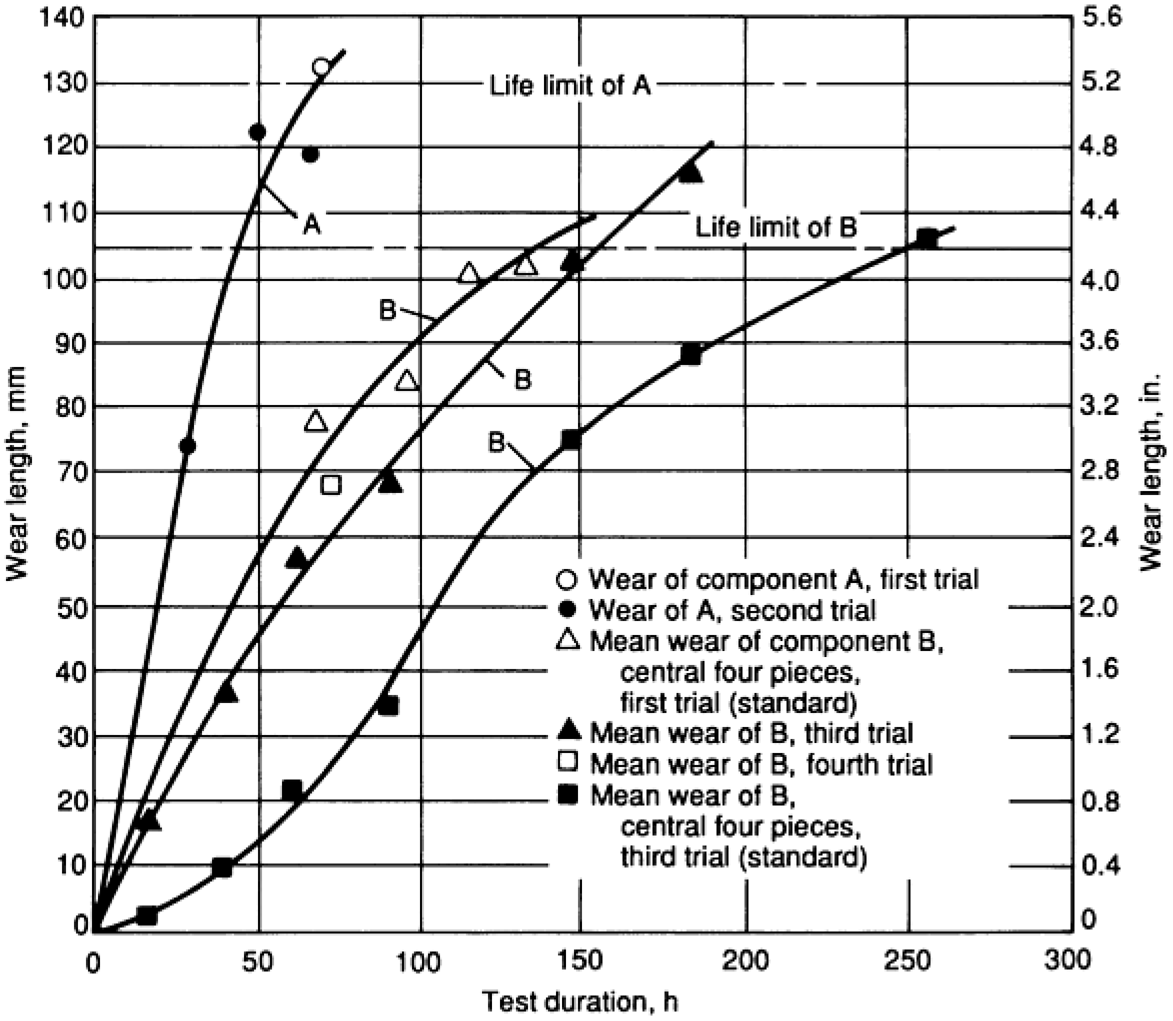

Fig. 6 Wear length results from different components and tests (Ref 5)

A second example of linear wear measures is drawn from laboratory testing results obtained using a standard test methodology. The standard, ASTM G 99, describes a method for pin-on-disk sliding wear testing (Ref 6). The pin, which in many cases shows the majority of wear for the two specimens in contact, is typically one of two shapes: a small solid cylinder with a spherical end or a sphere that is constrained not to rotate while in sliding contact. In either case, a wear scar develops during the test. The scar is relatively flat and circular in cases where the disk wear is relatively small. Figure 7 shows a steel pin wear scar taken from an interlaboratory test series (Ref 7).

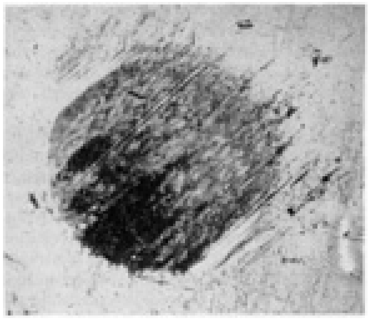

Fig. 7 Wear scar on spherically surfaced steel pin taken from test that was part of interlaboratory comparison. Magnification: 93×

Figure 8 presents a set of scar measurements from five different laboratories in the test series mentioned above. The graph indicates the variability found within and between the different laboratories. The average scar diameter was 2.13 mm (0.09 in.) with a standard deviation of 0.35 mm (0.014 in.). Those measurements involve optical microscope determinations of the average wear scar diameter, an approach that can usually be carried out to the nearest 0.01 mm (0.4 mil). One advantage of this particular wear test specimen configuration is the ease of measuring small amounts of wear.

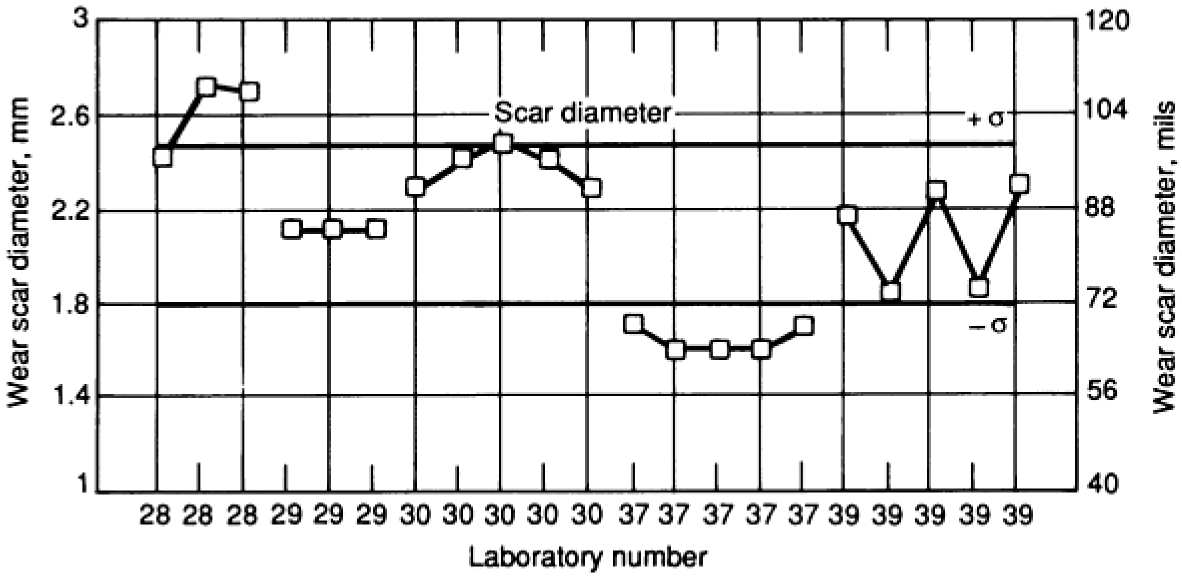

Fig. 8 Set of wear scar measurements from five different laboratories; graph indicates the variability found within and between the different laboratories. σ, standard deviation

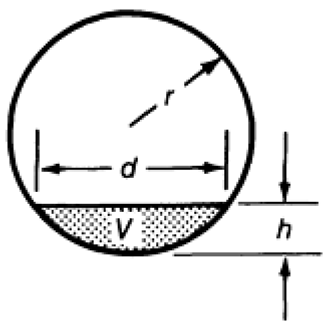
Although the basic method involves a linear measurement of wear amount, in many cases the result is converted to a calculated wear volume, usually for the purpose of comparing materials with different densities. That conversion uses geometric relations and assumes a planar wear scar; the equations are shown in Fig. 9 (Ref 8) and discussed in ASTM standard G 99. In some cases, a flat-ended pin is used in this type of test, and then the change in pin length can be determined and used as the wear measure, although with considerably reduced sensitivity.



d = wear scar diameter
V = worn volume

$$V = \frac{\pi}{6}h\left(3\frac{d^2}{4} + h^2\right) = \frac{1}{3}\pi h^2(3r - h)$$

$$h = r - \sqrt{r^2 - d^2/4}$$

For $h/r \ll 1$

$$h \approx \frac{d^2}{8r}$$

$$V = \frac{\pi d^4}{64r}$$

Fig. 9 Geometric relations used to convert wear scar size to wear volume, assuming a planar wear scar on a spherical specimen; see ASTM Standard G 99 for discussion. Source: Ref 8

A novel use of a linear measure of wear was developed by Glaeser (Ref 9), who placed microhardness indentations on the surface of a bronze bushing and measured their size changes during the running time of the bushing as an indicator of wear. A variant of that method (Ref 10) involved placing a number of indents of different depths on a wearing surface, and periodically determining which indents remained after various amounts of wear occurred on the surface. Scratches of different controlled depths can also be used in this way.

Area Measures of Wear

Certain wear contact geometries produce material loss over a localized area on the two surfaces. In many cases, those areas of wear loss can be measured and are proportional to the amount of wear. Examples would include worn areas on gear teeth, on bearing retainers, and on sliding pads with contoured surfaces. If the curvature of the surface is known, then the amount of wear can be quantified on the basis of the area worn. Because many tribological components involve area contacts, as contrasted to point or line contacts, area measures of wear are important. Two examples are described below.

One frequently used laboratory test system comprises a stationary block and a rotating ring. Several ASTM standards, such as Ref 11, that are concerned with lubricants and material wear, utilize this type of system. Although the initial contact between the two specimens is nominally a line (there is actually a small lateral width associated with elastic deformation along the contact line), the resulting scar on the block becomes a curved rectangular surface as the two components wear. The volume worn from the block can be calculated from the two scar dimensions and the ring (or scar) curvature, but it is also common to find the projected scar area reported. The ASTM standard involves scar width measurement only because it specifies the specific block size, and, hence, scar length and ring diameter.

An optical micrograph of a portion of a wear scar on a Ag-Cu alloy block is shown in Fig. 10, along with a profile measurement taken perpendicular to the scar length (that is, the sliding direction). Figure 11 shows a schematic of the

worn volume in this type of geometry and the geometric relations that are used to calculate wear volume under the assumption of an ideal scar shape.

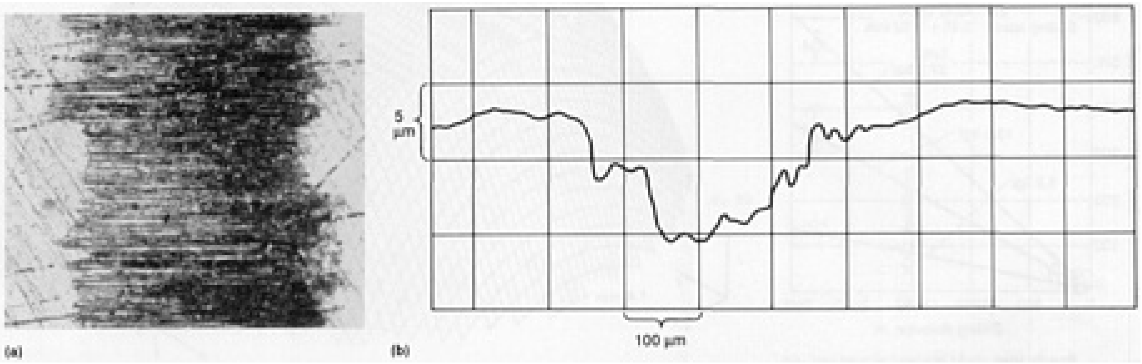


Fig. 10 (a) Optical photograph of portion of wear scar on a Ag-Cu alloy block. Magnification: 32×. (b) Profile measurement taken perpendicular to scar length (in sliding direction)

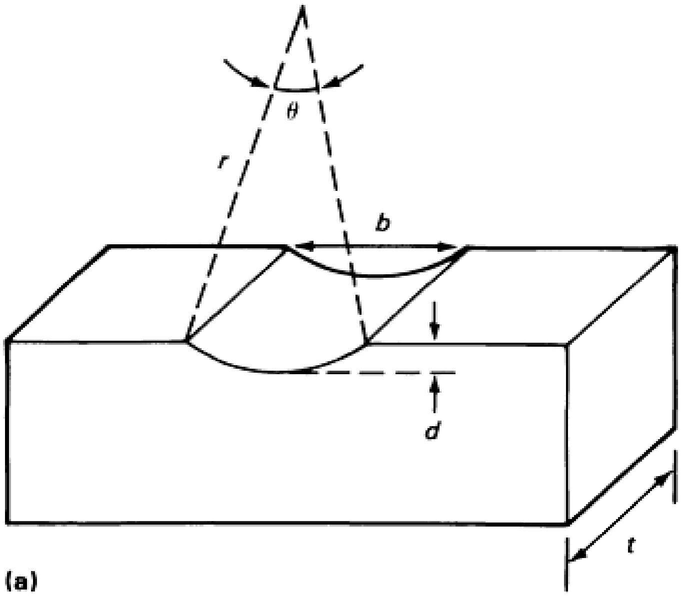

(a)

Scar width $= b = D \sin \frac{\theta}{2}$

Scar volume $= \frac{D^2 t}{8} (\theta - \sin \theta)$

where $\theta = 2 \sin^{-1} \frac{b}{D}$

Scar volume $= \frac{D^2 t}{8} \left[2 \sin^{-1} \frac{b}{D} - \sin\left(2 \sin^{-1} \frac{b}{D}\right) \right]$

(b)

Fig. 11 (a) Worn volume of block specimen (top), where *t* is block width in mm, *r* is radius of ring in mm, *D* is 2*r* (diameter of ring) in mm, *b* is average scar width in mm, θ is sector angle in radians, and *d* is scar depth in mm. (b) Geometric relations used to calculate wear volume, assuming ideal scar shape. Source: Ref 11

An example of a laboratory study of wear that utilized a block and ring test method involved ceramic materials (Ref 12). The role of iron oxides, which were present on the surface of a rotating steel ring, in causing sliding wear of blocks of aluminum oxide was examined. Wear volume was calculated based on actual measurements of the scar width and length, and on the assumption that the scar surface curvature matched that of an unworn ring. Examples of the results, which indicate the effect of load and sliding distance on wear of the ceramic block, are shown in Fig. 12.

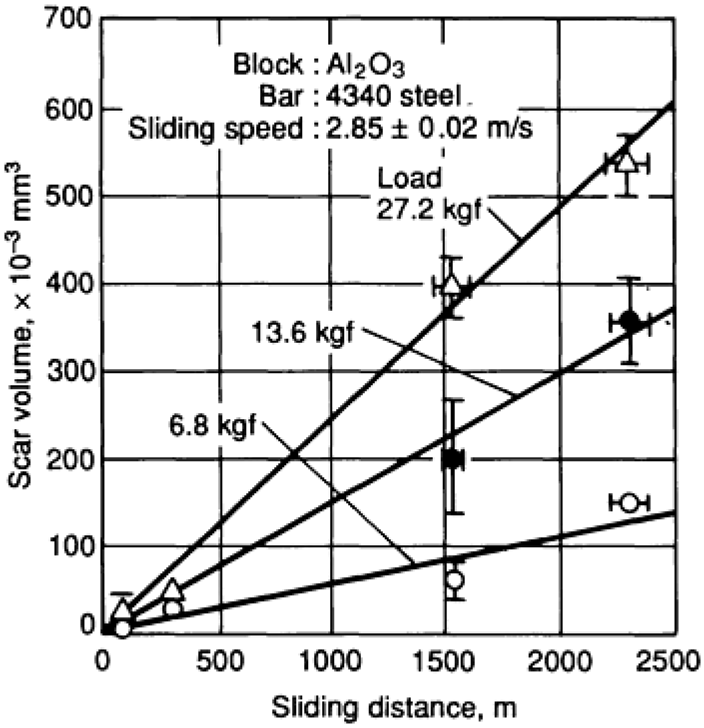

Fig. 12 Results from study of effect of load and sliding distance on wear of aluminum oxide test blocks versus steel. Source: Ref 12

The actual surface curvature within a worn area is often a significant point that is not carefully addressed. Earlier, it was stated that wear on a spherically curved surface can be expressed by a single measurement of circular scar size. However, that too involves an assumption about the flatness of the scar region. In general, it is necessary to determine the surface profile associated with the worn region. Based on those measurements, approximate methods for calculating wear may or may not be justified.

Another common laboratory wear test geometry requires the use of surface profiles to quantify the wear amount. This geometry involves reciprocal sliding of one body against a flat surface, usually referred to as a pin-on-flat test system. Wear on the flat specimen can be measured by determining the surface profile in the wear scar, perpendicular to the sliding direction. Numerical integration of a representative set of the profile curves gives the cross-sectional area of the scar and leads to an amount of wear per unit length of the sliding contact. One example of a wear scar profile from a wear test block was previously given in Fig. 10.

A portion of a linear wear scar on a flat (high-purity iron) specimen is shown in Fig. 13, along with two examples of the cross-sectional surface profiles at different locations. The wear cross-sectional area can be determined from such profiles. In the example shown, plastic deformation in the flat specimen has led to ridges of material on either side of the wear scar; such displaced material is usually ignored in calculating the wear cross-sectional area.

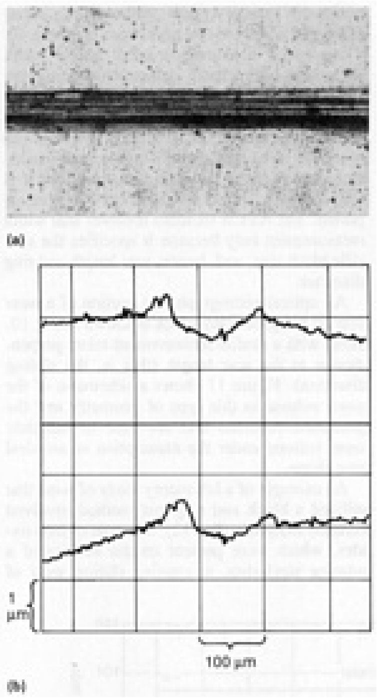

Fig. 13 (a) Portion of wear scar on flat, high-purity iron specimen tested in reciprocal sliding; magnification: 45×. (b) Two examples of cross-sectional surface profiles of scar at different locations, which can be used to measure wear area

Volume Measures of Wear

In a large proportion of reports that contain wear measurements, one finds the wear amount reported in volume units, for example, mm^3. This better enables a comparison of wear among materials having different densities, and also permits easy calculation of linear wear amounts or wear allowances. Many of the standards for wear testing require the reporting of wear in volume units (Ref 3).

In some cases, it is actually necessary to directly measure wear volume. This generally occurs when the worn region is very irregular or unsymmetric in shape, or when high accuracy in the result is needed. Unfortunately, such measurements are quite time-consuming. Two examples of direct volume determinations associated with laboratory wear testing are given next to illustrate the methods involved.

In one study (Ref 13), the worn surface of interest was neither flat nor smooth enough to permit accurate use of the usual geometric formulae. Therefore, the surface was traced on an *X*-*Y* stylus profiling system, and the resulting data were digitized to facilitate further calculations. Figure 14 shows a view of the worn surface reconstructed from the surface profile data. With such data, it is straightforward to calculate the volume difference between the worn specimen and the unworn original, which in this case was a sphere. This approach should be possible for most worn contacts, as long as they can be cleaned of extraneous matter, such as wear debris particles, and as long as sufficient lateral and vertical resolution are offered by the stylus tip and system.

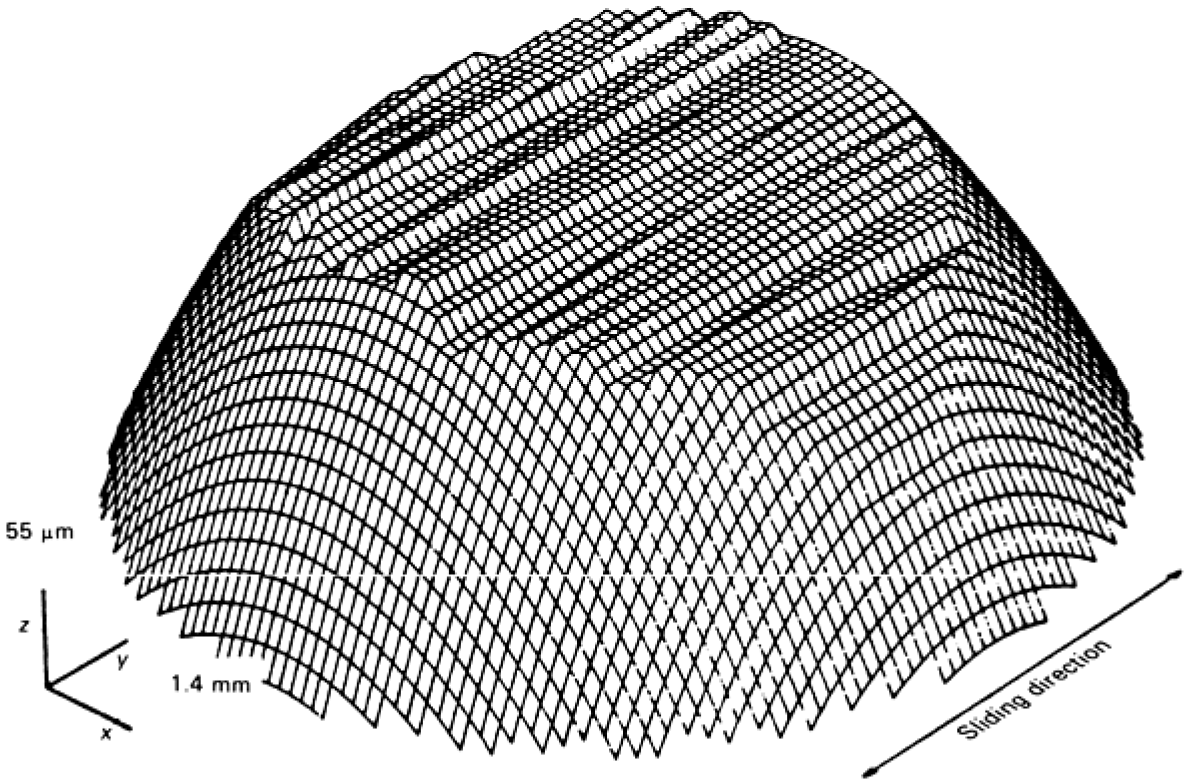

Fig. 14 Worn spherical surface reconstructed from three-dimensional surface profile data. Note that magnifications in *X* and *Y* directions are both the same, but are much less than in *Z* direction.

Another example focuses on the phenomenon of galling wear. When certain material combinations are moved relative to each other in contact under high loads, it is possible to cause localized material adhesion. This process of local seizure leads to severe damage on the moving surfaces (Ref 14). The damage consists of depressions in either surface where material has been torn out, and protrusions on either surface where material has been added, by a process sometimes described as cold-welding. It is possible to describe such damage in quantitative terms in several ways (Ref 15).

One approach is to measure the volume of material either removed from or added to the original surfaces, based on three-dimensional profiling of the contact regions on the surfaces. A reconstruction of one of the surfaces after a single sliding pass is shown in Fig. 15 in oblique projection using the profile data.

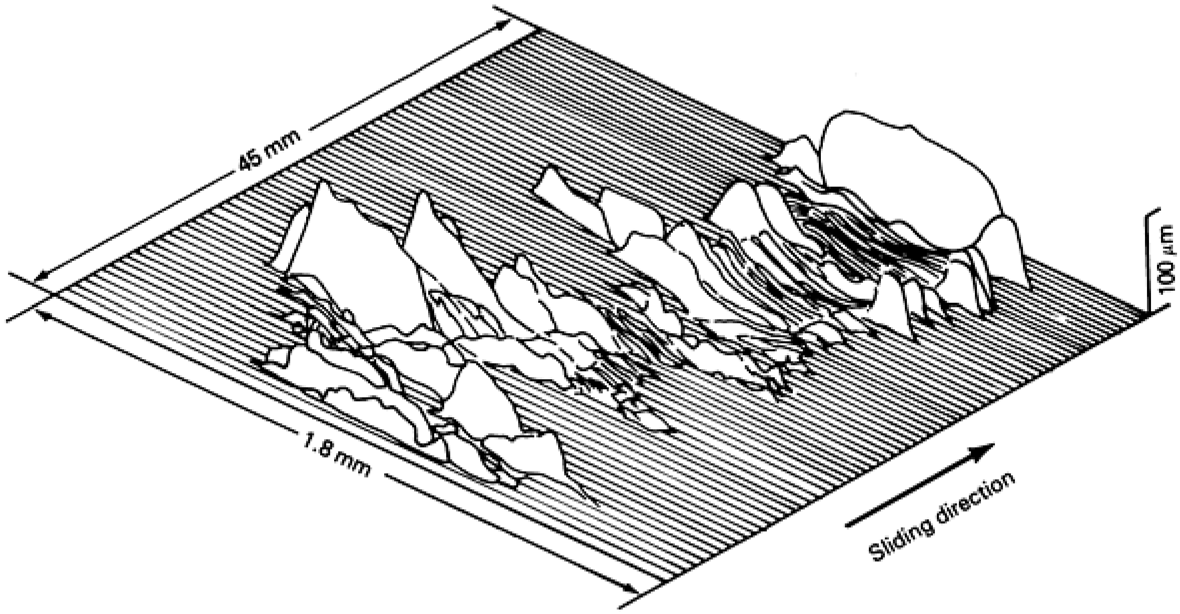

Fig. 15 Reconstruction of galled surface after a single sliding pass shown in oblique projection using three-dimensional profile data. Source: Ref 15

The worn or displaced volume can be calculated by numerical methods from the profile data; those results are shown in Fig. 16 for a nickel flat specimen (the opposing surface was copper). The volume shown represents incremental slices perpendicular to the sliding direction at different distances of sliding. At the initial part of the wear track, considerable copper material was deposited, and the amount decreased as sliding continued. Further details on the method can be found in Ref 15.

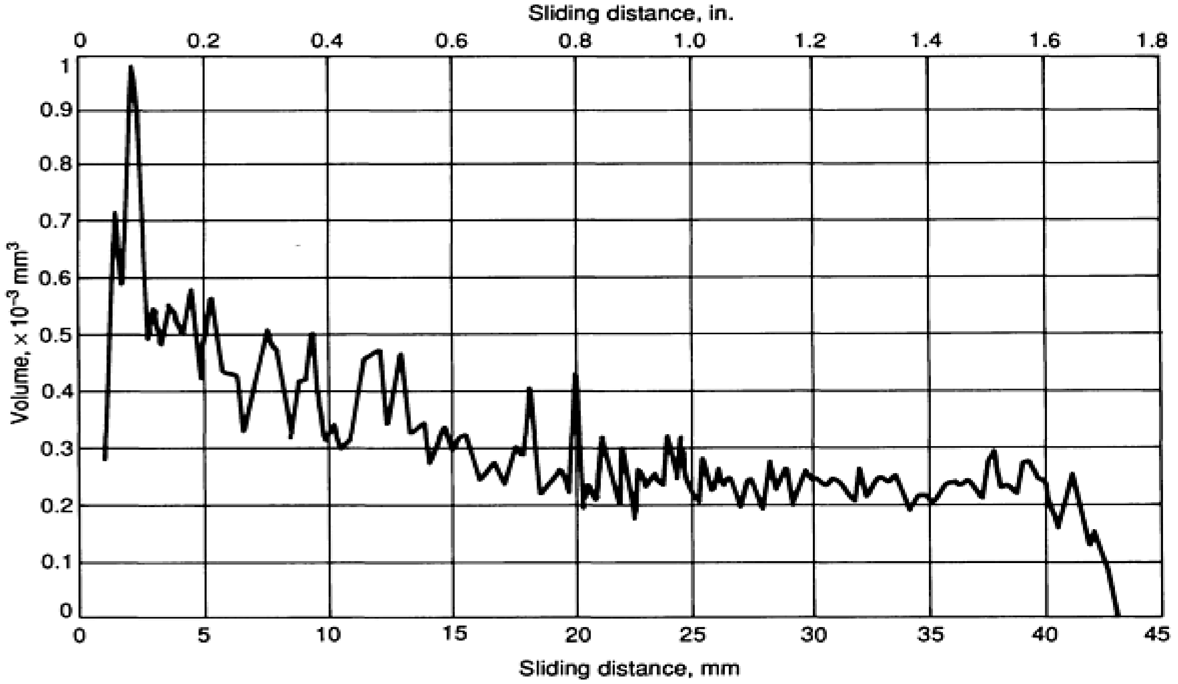

Fig. 16 Results of calculation of worn (displaced) volume for a nickel flat specimen. Volume shown represents incremental slices perpendicular to sliding direction at different distances of sliding.

Other Measures of Wear Damage

Wear is defined in ASTM G 40 as: "Damage to a solid surface, generally involving progressive loss of material.. . ." This statement recognizes the practical importance of surface damage and surface alteration in affecting, possibly, the function of a tribological component, particularly for systems designed with close tolerances in critical areas. The discussion that follows is intended to alert the reader to several other important issues often associated with the wearing process.

In many mechanical systems, certain contact surfaces are manufactured with close control over surface roughness and finish. They can be surfaces that are lubricated by oil during operation, requiring a surface finish of suitable smoothness to maintain an adequate but thin lubricant film in the contact zones. During service, those surfaces may become roughened and scratched, leading to regions where the lubricant film may not be able to cover the peaks in the topography. Such regions are then prone to local adhesion and seizure. In such a case, measurement of the state of wear would involve visual inspection of the surface and measurement of the current value of surface roughness. Published failure analyses in the technical literature give evidence that changes in surface finish are a frequent factor in tribological component failure. Often, scratches are found to have occurred during either installation of a part or servicing of a system. Abrasive particle contamination, sometimes involving lubricant contamination, is also a frequent source of surface scratching. Microscopic analysis and profile measurement of the contact surface are valuable techniques that reveal damage and change in surface finish.

A related issue is surface deformation during service. In component designs that involve high contact pressures, plastic flow of material may occur in the contact region over a period of time, altering surface topography. Principal causes of surface deformation are higher loads than the design allowed and lower resistance to plastic flow in certain regions of the material, possibly because of insufficient processing control on composition, microstructure, and hardening treatments. Microscopic examination of the contact surface may reveal evidence of surface deformation.

In certain types of materials, resistance to localized cracking (toughness) can be relatively low, and the designer involved must carefully consider the possibility of local fracture processes that are associated with the contact region and lead to component failure. Examples of such materials are ceramics, as well as metals that are either treated to high levels of hardness or possibly used at very low service temperatures. Local surface cracking may develop slowly, with time, as a fatigue process, or even suddenly, as a result of a transient overload on the contact. In any event, the cracks that develop may continue to grow with time and eventually lead to loss of material, either in the form of surface spalls or by crater formation. Surface examination can reveal the cracking, although in many cases the cracks may be obscured by other surface topography. Dye penetrant treatment and examination may be a useful approach for detection of small cracks.

An important but poorly appreciated feature of tribological contacts is the pattern of stresses in and beneath the contact surfaces. Frequently, the maximum shear and tensile stresses are found somewhat beneath the contact surface. The depth depends on material properties, load, and friction coefficient. This situation can lead to subsurface damage of one form or another. Thus, an observed lack of any component surface damage during service cannot be taken as an indication of the true subsurface condition. Cracking can be an active subsurface process, particularly near particulate inclusions, with little surface evidence of the problem. The detection and analysis of such cracks may be difficult; possible techniques to apply include x-radiography and ultrasonic inspection or destructive cross-section metallography.

Another common feature in wearing systems is material transfer. The earlier discussion of galling wear provided an example. Much less severe transfer can also lead to failure problems. In unlubricated sliding systems, it is very common to find transfer films that are formed on the contact surfaces. The films represent an intermediate stage in the wear process and are a source of wear debris as they change dynamically during service. Both the friction and wear characteristics of the system can be largely determined by the characteristics of such transfer films.

In lubricated systems, other types of films, both desirable and undesirable, frequently form. In the former case, most lubricants contain chemical additives that are designed to deposit very thin films of reaction products in order to aid in surface protection and to lower friction. In the latter case, thicker films can form from the service (process) environment and interfere with the tribological function. Surface inspection and, possibly, chemical microanalysis may be needed to determine the nature of surface films that are present.

This brief discussion of other attributes of tribological contact surfaces is not intended to completely describe all possibilities. Each case of interest must be evaluated in the context of the design requirements and the tolerance for surface change and damage.

Calculation of Geometric Wear Volume

The equations shown in Fig. 9 and 17 can be used to calculate the volume of material removed from a workpiece of specific geometry due to wear. These particular shapes are frequently used in laboratory wear testing.

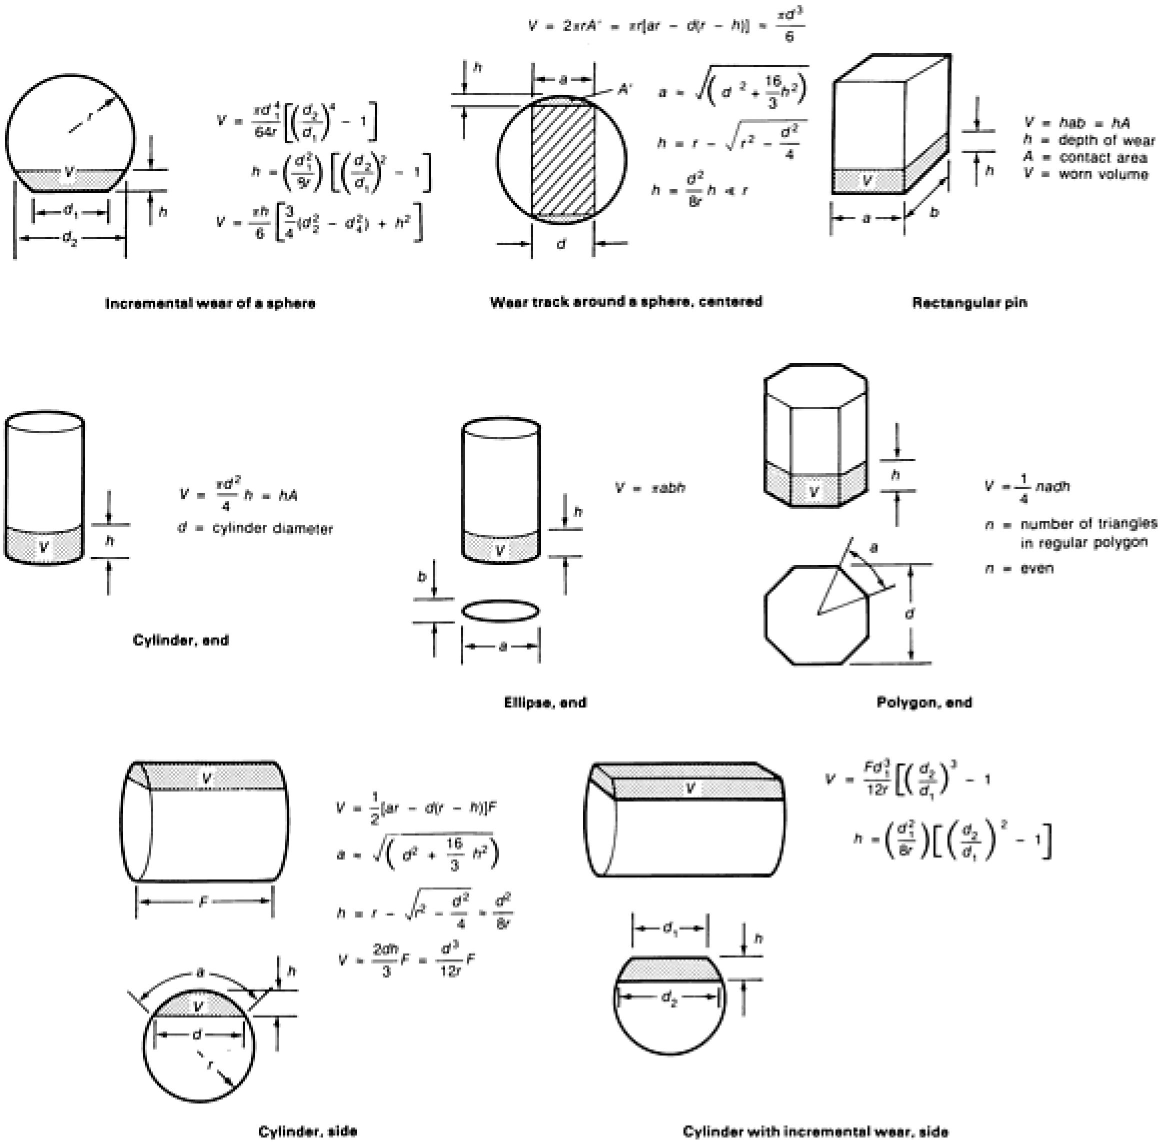

Fig. 17 Wear volume calculations of selected workpiece configurations subjected to contact with flat surfaces. Source: Ref 8

It should be noted that all of these relations assume that the opposing surface is planar and does not change its shape during the test. This is frequently not the case in wear testing. Thus, the accuracy of these equations for determining the wear volume is frequently inadequate. A more accurate approach is to determine the initial and the final shape of both specimens by surface profiling, and then to calculate the volume removed using those data.

Introduction

WEAR SCARS are sometimes complex in morphology and can indicate various wear modes by their characteristics. Wear scars will contain microscopic features like extrusions, transfer patches, pits, and fine scratches. Therefore, microscopy is essential in the study of wear processes and the identification of wear modes. Diagnosis of wear failures has parallels with fractography. There are recognizable patterns in wear scars that help to classify the wear mode, just as there are characteristic patterns for ductile-dimple fracture and intergranular fracture.

Recognition and classification of wear modes require some experience in the interpretation of the microtopography of wear surfaces. For instance, true adhesive wear, or the transfer of material from one surface to another, is often mistaken for abrasion. Initial adhesive wear can leave long striations in the surface that look like abrasive wear marks. In the abrasive wear of mining machinery, it is necessary to distinguish between high-stress abrasion and low-stress abrasion (the former being a condition where the abrasive media are crushed in the contact zone) when making a choice of materials for wear control. For example, detecting the difference between solid-particle erosion and liquid-drop erosion in a centrifugal air compressor is essential to the solution of excessive impeller damage because it means choosing between the elimination of moisture condensation in the compressor or selecting a material resistant to erosion by hard particles. It is obvious that the latter condition represents a much more difficult and expensive solution to the problem.

Low magnification light micrographs are often used for permanent records of wear failures during a failure analysis. In fact, it is highly recommended that photographs at between 5 and 10× magnification be taken before any other form of analysis is carried out. Often, in the hurry to track down a possible cause for a failure, the part is destroyed and its original condition is a matter of someone's memory.

In research, close examination and definition of the microtopography of wear scars is very useful in finding out about wear mechanisms. The investigation can include surface analysis, analysis of the morphology of wear debris, and examination of near-surface microstructure by metallographic sections and by transmission electron microscopy (TEM) of foils made from sections through wear scars. Usually, several types of microscopy must be used to define a wear pattern. These include light microscopy, scanning electron microscopy (SEM), transmission electron microscopy, and interferometry. In addition, it is essential that the basic principles of tribology are applied to the interpretation of the wear process, both in failure analysis and wear research.

Light microscopy is an essential part of the characterization of a wear scar. It should be used in the analysis to provide an initial idea of the surface structure and its relation to the function and the component of the assembly as a unit. It is essential that both mating surfaces involved in the wear process be examined. A sample of wear debris is also very helpful in making the final diagnosis.

Light microscopy provides some features for analysis not available by electron microscopy analysis. The viewer can see colors that indicate the nature of a transfer product or a lubricant decomposition film. The oxidation of a metal surface by frictional heating can be detected by the tarnish color left on the contact region. One can use a needle to probe the specimen while viewing it with a light microscope to dig out an embedded particle or to determine the friability or softness of a deposit on the surface. Polarized light can be used to determined the crystallinity of an embedded particle or a phase exposed in the surface. A magnet can be used to probe a deposit under the microscope to check for ferromagnetic material. A microindenter can be used to determine the hardness of a microscopic area exposed in a wear scar.

An oil soaked surface can be viewed to determine the distribution of a film of oil. Polymers and elastomers, which require special preparation for electron microscopy, can be easily examined with the light microscope.

Light Microscopy Equipment

The following equipment should be available for microscopy analysis of wear scars:

- Pocket magnifier (10× is a good choice)
- Stereoscopic microscope (magnification from 2.5× to 60 or 90×)
- High-quality metallographic microscope with high resolution, good depth of focus, capable of magnification up to 1000× without oil immersion, movable *x*-*y* stage, and generous space under the objective lens for bulky specimens.
- Metallograph with Nomarski attachment and high-quality photographic capability
- Ultrasonic cleaner
- Needle probes
- Surface replication kit

A complete metallographic laboratory including mounting, sectioning, polishing, and etching facilities for metallographic sections is a valuable adjunct to successful analysis of tribological surfaces. Often, it is just as important to know what is going on under the surface as well as what is happening on the surface.

Analytical Procedures

The macroscopic morphology of a worn surface should by analyzed initially. The size of the wear scar, its relation to the rest of the part, and the way the mating surface scar relates to it are all necessary information to have before the microscopic details of the surfaces are investigated. This indicates to the engineer where the microoptical investigation should be concentrated.

Example 1: Spall on the Surface of a Babbitt Metal Journal Bearing.

Consider, for example, the spall in a babbitt journal bearing surface (Fig. 1). The macrograph shows several important features in this bearing failure:

- The steel backing has been uncovered by the spall (the grooved surface in the middle of the spall)

suggesting a problem with weak bond between the babbitt and the steel shell

- A "footprint" left by a large chunk of the babbitt that came out during the spalling process can also be seen (nose that the profile of the footprint matches the shape of the spall)
- Fine cracks in the vicinity of the spall indicate areas that require closer examination, perhaps through the use of metallographic cross section. (The fine lines running up and down on the micrograph are marks caused during removal of the bearing from the assembly)

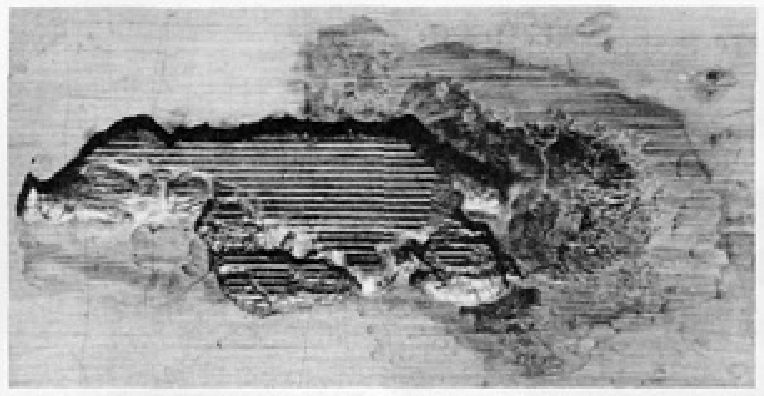

Fig. 1 Macrograph of a spall in a babbitt metal journal bearing. 8×

Example 2: Contact Fatigue Induced Spall in a Bearing Race.

Parts should be examined with a hand magnifier and with the stereoscopic microscope to obtain a general idea of the nature of the surface damage or scarring. A preliminary diagnosis of the wear mode might be made at this time. The spall mark in the bearing race shown in Fig. 2 indicates contact fatigue. The cause for the spalling is not apparent, and therefore, more detailed microscopy needs to be done in the area of the spall. In addition, the wear marks made in a bearing race can be used to detect misalignment, excessive thrust load, faulty installation, lubricant failure, or fretting.

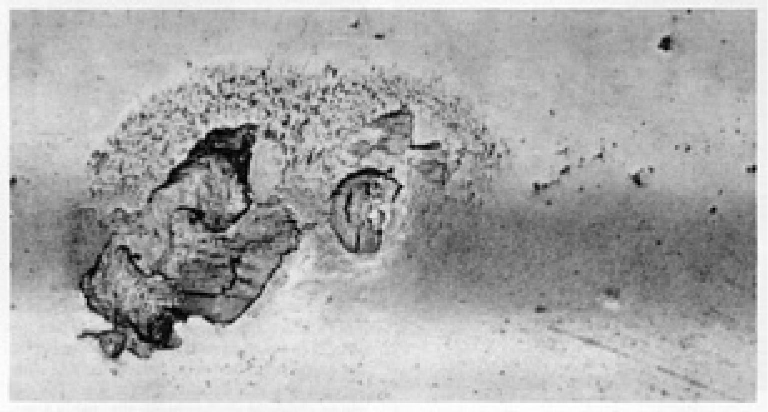

Fig. 2 Spall in a ball bearing caused by rolling contact fatigue. 10×

Example 3: Wear Scars Generated in Wire Strand Segments of Wire Rope in a Dragline Excavator.

Figure 3 shows wire segments cut from the interior strands of a wire rope from a dragline excavator. The wear scars shown on each of the three segments of wire are indicative of three contact conditions on the wire rope. The top wire contains a long scar typical or crosswire contacts where wires cross at low angles. The second wire contains cross-wire contact scars from wire contact at high angles. The third, or bottom, segment contains scars from longitudinal wire contact within the weave. All three segments indicate severe internal wear of the wire rope. The top segment shows signs

of adhesive contact, suggesting failure of the rope lubricant. The scars on the bottom segment are essentially the result of plastic deformation or bedding in of the rope assembly.

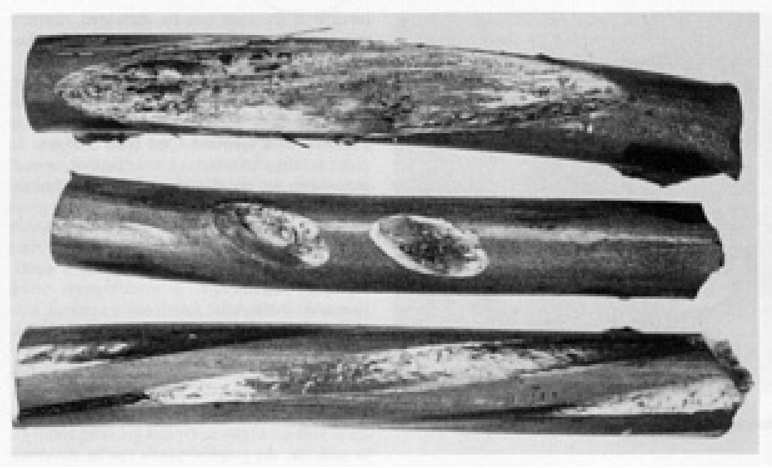

Fig. 3 Wear scars in steel wire segments cut from inner strands of a severely internally worn wire rope used in dragline operations. (Top) Long scar typical of low-angle cross-wire contact. (Middle) Scar typical of high-angle cross-wire contact. (Bottom) Longitudinal scar caused by plastic deformation of contacted wires within the weave

Example 4: Assessment of the Failure of a Ball Bearing Race Based on A Fluting Pattern Generated by Electrical Discharge and Vibration.

The fluting pattern in the ball bearing race in Fig. 4 provides an example of how a macrograph can be used for analysis of a failure. The fluting, or evenly spaced marks, in the race are the result of electrical discharge between the balls and the race surface while the bearing is experiencing a vibration mode. Using the photograph, the number of marks per inch on the surface of the race can be measured, thereby providing a mechanism for estimating the frequency of vibration.

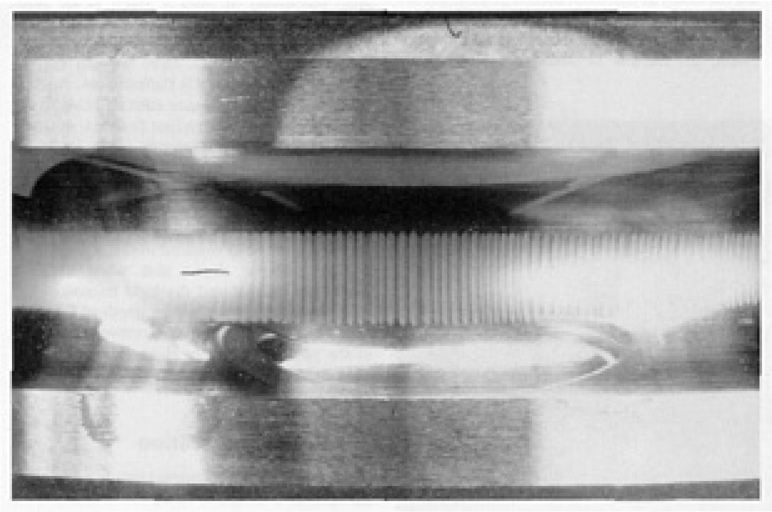

Fig. 4 Fluting pattern in a ball bearing race caused by an electrical discharge between the rolling elements and the race during mechanical vibration. 2 ×

Example 5: Application of Metallographic Microscopy, Nomarski Contrast Illumination, and SEM Techniques to Analyze Wear Patters in a Ground Cast Iron Surface.

In order to fully characterize a wear pattern, several techniques are required because one technique (metallographic microscopy, for example) gives only part of the picture. This can be illustrated in the three micrographs shown in Fig. 5. A ground cast iron surface was examined with a metallographic microscope, a metallograph using Nomarski differential interference contrast illumination (Ref 1), and a scanning electron microscope.

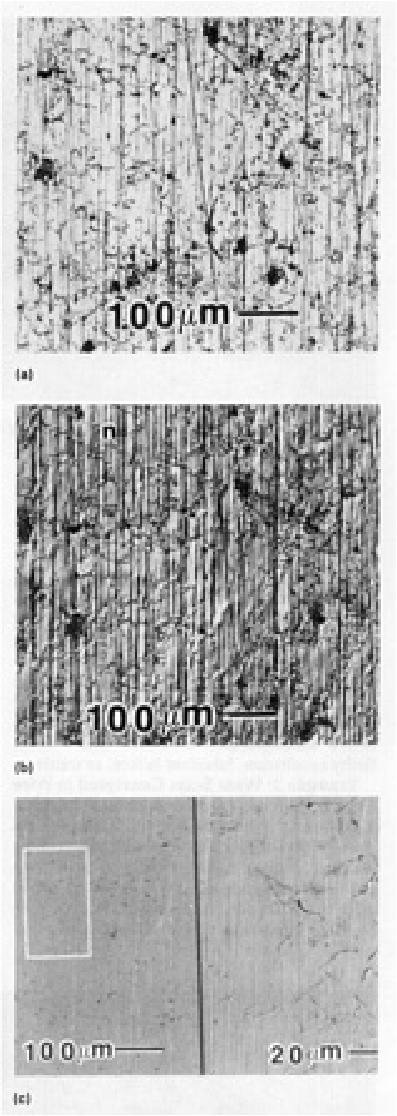

Fig. 5 Ground cast iron surface as viewed by three optical methods. (a) Metallograph. (b) Nomarski contrast illumination. (c) SEM micrographs at two magnifications

Figure 5(a), taken at 100× in a metallographic microscope, shows a fine scratch pattern, which some scratches cutting across the others at various angles (a typical grinding pattern). In addition, the graphite phase can be discerned as fine line segments at random angles. The dark spots are assumed to be shallow pits.

When the same area is viewed using Nomarski contrast, more details of the surface topography can be seen (Fig. 5b). Nomarski contrast illumination at relatively low magnification can show shallow surface relief on reflective surfaces. Figure 5(b) shows that the graphite phase is revealed by lips of metal smeared over the graphite flakes exposed end-on.

When the same surface was examined with the scanning electron microscope, some features do not show up but others become clear. Figure 5(c) is an SEM split-field photomicrograph showing two different magnifications of the same area. The field on the left is at 100× and the field on the right is of the are shown by the rectangle taken at 350× magnification. Note that the scratch pattern, so prominent in Fig. 5(b), can hardly be seen at 100× in the SEM micrograph (Fig. 5c). One does not begin to see good detail until a higher magnification is used, as the left field shows. Here we can see the scratch pattern--only it is flattened out. Nomarski differential interference contrast tends to exaggerate sharpness of surface

features, whereas scanning electron microscopy tends to flatten them (especially in the secondary electron imaging mode). Note that the SEM micrograph shows definite pits that are associated with the graphite phase. The SEM micrograph also shows lips of metal smeared over the graphite.

This example shows that when abrasion marks are present and the light microscope is used at magnifications where depth of focus allows the peaks and valleys to be revealed, details of the pattern are nicely characterized by ordinary light microscopy and Nomarski enhanced microscopy.

Specimen Preparation

Before any surface preparation is attempted, the specimen should be looked at carefully in the as-received condition. Using a hand magnifier and the stereoscopic microscope, one can look at the condition of the lubricant and detect the presence of dirt or other contaminants, corrosion, wear debris, cracks, and so on, in order to make an initial assessment of the wear mode and to determine the direction further investigation should take. Sometimes, if the observer is fortunate, the probable cause of surface damage can be determined by this type of examination. For instance, fretting corrosion of a carbon steel part can be detected by the presence of a red-colored greaselike material surrounding the wear scar. This material is the hydrated oxide of iron that has exuded from the fretting contact.

For closer examination of a wear scar using the metallographic microscope, the surface has to be cleaned. A surface contaminated with oil, grease remnants, or loose debris will mislead the observer when viewed at 500× with the microscope. It will appear that the surface is pitted, or important surface features can be completely obscured.

If the specimen is a metal covered with oil or grease, it should be cleaned in an ultrasonic bath containing a solvent. A detergent solution in water should be used in the ultrasonic bath for a polymer or for a surface with a stain on it. It is imperative that no fingerprints are left on the surface to be examined after the specimen is removed from the cleaning solution.

A failed part may have languished outdoors in inclement weather and become rusted before it is brought in for analysis. Rust can obscure important clues. It is possible to remove the rust without changing fine detail in a wear scar. The rust can be removed electrochemically, using a special electrolyte (Ref 2). The electrolyte is composed of a solution of Endox 214 (Enthrone Inc.) in cold water (240 mL, or 8 oz, Endox to 1000 mL, or 34 oz, water). A small amount of Photo-flow is added to the solution (the solution contains sodium cyanide and therefore requires caution in handling and should be opened only under a well-ventilated laboratory hood). The specimen is wired as the cathode in an electrolytic cell and should preferably be rotatable. The anode material is either carbon or platinum. An electric potential is applied at a current density of 250 mA/cm^2. The current is allowed to flow for about 1 min while the specimen is rotated. After the first minute, the specimen surface should be inspected. If not sufficiently clean, it should be given a second cleaning of 1 min duration. Final cleaning is done in an ultrasonic bath with a detergent, followed by a rinse in methanol.

Taper Sectioning

Taper sectioning can be used to study details of surface topography and the subsurface microstructure as it relates to surface features. Taper sectioning magnifies the fine surface topography and any transfer or oxide layers. Example 6 illustrates the use of taper sectioning to analyze abrasive wear on a coated steel surface.

Example 6: Application of Taper Sectioning to Determine Abrasive Wear of a Plasma Spray Coated Steel Surface.

A plasma-sprayed steel part has been sectioned (Fig. 6), and the nature of the coating bond to the substrate can be seen as well as the surface topography generated by abrasive wear. A profile of the surface roughness can be seen at the intersection of the plane of the taper section and the surface. The effect of porosity on the surface profile is revealed by the taper section. Note that the vertical magnification is about twice the horizontal magnification. Taper sectioning preserves much of the near-surface material that would not be seen in a right-angle section (normal sectioning for metallographic purposes causes rounding of the edges, unless the surface is plated before sawing and grinding). The surface can also be nickel plated before a taper section is made.

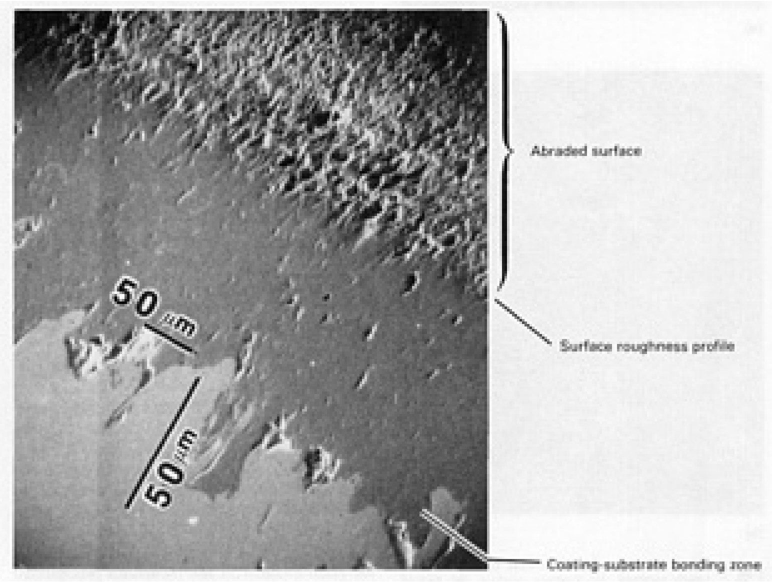

Fig. 6 Taper section of a plasma spray coated steel surface in which the surface has been subjected to abrasive wear

Example 7: Determination of Coating Thickness by Taper Sectioning for a Rectangular Block and a Cylindrical Shell.

Two types of taper section are shown schematically in Fig. 7. Figure 7(a) shows a rectangular specimen sectioned for measuring the thickness, *h*, of a coating. If the specimen is mounted for cutting so that the taper angle can be determined, the thickness of the coating revealed on the taper surface can be measured and the actual thickness determined using the equations shown below. Figure 7(b) shows a taper section made on a cylindrical specimen. Microhardness of a thin surface layer can be measured by taper sectioning because sufficient material is exposed for indenting.

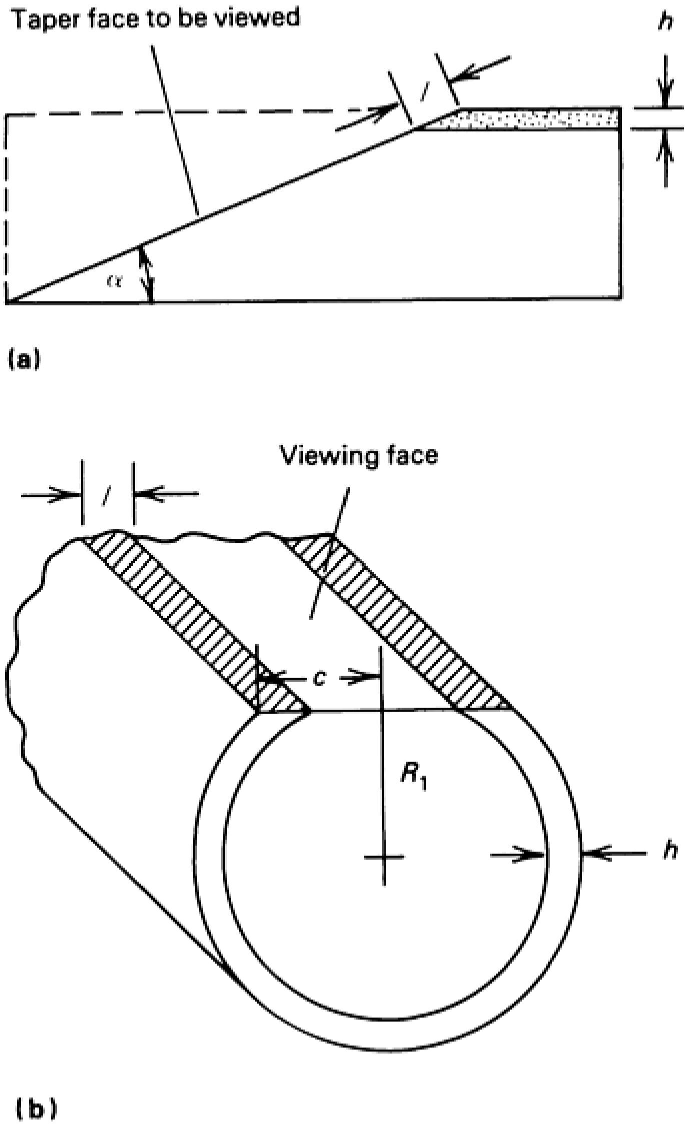

Fig. 7 Schematic showing parameters needed to determine coating thickness, *h*, of two types of taper sections. (a) Rectangular block. (b) Cylindrical

Direct geometrical measurements from a photomicrograph of a taper section on a rectangular block can be converted to real dimensions by the equation:

$$h = l \sin \alpha \qquad \textbf{(Eq 1)}$$

where h is the vertical thickness, l is the measured thickness on the photomicrograph, and α is the taper angle.

Direct geometrical measurements from a photomicrograph of a taper section on a cylinder can be converted to real dimensions by using the equation:

$$h = l \cos \left[\tan^{-1} \left(\frac{R_1}{c} \right) \right] \qquad \textbf{(Eq 2)}$$

where h is the coating thickness and dimensions l, R_1, and c are as shown in Fig. 7(b).

Surface Replication

Surface replication is a useful tool for examination of surfaces that, because of excessive size, cannot be placed directly under the microscope. It is also used for making a permanent record of a wearing surface so that the morphology of the wear scar can be recorded as a function of running time. Samples of wear scars from machinery in the field can be brought back to the laboratory for microscopy as surface replicas.

Film Replicas. Acetate films have been used for surface replication ever since electron microscopy became a practical reality. The microscopic surface features are so well recorded on the acetate film surface that high-resolution micrographs are possible at magnifications as high as 100,000×. Thus equal fidelity of surface replication for examination in the metallograph can be expected.

Film replicas of large, rough wear scars or fracture surfaces can be made with dental cement. These replicas provide a permanent record of a failure and can be used for macrographs. The area and volume of a wear scar can be determined by measurements on dental cement replicas (Fig. 8). Dental cement comes as a powder that must be mixed with a liquid and then applied to the surface as a putty and allowed to harden.

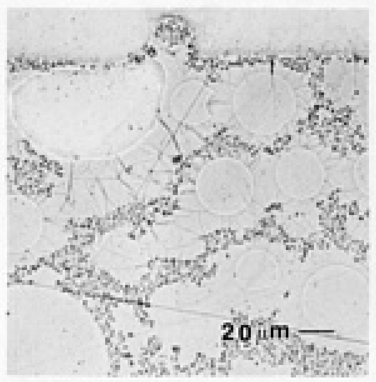

Fig. 8 Plastic-replica of a 24 μm (960 μin.) groove in a metal surface obtained using dental cement

Film replicas can be made by a number of techniques. The technique used by electron microscopists requires cutting a piece of acetate film to size, softening the film with acetone, and then pressing against the surface and holding the film in place until it hardens. The area containing the feature of concern that is recorded on the film can then be cut out and mounted on a grid for coating with gold or carbon. This process requires a certain amount of skill and is time consuming. However, if done properly, it produces the highest fidelity surface recording of any of the techniques.

Acetate Cement Films. A simpler film replica technique involves the use of an acetate cement (for example, Duco). A small drop of cement is smeared across the surface in question. This can be done by taking a drop on the finger and quickly wiping the finger over the surface to be replicated. The cement film should be thin because thick coatings can develop bubbles in them. After the cement film dries, a piece of Scotch tape is firmly pressed against the film (rubbing the tape with the eraser end of a pencil will seat it firmly against the acetate film). The Scotch tape is then pulled off with a quick snap, thus pulling off the cement film. Difficulty will sometimes be encountered in removing the replica film with tape. This is usually caused by extremely dry, clean surfaces or by interlocking of the film with surface scratches. This can usually be remedied by smearing a thin coating of oil on the surface to be replicated.

A glass slide is prepared by attaching a piece of double-stick tape to the slide. The Scotch tape with the replica on it is then attached to the double-stick tape surface so that the cement film is face up. This is gently flattened out and then viewed with the metallographic microscope. The replica surface is best viewed at 250 to 500× magnification, using the same light system as is used for viewing metallographic specimens. Although the high points are the valleys and the low points are the ridges on the plastic replica, the surface features appear normal when viewed in the microscope.

Example 8: Comparison of Surface Replica Versus SEM Micrograph of a Honed Cast Iron Gear Tooth Surface.

Figure 9(a) is a photomicrograph of a surface replication of a honed cast iron gear tooth; this replication can be compared with an SEM micrograph made of the actual gear surface shown in Fig. 9(b). Note that metal particles, which are visible as tiny white spots in the micrograph, have been picked up from the gear surface by the replica.

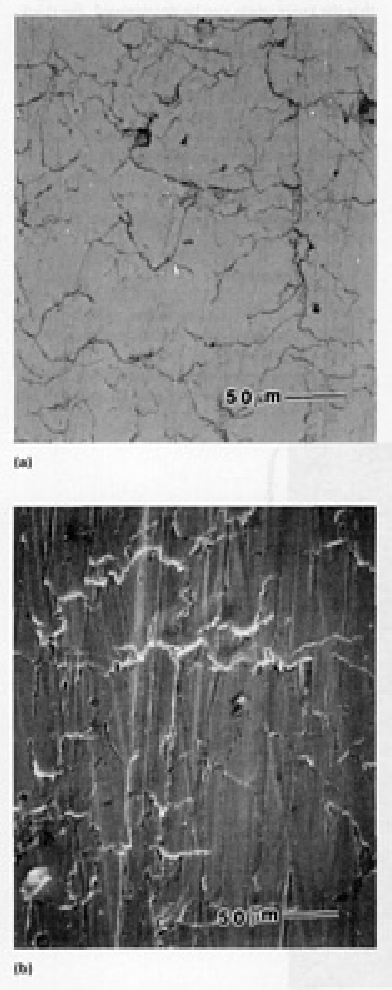

Fig. 9 Photomicrographs of honed cast iron gear tooth surface. (a) Surface replica. (b) Actual surface view obtained with scanning electron microscopy

Example 9: Application of Replicas to Remove Loose Metal Particles from the Machined Surface of a Surgical Instrument for Subsequent SEM and EDXA Analysis.

Replicas can be used to remove loose metal or other particles from a machined surface for metallographic study. This process was used in a study of the origin of metal particles in a surgical instrument (Ref 3). Metal particles picked off of the instrument surface were similar to those shown in Fig. 9(b). These particles can be located using scanning electron microscopy and identified by energy dispersive x-ray analysis (EDXA). Before the replica is examined with scanning electron microscopy, it should be carbon coated by vapor deposition to make it electrically conductive.

Metallographic Sections

Wear occurs in three dimensions. Not only is the surface involved, but the subsurface zone in the wear scar region is also significantly changed. The subsurface is subjected to very high plastic strain and microstructural changes do occur.

Subsurface voids and laminations are generated during the wear of some materials. The ferrite phase in nodular iron tends to extrude around the graphite nodules and flow to the surface. During rolling contact fatigue, carbides decompose and white etching phases develop in the maximum shear stress zone in the near-surface region. Subsurface crack patterns develop in ceramics as a result of excessive contact stresses. Because of the above phenomena, examination of the

subsurface wear scar region is usually required to completely define the wear process. Regular metallographic sectioning is used with the precaution of nickel plating the wear surface to preserve the near-surface features. Taper sectioning can also be employed when very shallow features cannot be resolved in a normal section. Subsurface features associated with the wear process are shown in Fig. 10, 11, 12.

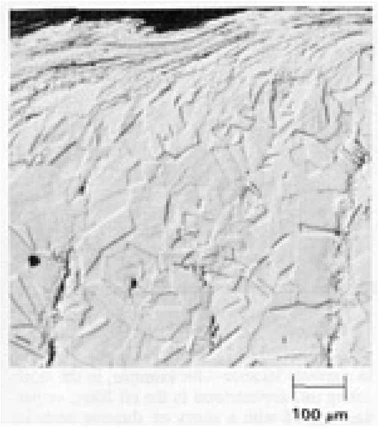

Fig. 10 Metallographic section through a wear scar that was generated by a ring-on-block wear test on a type 304 stainless steel block. Specimen was etched and the texture enhanced through the application of Nomarski contrast illumination.

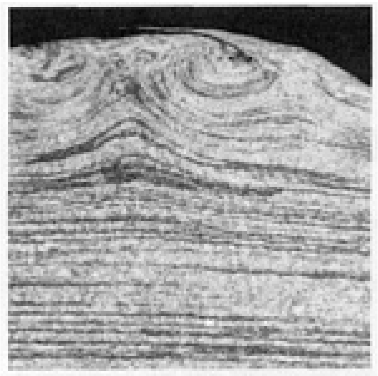

Fig. 11 Etched cross section of a hardened steel link component from a chain hoist that shows subsurface deformation caused by contact wear. 25×

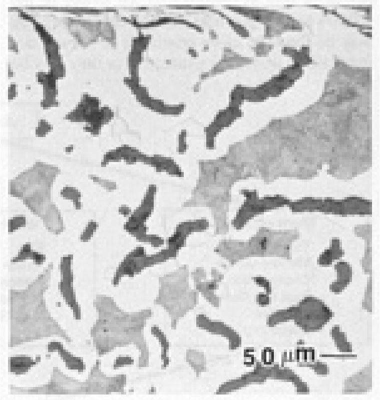

Fig. 12 Cross section of a wear scar on a nodular iron component to show deformation of the ferrite phase

(white regions) that surrounds the graphite phase (dark regions)

Example 10: Use of Metallographic Sections to Detect Subsurface Deformation in a Wear Scar Generated by Block-on-Ring Testing of a Type 304 Stainless Steel Component.

Figure 10 shows a section through a wear scar on type 304 stainless steel produced by a block-on-ring test. The section was etched and the texture enhanced by using Nomarski contrast illumination. Subsurface deformation can be seen in several stages. In the zone near the edge of the ring contact, slip lines can be seen in the metal crystals. Further back in the contact zone, much heavier deformation and flow is indicated. Some evidence of folding in of surface material into the subsurface structure can be seen. Extrusion of the flowed metal from the contact region can be seen as "fingers" of metal that break off to form debris. In the extrusion area, laminations are visible. The lamination process can be seen as the drawing out of grains into long flat plates; the grain boundaries and inclusions precipitated along the grain boundaries make up the laminations.

Example 11: Subsurface Deformation in a Chain Hoist Hardened Steel Load Link Caused by Contact Wear.

Figure 11 shows a cross section of a load link in a chain from a chain hoist. When etched, the wire forming pattern in the link can be seen. At the top of the micrograph, in the center, the deformation pattern from wear can be seen. The link surface, loaded against the mating link surface, was subjected to a rocking motion under load. The resulting subsurface deformation tended to push metal toward the center of contact to form a mound. The extrusion at the surface indicates the direction in which the link wore.

Example 12: Cross Section of a Wear Scar in a Nodular Iron Component Generated by Sliding Contact.

The third micrograph (Fig. 12) illustrates the effects of sliding contact on a nodular iron material. Note the dark phase (graphite) surrounded by a white phase (soft ferrite). Deformation and flow of the ferrite at the surface can be seen as well as cracks generated in the stretched-out graphite phase.

Wear Debris

The collection and analysis of wear debris is an important element in the determination of wear modes. The debris often contains clues to the wear mechanism and the cause of the wear. Size, shape, and color of wear debris are all indicators of the wear mode. Wear debris can be collected from the lubricant by the use of ferrography, centrifuging, and filtering.

Ferrography is useful and most successful for separating ferromagnetic debris from an oil sample (Ref 4). Ferrography separates the debris according to the size of the particles so that the distribution of debris sizes can be determined.

Filtering collects all debris, both metallic and nonmetallic, and may uncover some abrasive contaminants that might be responsible for unexpected abrasive wear. In addition, some abrasive contaminants can initiate a wear process that embeds sharp particles in a soft bearing material to cause machining of the counter surface. Filtered debris such as that shown in Fig. 13 is typical for the abrasive wear of a brittle material.

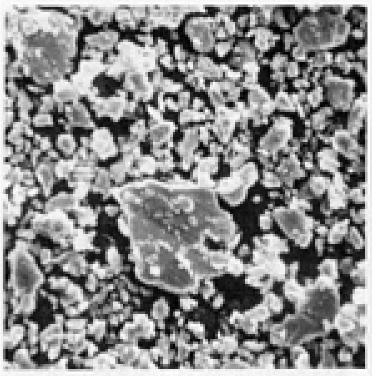

Fig. 13 Wear debris generated by the abrasive wear of a brittle material

Very fine debris can be filtered out of a lubricant after centrifuging and diluting with a solvent using a Nuclepore membrane filter. This can then be washed with a solvent and mounted on a grid for electron microscopy. A light microscope can then be used to examine the larger particles first. Wear debris from a bronze bearing test is shown in Fig. 14. The debris suggests a combined deformation and abrasive wear process. Some curled minichips that are evidence of cutting abrasion can also be identified. When this sample was viewed with a transmission electron microscope, another phase of wear debris was found: submicron size metal particles embedded in an organic gel or soap (Ref 5).

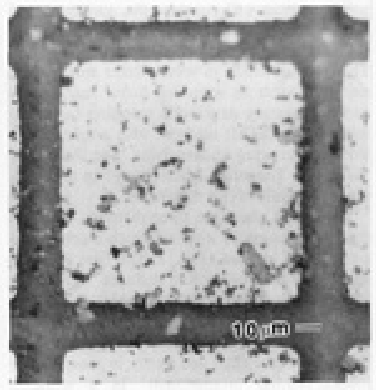

Fig. 14 Bronze wear debris generated during a lubricated block-on-ring test. The debris was obtained by centrifuging the oil through a Nuclepore membrane filter.

Introduction

A COMPREHENSIVE UNDERSTANDING of wear processes requires a thorough knowledge of the nature and changes experienced by the contacting bodies. The first stage in the investigation of a wear problem consists of collecting all pertinent data concerning contact parameters, wear rates, friction forces, and the surrounding environment. The next step is usually the observation of the worn surfaces by means of an optical microscope. In most research laboratories, this is routinely followed by more extensive examination using a scanning electron microscope (SEM). The great depth of field and high resolution of the SEM compared with the optical microscope, and its capability for determining composition by means of associated x-ray analysis facilities, have made the SEM the premier instrument utilized in the study of worn surfaces. In fact, of the 101 papers in the most recent proceedings of the International Conference on Wear of Materials (Ref 1), 63 contained SEM micrographs, and many of these included x-ray analysis information collected in the SEM. When more detailed information about the microstructure is required, a transmission electron microscope (TEM) may be employed; three of the above-cited conference papers (Ref 2, 3, 4) contained TEM micrographs.

This article will consider the application of scanning electron microscopy and transmission electron microscopy (also abbreviated SEM and TEM) to the study of wear. Other microscopy methods, such as scanning Auger microscopy and the recently developed scanning tunneling microscopy (STM) method, also employ electrons for imaging and analysis. See the article "Scanning Tunneling Microscopy" in this Volume for details of this technique.

In general, there are three different facets in the investigation of wear to which electron microscopy is applied (Fig. 1). The first involves the study of the contacting surfaces. In a power transmission system, for example, these surfaces may include the teeth of mating gears, the ball and race components of rolling-element bearings, or the shaft and sleeve in the case of a journal-bearing arrangement. In a situation where abrasion or solid particle erosion is encountered, examination of the abrading or eroding particles as well is almost always of vital importance. Particle size, shape, composition, and microstructure often have a controlling influence on the wear process. Because changes in the surface caused by wear are usually a critical issue, the analysis will typically include a comparative examination of a similar or adjacent surface region that has not been subjected to wear. (It should be noted here that use of the term "surface" is somewhat ambiguous, referring not only to the outer boundary of the body but also to a volume of material within the body below the boundary that has been affected by tribological contact. This may include reaction films, transferred material, and compacted debris, as well as original material of the body. When specific reference is made to the region below the boundary, the term "subsurface" is often used.)

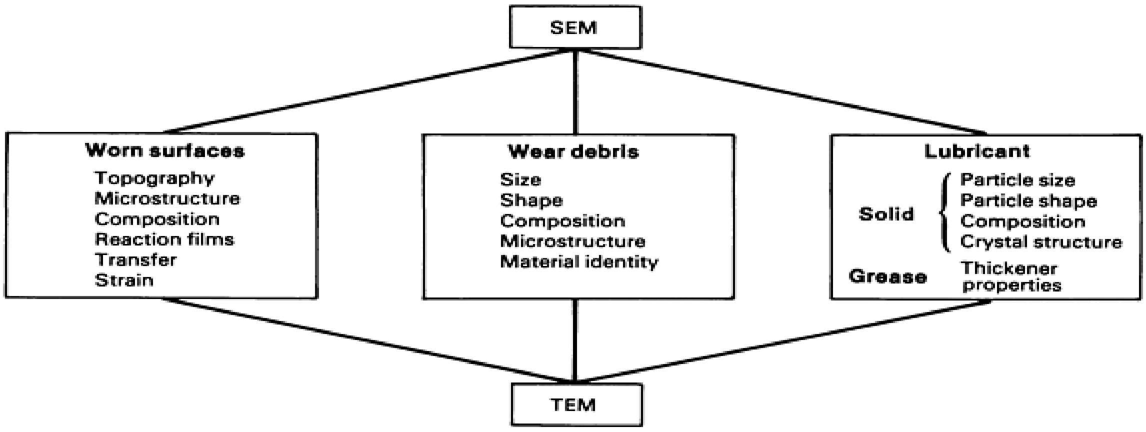

Fig. 1 Three different facets of wear to which SEM and TEM are applied

The material or "debris" that is removed from the surface constitutes the second facet of wear to which electron microscopy is applied. The shape, size, composition, and microstructure of the debris can provide important clues about the nature of the operating wear mechanisms, the conditions in the contact where wear is occurring, and the influence of the environment. Also, debris particles are not merely generated but often participate in and may even play a dominant role in determining the nature of the friction and wear processes. The debris particles may be found in close proximity to the contact from which they were generated, or they may be in a remote location--for example, in the lubricating oil, accumulated in the oil filter, or perhaps mixed with a slurry of abrasive particles that was responsible for the wear. Collection of the debris particles for examination may range from quite routine to nearly impossible, as, for example, when they are widely dispersed in an abrasive slurry medium.

In some cases a third facet, the lubricant, can be included in the microscopic analysis. In the case of solid lubricants, electron microscopy is an important analytical tool (Ref 5). Normally, electron microscopy is not applied directly to the study of oils and greases because of their high vapor pressures and rapid degradation in the electron beam. However, they can be studied using cryomicroscopy methods, where the specimen is mounted on a cold stage (Ref 6). The solid thickener component of greases has long been studied by electron microscopy (Ref 7).

Electron microscopy has played a substantial and critical role in virtually all areas of materials science. A number of text and reference books are available, covering the subject in nearly all levels of detail and thoroughness. The bibliography at the end of this article includes some of the more recent general references on SEM (Ref 8, 9, 10, 11, 12) and TEM (Ref 13, 14, 15, 16, 17, 18, 19, 20). Two shorter summary reviews on SEM (Ref 21) and TEM (Ref 22) and two references that review both SEM and TEM together (Ref 23, 24) are included for those desiring a briefer treatment than is provided in the general texts but requiring considerably more detail than is given here. Quinn has written two monographs, an early volume (Ref 25) and a more recent one (Ref 26) that deal with the application of analytical techniques, including electron microscopy, to tribology. Reference may also be made to a review by Ruff *et al.* (Ref 27) that is directly concerned with the application of SEM and TEM to the study of wear.

Two societies are devoted to the advancement of the field of electron microscopy: the Microscopy Society of America (MSA) (formerly the Electron Microscopy Society of America) and the Microbeam Analysis Society (MAS). Both groups actively promote informational and educational programs. MSA has developed and maintains a videotape library, providing information and instruction on a wide range of microscopy techniques and applications. These videotapes are available to society members for a small rental fee.

The discussion that follows is organized into several sections. First, electron-specimen interactions are briefly discussed, because this is the basis by which SEM and TEM methods are able to reveal the characteristics and properties of materials. This is followed by a short overview of TEM and SEM instruments and a summary of specimen preparation methods, particularly in connection with wear. Finally, SEM and TEM methods are considered in somewhat greater detail, with examples from actual wear investigations.

Because of the large amount and ready availability of information on electron microscopy, as well as the vastness of the subject, only a brief outline will be given here. The references should be consulted for greater detail.

Electron-Specimen Interactions

In both TEM and SEM, an electron beam is directed onto a specimen. Interactions that may occur are depicted schematically in Fig. 2. Each of these interactions is a source of information that can be exploited to reveal specimen properties. Through control of the incident electron beam and use of an appropriate detection system, unique information can be obtained regarding specimen surface topography, crystal structure, lattice defects (for example, dislocations and stacking faults), the distribution and morphology of phases, magnetic domain structure, the presence of an electrical charge, voltage variations, atomic composition, and atomic bonding. The information can be presented in the form of an image, a graph, or as tabulated data.

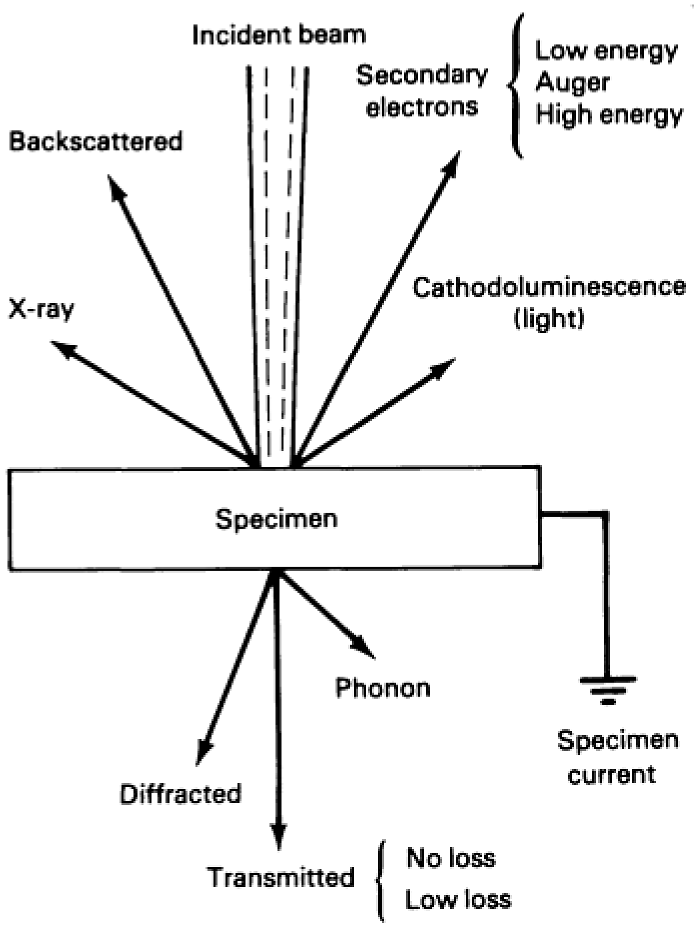

Fig. 2 Electron-specimen interaction signals

Sometimes the investigator can use this information with little knowledge of its origin. Usually, however, meaningful interpretation requires a basic understanding of the electron-specimen interaction process. A rigorous treatment of the various electron-specimen interactions generally lies in the realm of physics, particularly quantum mechanics. This approach can be greatly simplified by treating electrons and atoms as simple charged particles and applying the principles of Newtonian mechanics. Alternatively, when interference phenomena or diffraction is involved, the electrons are treated as plane waves and the principles of geometrical optics are employed. The following brief discission offers only the simplest explanations. For a detailed discussion, see the cited references.

The interaction processes in Fig. 2 can be categorized as elastic or inelastic. In an elastic interaction, the incident electron does not lose energy, but its direction is changed. In an inelastic interaction, the incident electron does lose energy and its direction is usually changed as well. Elastic scattering occurs as a result of one or more encounters with the positive Coulomb field (screened by inner-shell electrons) of atomic nuclei. Because of the comparatively large mass of the nucleus, the incident electrons may be deflected without appreciable loss of energy. The angle of deflection can reach 180°; that is, the incident electron undergoes complete reversal in direction. Elastically scattered electrons that leave the specimen contribute to the backscattered signal in Fig. 2. It should be noted that collisions with atomic nuclei at the energies available in high-voltage TEMs may result in considerable energy transfer--to the extent that atoms in the specimen are displaced, resulting in radiation damage. In that case, of course, the scattering would be inelastic.

Interaction with specimen electrons is the predominant source of inelastic scattering. The specimen electrons may acquire considerable energy in the process and thus participate in additional scattering interactions themselves. The scattered specimen electrons are referred to as secondary electrons. Those secondary electrons that leave the specimen are the source of the signal so designated in Fig. 2. One type of inelastic interaction that is especially important in connection with chemical analysis occurs when an inner-shell electron is ejected from an atom, leaving the atom in a high-energy, ionized state. For this to happen, the incident electron must have an energy that exceeds the critical absorption energy for

the electron shell of the particular atom involved. The presence of such absorption edges in the energy spectrum of inelastically scattered electrons is the basis for chemical analysis by means of electron energy loss spectroscopy (EELS).

De-excitation of the ionized atom by means of an electron transition from an outer shell to the inner vacant shell may be accompanied by the ejection of an Auger electron or the emission of a characteristic x-ray. The former serves as the basis for Auger spectroscopy and the latter for x-ray spectroscopy. Other inelastic responses are the collective excitation of conduction and valence electrons to produce plasmon waves, lattice excitations to produce phonons, and the production of electron-hole pairs in semiconductors. All of these are discussed later.

Diffraction is a direct consequence of the wave nature of the electrons and results from the interference between electrons scattered by atoms in the periodic array of a crystalline solid. Incident-beam electrons as well as previously scattered electrons are subject to diffraction.

If the specimen is sufficiently thin, electrons may leave the back surface. Incident electrons that have lost little or no energy and are not deflected during their passage are often referred to as primary-beam transmitted electrons.
